

Acrobat® Edition

Thanks to special permission from Cambridge University Press, we are able to bring you the complete **Numerical Recipes in Fortran 77** book On-Line! To utilize this resource, you will need an Adobe Acrobat viewer linked as a helper program to your web browser. Permission is granted by the copyright owners for users of this resource to make one paper copy of these Acrobat files for their own personal use. Further reproduction, or the extraction of, or copying of, machine readable files to any server computer, is strictly prohibited. This on-line resource is not intended as a substitute for [purchasing the book](#), or for [obtaining a license](#) for the use of Numerical Recipes source code.

Downloads of the Numerical Recipes source code in machine-readable format are not available as part of this free resource. For information on downloads, please go to the [Numerical Recipes On-Line Software Store](#).

- Front Matter, Contents, and Prefaces xi
- Legal Matters xvi
- Computer Programs by Chapter and Section xix

1 Preliminaries

- 1.0 Introduction 1

-  1.1 Program Organization and Control Structures 5
-  1.2 Error, Accuracy, and Stability 18

2 Solution of Linear Algebraic Equations

-  2.0 Introduction 22
-  2.1 Gauss-Jordan Elimination 27
-  2.2 Gaussian Elimination with Backsubstitution 33
-  2.3 LU Decomposition and Its Applications 34
-  2.4 Tridiagonal and Band Diagonal Systems of Equations 42
-  2.5 Iterative Improvement of a Solution to Linear Equations 47
-  2.6 Singular Value Decomposition 51
-  2.7 Sparse Linear Systems 63
-  2.8 Vandermonde Matrices and Toeplitz Matrices 82
-  2.9 Cholesky Decomposition 89
-  2.10 QR Decomposition 91
-  2.11 Is Matrix Inversion an N^3 Process? 95

3 Interpolation and Extrapolation

-  3.0 Introduction 99
-  3.1 Polynomial Interpolation and Extrapolation 102
-  3.2 Rational Function Interpolation and Extrapolation 104
-  3.3 Cubic Spline Interpolation 107
-  3.4 How to Search an Ordered Table 110
-  3.5 Coefficients of the Interpolating Polynomial 113
-  3.6 Interpolation in Two or More Dimensions 116

4 Integration of Functions

-  4.0 Introduction 123
-  4.1 Classical Formulas for Equally Spaced Abscissas 124
-  4.2 Elementary Algorithms 130
-  4.3 Romberg Integration 134
-  4.4 Improper Integrals 135
-  4.5 Gaussian Quadratures and Orthogonal Polynomials 140
-  4.6 Multidimensional Integrals 155

5 Evaluation of Functions

-  5.0 Introduction 159
-  5.1 Series and Their Convergence 159
-  5.2 Evaluation of Continued Fractions 163
-  5.3 Polynomials and Rational Functions 167
-  5.4 Complex Arithmetic 171
-  5.5 Recurrence Relations and Clenshaw's Recurrence Formula 172
-  5.6 Quadratic and Cubic Equations 178
-  5.7 Numerical Derivatives 180
-  5.8 Chebyshev Approximation 184
-  5.9 Derivatives or Integrals of a Chebyshev-approximated Function 189
-  5.10 Polynomial Approximation from Chebyshev Coefficients 191
-  5.11 Economization of Power Series 192
-  5.12 Pad'e Approximants 194
-  5.13 Rational Chebyshev Approximation 197
-  5.14 Evaluation of Functions by Path Integration 201

6 Special Functions

-  6.0 Introduction 205
-  6.1 Gamma Function, Beta Function, Factorials, Binomial Coefficients 206

-  6.2 Incomplete Gamma Function, Error Function, Chi-Square Probability Function, Cumulative Poisson Function 209
-  6.3 Exponential Integrals 215
-  6.4 Incomplete Beta Function, Student's Distribution, F-Distribution, Cumulative Binomial Distribution 219
-  6.5 Bessel Functions of Integer Order 223
-  6.6 Modified Bessel Functions of Integer Order 229
-  6.7 Bessel Functions of Fractional Order, Airy Functions, Spherical Bessel Functions 234
-  6.8 Spherical Harmonics 246
-  6.9 Fresnel Integrals, Cosine and Sine Integrals 248
-  6.10 Dawson's Integral 252
-  6.11 Elliptic Integrals and Jacobian Elliptic Functions 254
-  6.12 Hypergeometric Functions 263

7 Random Numbers

-  7.0 Introduction 266
-  7.1 Uniform Deviates 267
-  7.2 Transformation Method: Exponential and Normal Deviates 277
-  7.3 Rejection Method: Gamma, Poisson, Binomial Deviates 281
-  7.4 Generation of Random Bits 287
-  7.5 Random Sequences Based on Data Encryption 290
-  7.6 Simple Monte Carlo Integration 295
-  7.7 Quasi- (that is, Sub-) Random Sequences 299
-  7.8 Adaptive and Recursive Monte Carlo Methods 306

8 Sorting

-  8.0 Introduction 320
-  8.1 Straight Insertion and Shell's Method 321

-  8.2 Quicksort 323
-  8.3 Heapsort 327
-  8.4 Indexing and Ranking 329
-  8.5 Selecting the \$M\$th Largest 333
-  8.6 Determination of Equivalence Classes 337

9 Root Finding and Nonlinear Sets of Equations

-  9.0 Introduction 340
-  9.1 Bracketing and Bisection 343
-  9.2 Secant Method, False Position Method, and Ridders' Method 347
-  9.3 Van Wijngaarden--Dekker--Brent Method 352
-  9.4 Newton-Raphson Method Using Derivative 355
-  9.5 Roots of Polynomials 362
-  9.6 Newton-Raphson Method for Nonlinear Systems of Equations 372
-  9.7 Globally Convergent Methods for Nonlinear Systems of Equations 376

10 Minimization or Maximization of Functions

-  10.0 Introduction 387
-  10.1 Golden Section Search in One Dimension 390
-  10.2 Parabolic Interpolation and Brent's Method in One Dimension 395
-  10.3 One-Dimensional Search with First Derivatives 399
-  10.4 Downhill Simplex Method in Multidimensions 402
-  10.5 Direction Set (Powell's) Methods in Multidimensions 406
-  10.6 Conjugate Gradient Methods in Multidimensions 413
-  10.7 Variable Metric Methods in Multidimensions 418
-  10.8 Linear Programming and the Simplex Method 423
-  10.9 Simulated Annealing Methods 436

11 Eigensystems

-  11.0 Introduction 449
-  11.1 Jacobi Transformations of a Symmetric Matrix 456
-  11.2 Reduction of a Symmetric Matrix to Tridiagonal Form: Givens and Householder Reductions 462
-  11.3 Eigenvalues and Eigenvectors of a Tridiagonal Matrix 469
-  11.4 Hermitian Matrices 475
-  11.5 Reduction of a General Matrix to Hessenberg Form 476
-  11.6 The QR Algorithm for Real Hessenberg Matrices 480
-  11.7 Improving Eigenvalues and/or Finding Eigenvectors by Inverse Iteration 487

12 Fast Fourier Transform

-  12.0 Introduction 490
-  12.1 Fourier Transform of Discretely Sampled Data 494
-  12.2 Fast Fourier Transform (FFT) 498
-  12.3 FFT of Real Functions, Sine and Cosine Transforms 504
-  12.4 FFT in Two or More Dimensions 515
-  12.5 Fourier Transforms of Real Data in Two and Three Dimensions 519
-  12.6 External Storage or Memory-Local FFTs 525

13 Fourier and Spectral Applications

-  13.0 Introduction 530
-  13.1 Convolution and Deconvolution Using the FFT 531
-  13.2 Correlation and Autocorrelation Using the FFT 538
-  13.3 Optimal (Wiener) Filtering with the FFT 539
-  13.4 Power Spectrum Estimation Using the FFT 542
-  13.5 Digital Filtering in the Time Domain 551

-  13.6 Linear Prediction and Linear Predictive Coding 557
-  13.7 Power Spectrum Estimation by the Maximum Entropy (All Poles) Method 565
-  13.8 Spectral Analysis of Unevenly Sampled Data 569
-  13.9 Computing Fourier Integrals Using the FFT 577
-  13.10 Wavelet Transforms 584
-  13.11 Numerical Use of the Sampling Theorem 600

14 Statistical Description of Data

-  14.0 Introduction 603
-  14.1 Moments of a Distribution: Mean, Variance, Skewness, and So Forth 604
-  14.2 Do Two Distributions Have the Same Means or Variances? 609
-  14.3 Are Two Distributions Different? 614
-  14.4 Contingency Table Analysis of Two Distributions 622
-  14.5 Linear Correlation 630
-  14.6 Nonparametric or Rank Correlation 633
-  14.7 Do Two-Dimensional Distributions Differ? 640
-  14.8 Savitzky-Golay Smoothing Filters 644

15 Modeling of Data

-  15.0 Introduction 650
-  15.1 Least Squares as a Maximum Likelihood Estimator 651
-  15.2 Fitting Data to a Straight Line 655
-  15.3 Straight-Line Data with Errors in Both Coordinates 660
-  15.4 General Linear Least Squares 665
-  15.5 Nonlinear Models 675
-  15.6 Confidence Limits on Estimated Model Parameters 684
-  15.7 Robust Estimation 694

16 Integration of Ordinary Differential Equations

-  16.0 Introduction 701
-  16.1 Runge-Kutta Method 704
-  16.2 Adaptive Stepsize Control for Runge-Kutta 708
-  16.3 Modified Midpoint Method 716
-  16.4 Richardson Extrapolation and the Bulirsch-Stoer Method 718
-  16.5 Second-Order Conservative Equations 726
-  16.6 Stiff Sets of Equations 727
-  16.7 Multistep, Multivalue, and Predictor-Corrector Methods 740

17 Two Point Boundary Value Problems

-  17.0 Introduction 745
-  17.1 The Shooting Method 749
-  17.2 Shooting to a Fitting Point 751
-  17.3 Relaxation Methods 753
-  17.4 A Worked Example: Spheroidal Harmonics 764
-  17.5 Automated Allocation of Mesh Points 774
-  17.6 Handling Internal Boundary Conditions or Singular Points 775

18 Integral Equations and Inverse Theory

-  18.0 Introduction 779
-  18.1 Fredholm Equations of the Second Kind 782
-  18.2 Volterra Equations 786
-  18.3 Integral Equations with Singular Kernels 788
-  18.4 Inverse Problems and the Use of A Priori Information 795
-  18.5 Linear Regularization Methods 799
-  18.6 Backus-Gilbert Method 806

-  18.7 Maximum Entropy Image Restoration 809

19 Partial Differential Equations

-  19.0 Introduction 818
-  19.1 Flux-Conservative Initial Value Problems 825
-  19.2 Diffusive Initial Value Problems 838
-  19.3 Initial Value Problems in Multidimensions 844
-  19.4 Fourier and Cyclic Reduction Methods for Boundary Value Problems 848
-  19.5 Relaxation Methods for Boundary Value Problems 854
-  19.6 Multigrid Methods for Boundary Value Problems 862

20 Less-Numerical Algorithms

-  20.0 Introduction 881
-  20.1 Diagnosing Machine Parameters 881
-  20.2 Gray Codes 886
-  20.3 Cyclic Redundancy and Other Checksums 888
-  20.4 Huffman Coding and Compression of Data 896
-  20.5 Arithmetic Coding 902
-  20.6 Arithmetic at Arbitrary Precision 906
-  References and Program Dependencies 916
-  General Index 935

Problems?	Other Stuff

We are an Associate of Amazon.com. That means that the links on this page connect you directly into Amazon.com's efficient order fulfillment and shipping services. This gives you convenient one-stop ordering, not just of Numerical Recipes books and CDROMs, but also of your choices from our carefully chosen reading lists of recommended books on

numerical and scientific computing (including the recommendations from the *Numerical Recipes* book).

On the left: Amazon.com's automated suggestions for Numerical Recipes readers. These are generated using data on books that our readers have actually bought; the suggestions change (a bit) every time you reload this page. Here, links to our own **Numerical Recipes reading lists**:

- [Best-selling Numerical Recipes books](#)
- [Numerical Recipes CDROMs](#)
- [Numerical Recipes diskettes](#)
- [Numerical Recipes 1st ed. items in print](#)
- [Core reference list from Numerical Recipes](#)
- ["Numerical Classics" in paperback](#)
- [Popular science recommendations](#)
- [Our other favorites \(math, writing, cryptography...\)](#)
- [Fortran 90](#)
- [Parallel Programming](#)
- [Scientific C++](#)

Or, search for any keywords (title, author, subject, etc.) among Amazon.com's millions of listings (or pick music, video, or electronics search for your other needs):

Books	Music	Video	Electronics

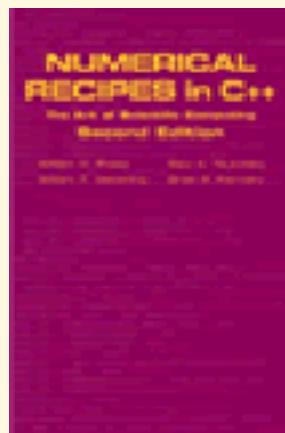

For more search options, see [Amazon.com Home Page](#).

- [Amazon.com customer service \(payment and shipping options and other help\)](#)
- [Amazon.com privacy policy](#)
- [Amazon.com frequently asked questions](#)
- [Welcome letter from the President of Amazon.com Books](#)

[While Amazon.com is our favorite, many [other bookstores](#) also stock our Numerical Recipes titles.]

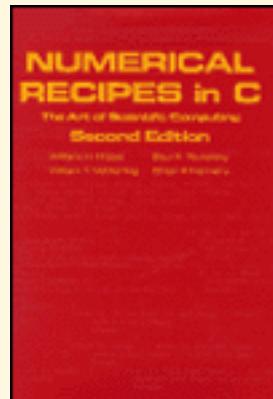

Click on any title for more details, including availability and any price changes.

The best-selling books...

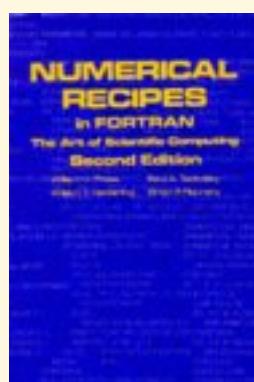

[Numerical Recipes in C++ : The Art of Scientific Computing](#); William H. Press, et al; Hardcover; \$69.95

[Numerical Recipes Example Book \(C++\)](#); William T. Vetterling, et al; Paperback; \$32.95

[Numerical Recipes in C : The Art of Scientific Computing](#); William H. Press, et al; Hardcover; \$64.95

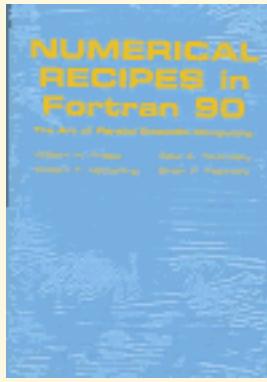

[Numerical Recipes Example Book \(C\)](#); William T. Vetterling, et al; Paperback; \$32.95

[Numerical Recipes in Fortran 77: The Art of Scientific Computing](#); (Fortran Numerical Recipes, Vol 1) William H. Press, et al; Hardcover; \$64.95

- This Vol 1 **does not** require Vol 2, below, for use with Fortran 77

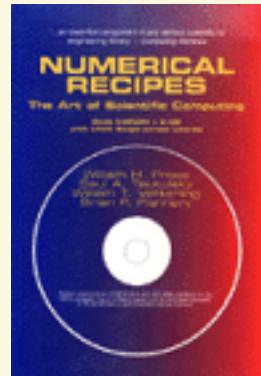

[Numerical Recipes Example Book \(Fortran\)](#); William T. Vetterling, et al; Paperback; \$32.95

[Numerical Recipes in Fortran 90 : The Art of Parallel Scientific Computing \(Fortran Numerical Recipes, Vol 2\)](#); William H. Press, et al; Hardcover; \$59.95
o This Vol 2 **does** require Vol 1, above, for effective use.

Numerical Recipes Multi-Language Code CDROMs...

The new CDROMs contain all the source code from all the language versions of Numerical Recipes, past and present, for all platforms (Windows, Macintosh, UNIX, Linux). Here's [more information](#) about what's on these new CDROM products.

[Numerical Recipes Multi-Language Code CDROM With Windows or MacIntosh Single Screen License](#); CDROM; \$89.95

[Numerical Recipes Code CDROM With Unix or Linux Single Screen License](#); CDROM; \$149.95

Single-Language Diskettes/CDROMs for Windows...

Note that the **same software** that is on these diskettes/CDROMs can be downloaded electronically, for immediate purchase and use, from the [Numerical Recipes On-Line Software Store](#). Formats for other machines (Macintosh, UNIX) are also available [there](#). We suggest ordering from here only if you are unable to download electronically, and want Amazon.com to send you the physical diskette or CDROM.

[Numerical Recipes in C++ and C Code CDROM \(Windows\)](#); William H. Press, et al; CDROM; \$49.95

[Numerical Recipes in Fortran 77 and Fortran 90 IBM Diskette : The Art of Scientific and Parallel Computing](#); diskette 3.5 in; \$39.95

First Edition items still in print...

Since these are special order items from Amazon.com, you may want to go back to our Mail-Order counter and [order them directly from Cambridge University Press](#). Or, you can order them here to take advantage of Amazon.com's different shipping options. Note also that all the machine-readable code from these books is available on the CDROMs, above.

[Numerical Recipes Routines and Examples in Basic : Companion Manual to Numerical Recipes : The Art of Scientific Computing](#); Julien C. Sprott; Paperback; \$37.50. (*Special Order*)

[Numerical Recipes in Pascal : The Art of Scientific Computing](#); William H. Press, Brian P. Flannery; Hardcover; \$59.95 (*Special Order*)

[Numerical Recipes Example Book \(Pascal\)](#); William T. Vetterling; Paperback; \$29.95 (*Special Order*)

The 1992 Recommended Core Library...Updated

"We first list a small number of books that form the nucleus of a recommended personal reference collection on numerical methods, numerical analysis, and closely related subjects. These are the books that we like to have within easy reach."

-- From *Numerical Recipes: The Art of Scientific Computing*, References section (1992)

Abramowitz, M., and Stegun, I.A. 1964, [Handbook of Mathematical Functions](#), Applied Mathematics Series, Volume 55 (Washington: National Bureau of Standards; [reprinted in paperback 1968 by Dover Publications](#), New York)

- You've **got** to own this. Sell your copy of NR if necessary! The hardcover is a bargain, the paperback even more so.

Acton, F.S. 1970, [Numerical Methods That Work](#); 1990, corrected edition (Washington: Mathematical Association of America)

- If you're an Acton fan, as we are, don't miss his second volume (see our [Other Favorites](#) list).

Ames, W.F. 1977, [Numerical Methods for Partial Differential Equations](#), 2nd ed. (New York: Academic Press)

Bratley, P., Fox, B.L., and Schrage, E.L. 1983, [A Guide to Simulation](#) (New York: Springer-Verlag)

Dahlquist, G., and Bjorck, A. 1974, *Numerical Methods* (Englewood Cliffs, NJ: Prentice-Hall) [out of print?]

Delves, L.M., and Mohamed, J.L. 1985, [*Computational Methods for Integral Equations*](#) (Cambridge, U.K.: Cambridge University Press)

Dennis, J.E., and Schnabel, R.B. 1983, [*Numerical Methods for Unconstrained Optimization and Nonlinear Equations*](#) (Englewood Cliffs, NJ: Prentice-Hall)

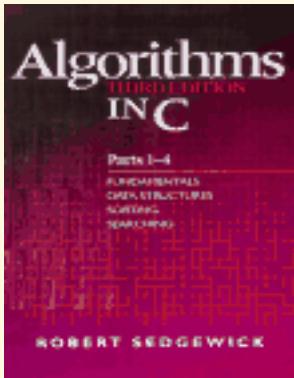

Gill, P.E., Murray, W., and Wright, M.H. 1991, [*Numerical Linear Algebra and Optimization*](#), vol. 1 (Redwood City, CA: Addison-Wesley)

Golub, G.H., and Van Loan, C.F. 1996, [*Matrix Computations*](#), 3rd ed. (Baltimore: Johns Hopkins University Press)

Knuth, D.E. 1997 (new edition!), [*The Art of Computer Programming: Fundamental Algorithms \(Vol 1, 3rd Ed\)*](#)(Addison-Wesley)

Knuth, D.E. 1997 (new edition!), [*The Art of Computer Programming: Seminumerical Algorithms \(Vol 2, 3rd Ed\)*](#)(Addison-Wesley)

Oppenheim, A.V., and Schafer, R.W. 1989, [*Discrete-Time Signal Processing*](#) (Englewood Cliffs, NJ: Prentice-Hall)

Ralston, A., and Rabinowitz, P. 1978, [*A First Course in Numerical Analysis*](#), 2nd ed. (New York: Dover)

Sedgewick, R. 1997, [*Algorithms in C*](#), 3rd ed. (Reading, MA: Addison-Wesley)

Stoer, J., and Bulirsch, R. 1992, [*Introduction to Numerical Analysis*](#), Second Edition (New York: Springer-Verlag)

Wilkinson, J.H., and Reinsch, C. 1971, *Linear Algebra*, vol. II of *Handbook for Automatic Computation* (New York: Springer-Verlag) [out of print?]

Some Additionally Recommended "Classics" in Paperback:

[Numerical Methods for Scientists and Engineers](#); R.W. Hamming; Paperback; \$16.15

- A classic text from the previous generation.

[Applied Analysis](#); Cornelius Lanczos; Paperback; \$15.25

- Lanczos is a *gold mine* of clever, often very peculiar, techniques. Worth reading even 50 years later!

[Data Reduction and Error Analysis for the Physical Sciences \(Book and Disk\)](#); Philip R. Bevington, D.Keith Robinson; Paperback; \$29.37

- If your copy of NR falls open to Chapter 15, you may want to own Bevington

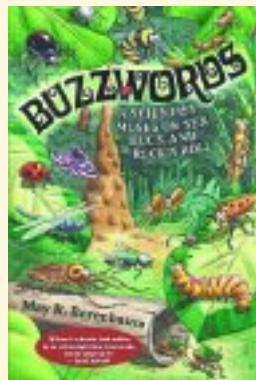

[Introduction to Numerical Analysis \(Dover Books on Advanced Mathematics\)](#); F.B. Hildebrand; Paperback; \$15.25

[A Survey of Numerical Mathematics Vol 1](#); David M. Young, Robert Todd Gregory; Paperback; \$15.25

[A Survey of Numerical Mathematics Vol 2](#); David M. Young, Robert Todd Gregory; Paperback; \$15.25

- From the times when men were men, and numerical analysts were, well, numerical analysts

Popular Science...

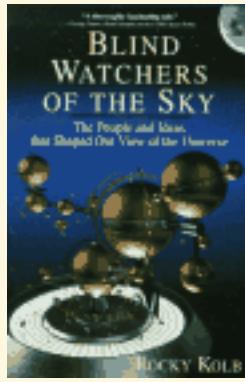

[Buzzwords, A Scientist Muses on Sex, Bugs, and Rock'N'Roll \(Joseph Henry Press\)](#); May Berenbaum; Paperback; \$14.95

- Now that you've squashed a bug with your copy of NR, you need to know more! Apparently, Dave Barry thinks that this is the funniest entomology book ever written. Like NR, a laugh on every page. Unlike NR, no equations.

[The Code Book : The Evolution of Secrecy from Mary, Queen of Scots to Quantum Cryptography](#); Simon Singh; Paperback; \$11.20

- Excellent history of cryptography with gorey details. A favorite of NR readers.

[Blind Watchers of the Sky : The People and Ideas That Shaped Our View of the Universe \(Helix Books\)](#); Rocky Kolb; Hardcover; \$22.50

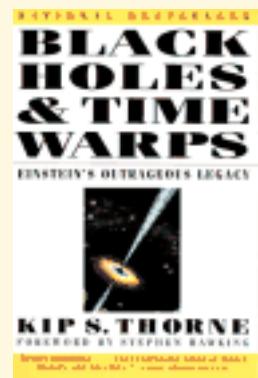

- Sort of "lifestyles of the astronomical and famous". Very droll and entertaining.

[Flattening the Earth : Two Thousand Years of Map Projections](#); John P. Snyder / Paperback / Published 1997; \$19.95

- We always wondered how all those weird map projections *really* work. This book tells all, mostly in precise words and pictures, but with enough equations for the mathematically curious. Amaze your friends with arcane knowledge!

[Wrinkles in Time](#); George Smoot, Keay Davidson; Paperback; \$11.70

- True story of the cosmic discovery that Stephen Hawking called "the greatest of this century, if not of all time," the primordial perturbations in the Universe!

[Black Holes and Time Warps : Einstein's Outrageous Legacy](#); Kip S. Thorne; Paperback; \$13.45

- Read about what two of your Numerical Recipes authors did in their misspent youths! Thorne's writing and explanations are excellent. Gorgeous line illustrations.

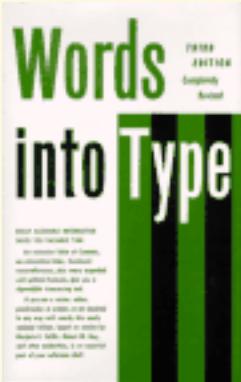

[Engineers of Dreams : Great Bridge Builders and the Spanning of America](#); Henry Petroski, Edward Kastenmeier; Paperback; \$13.50

- Petroski really knows how to write about engineering and engineers. When you get tired of Dilbert, move to this!

Highly Recommended...

[CRC Standard Mathematical Tables and Formulae \(30th Ed\)](#); Daniel Zwillinger; Hardcover; \$39.95

- This new edition is *full* of great mathematical stuff. It's not just tables any more... (One of your NR authors was an advisor.)

[Words into Type](#); Marjorie E. Skillin, Robert Malcolm Gay; Hardcover; \$31.96

- Simply the best manual of style for book writers. Lots of great trivia. It's what we use for Numerical Recipes books.

[Mathematics and Humor](#); John Allen Paulos; Paperback; \$12.60

- A serious study of jokes and their mathematical structure! Really! Enjoy!

[Algorithms for Image Processing and Computer Vision](#); James R. Parker; Paperback; \$65.00

- Readers of Numerical Recipes recommend this book.

[Concrete Mathematics : A Foundation for Computer Science](#); Ronald Graham; Hardcover; \$49.95

- Particular strong on number theory and integer functions. Good for cryptography.

[Atlas for Computing Mathematical Functions : An Illustrated Guidebook for Practitioners, With Programs in C and Mathematica](#); William J. Thompson; Hardcover; \$175.00

- Huge 900 pp. compendium of special functions, with equations, graphics, and algorithms implemented in both C and Mathematica. Very pricey, but includes a CDROM.

[Statistics in Theory and Practice](#); Robert Lupton; Hardcover; \$37.50

- Finally, a statistics book that is both *thin* and *high-level*! If chapters 14 and 15 in NR are your favorites, then you need this book.

[Probability, Random Variables, and Stochastic Processes](#); Athanasios Papoulis; Hardcover; \$100.94

- A good standard text on the subject.

[Elements of Information Theory](#) (Wiley Series in Telecommunication); Thomas M. Cover, Joy A. Thomas; \$79.95

- This is a fine text on information theory, particularly emphasizing connections with related fields.

[Time-Frequency Analysis \(Prentice Hall Signal Processing\)](#); Leon Cohen; Hardcover; \$69.00

- A very clear and well written book on an increasingly important subject. Good book for both serious substance and casual learning of faddish buzzwords!

[Real Computing Made Real : Preventing Errors in Scientific and Engineering Calculations](#);

Forman S. Acton; Hardcover; \$37.50

- Acton's newest collection of tricks, puzzles, and gotchas in numerical computation. For us numerical nerds, it's great entertainment.

[The Art of Electronics](#); Paul Horowitz, Winfield Hill; Hardcover; \$67.95

- Notice the similarity to NR's subtitle? It's not a coincidence. This is a great book, with a great style, a lot like NR. (Of course, the authors are friends of ours.)

[Postscript by Example](#); Henry McGilton, Mary Campione; Paperback;

\$29.56

- Our favorite book on PostScript programming.

[The Mathematica Book](#); Stephen Wolfram; Paperback; \$39.96

- Don't drop it on your toes! Giant new 4th Edition is published by Cambridge, as is NR.

[Applied Cryptography : Protocols, Algorithms, and Source Code in C](#); Bruce Schneier;

Paperback; \$43.96

- We're in the 21st century. Get with the program!

[Miss Rumphius : Story and Pictures \(Picture Puffins\)](#); Barbara Cooney; Paperback; \$6.29

- Amazon.com tells us that people who buy Numerical Recipes also tend to buy *this book!* Does that mean that our readers are 4-8 years old? Or some kinky fad that we don't know about? If you buy this book, please tell us why!

Fortran 90 ...

[Fortran 90/95 Explained](#); Michael Metcalf, John K. Reid; Paperback; \$32.00

- Highly recommended! Start with this to learn Fortran 90.

Parallel Programming ...

[The Design and Analysis of Parallel Algorithms](#); Selim G. Akl; Hardcover; \$75.00 (*Special Order*)

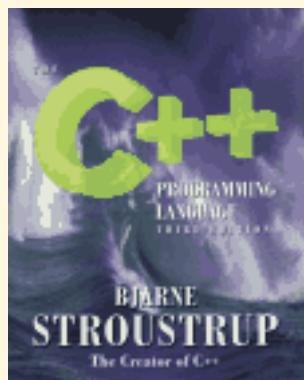

[Scientific Computing : An Introduction With Parallel Computing](#); Gene Golub, James M. Ortega; Hardcover; \$53.00 (*Special Order*)

[Parallel Computers 2 : Architecture, Programming and Algorithms](#); Roger W. Hockney, C.R. Jesshope; Paperback; \$47.00 (*Special Order*)

[Computational Frameworks for the Fast Fourier Transform \(Frontiers in Applied Mathematics, No 10\)](#); Charles Van Loan; Paperback; \$32.25 (*Special Order*)

[Solving Problems on Concurrent Processors : General Techniques and Regular Problems Vol 1](#); Geoffrey C. Fox; Hardcover; \$87.00 (*Special Order*)

Scientific C++...

[C++ Primer](#); Stanley B. Lippman, Josee Lajoie; Paperback; \$45.95

- Now in a new edition, this standard can once again be recommended as a good starting point for C++.

[C++ for C Programmers](#); Ira Pohl; Paperback; \$43.95

- Good starting point for C++ (if you know C)

[Scientific and Engineering C++ : An Introduction With Advanced Techniques and Examples](#); John J. Barton, Lee R. Nackman; Hardcover; \$55.95

- Very sophisticated text; if you are serious about C++, you'll need to read this one.

[Scientific C++ : Building Numerical Libraries the Object-Oriented Way/Book and Disk](#); Guido Buzzi-Ferraris; Paperback; \$42.19

- This is scientific C++ "lite", but good to have handy

[The C++ Programming Language](#); Third Edition, 1997; Bjarne Stroustrup; Paperback; \$47.66

- New edition of a classic, now based on the ANSI/ISO draft final standard.

Click [here](#) to review [prices and quantity discounts](#). Also, be sure to read the [terms of the Single-Screen License](#) before you make a purchase.

- If you encounter any difficulty with our automated ordering system (using the purchase buttons above) you can instead use our equally secure [direct order form](#). This communicates securely to a live person in our order department. (But you won't get the convenience of automatic instant downloading.)

About EDU licenses: We offer reduced prices on Linux/Unix licenses to full-time students and faculty at educational institutions. If you choose this licensing option in the pull-down menus, you will normally enter your ".edu" email address on the order form. In that case, no further action is required. If circumstances require you to use a non-edu address, we expect you to send an email **within 24 hours** to orders@nr.com referencing your order number and explaining your educational affiliation. Otherwise, we will consider your order **not fully paid**, and will invoice you for the difference between EDU and regular rates. Willful failure to pay constitutes fraud, and will be reported to the credit card issuer or appropriate authorities. Please do not hurt our student and faculty users by abusing our intentionally permissive ordering system!

About other licenses: To inquire about other kinds of licenses (site licenses, servers, etc.) or specialized products (e.g., Alpha/VAX VMS and other less-common operating systems), email to orders@nr.com . A good start on a site or server license is to purchase, download, and test in your environment a single-screen license copy (for not more than 30 days). We will subtract its cost, or refund it directly to you, when you convert to a higher level of license.

Tip: If you don't already have the Numerical Recipes main book in C++, C or Fortran, you can order one from [Amazon.com](#) or from [Cambridge University Press](#). (You'll need the book to use the software.)

Another Tip: You can examine and print out any part or parts of the Numerical Recipes books in C, Fortran 77, or Fortran 90 **for free** with the [Numerical Recipes Books On-Line](#) resource.

Without an additional license to use the contained software, this book is intended as a text and reference book, for reading purposes only. A free license for limited use of the software by the individual owner of a copy of this book who personally types one or more routines into a single computer is granted under terms described on p. xxi. See the section "License Information" (pp. xx–xxiii) for information on obtaining more general licenses at low cost.

Machine-readable media containing the software in this book, with included licenses for use on a single screen, are available from Cambridge University Press. See the order form at the back of the book, email to "orders@cup.org" (North America) or "trade@cup.cam.ac.uk" (rest of world), or write to Cambridge University Press, 110 Midland Avenue, Port Chester, NY 10573 (USA), for further information.

The software may also be downloaded, with immediate purchase of a license also possible, from the Numerical Recipes Software Web Site (<http://www.nr.com>). Unlicensed transfer of Numerical Recipes programs to any other format, or to any computer except one that is specifically licensed, is strictly prohibited. Technical questions, corrections, and requests for information should be addressed to Numerical Recipes Software, P.O. Box 243, Cambridge, MA 02238 (USA), email "info@nr.com", or fax 781 863-1739.

Contents

<i>Plan of the Two-Volume Edition</i>	xiii
<i>Preface to the Second Edition</i>	xv
<i>Preface to the First Edition</i>	xviii
<i>License Information</i>	xx
<i>Computer Programs by Chapter and Section</i>	xxiv
1 Preliminaries	1
1.0 Introduction	1
1.1 Program Organization and Control Structures	5
1.2 Error, Accuracy, and Stability	18
2 Solution of Linear Algebraic Equations	22
2.0 Introduction	22
2.1 Gauss-Jordan Elimination	27
2.2 Gaussian Elimination with Backsubstitution	33
2.3 LU Decomposition and Its Applications	34
2.4 Tridiagonal and Band Diagonal Systems of Equations	42
2.5 Iterative Improvement of a Solution to Linear Equations	47
2.6 Singular Value Decomposition	51
2.7 Sparse Linear Systems	63
2.8 Vandermonde Matrices and Toeplitz Matrices	82
2.9 Cholesky Decomposition	89
2.10 QR Decomposition	91
2.11 Is Matrix Inversion an N^3 Process?	95
3 Interpolation and Extrapolation	99
3.0 Introduction	99
3.1 Polynomial Interpolation and Extrapolation	102
3.2 Rational Function Interpolation and Extrapolation	104
3.3 Cubic Spline Interpolation	107
3.4 How to Search an Ordered Table	110
3.5 Coefficients of the Interpolating Polynomial	113
3.6 Interpolation in Two or More Dimensions	116

4 Integration of Functions	123
4.0 Introduction	123
4.1 Classical Formulas for Equally Spaced Abscissas	124
4.2 Elementary Algorithms	130
4.3 Romberg Integration	134
4.4 Improper Integrals	135
4.5 Gaussian Quadratures and Orthogonal Polynomials	140
4.6 Multidimensional Integrals	155
5 Evaluation of Functions	159
5.0 Introduction	159
5.1 Series and Their Convergence	159
5.2 Evaluation of Continued Fractions	163
5.3 Polynomials and Rational Functions	167
5.4 Complex Arithmetic	171
5.5 Recurrence Relations and Clenshaw's Recurrence Formula	172
5.6 Quadratic and Cubic Equations	178
5.7 Numerical Derivatives	180
5.8 Chebyshev Approximation	184
5.9 Derivatives or Integrals of a Chebyshev-approximated Function	189
5.10 Polynomial Approximation from Chebyshev Coefficients	191
5.11 Economization of Power Series	192
5.12 Padé Approximants	194
5.13 Rational Chebyshev Approximation	197
5.14 Evaluation of Functions by Path Integration	201
6 Special Functions	205
6.0 Introduction	205
6.1 Gamma Function, Beta Function, Factorials, Binomial Coefficients	206
6.2 Incomplete Gamma Function, Error Function, Chi-Square Probability Function, Cumulative Poisson Function	209
6.3 Exponential Integrals	215
6.4 Incomplete Beta Function, Student's Distribution, F-Distribution, Cumulative Binomial Distribution	219
6.5 Bessel Functions of Integer Order	223
6.6 Modified Bessel Functions of Integer Order	229
6.7 Bessel Functions of Fractional Order, Airy Functions, Spherical Bessel Functions	234
6.8 Spherical Harmonics	246
6.9 Fresnel Integrals, Cosine and Sine Integrals	248
6.10 Dawson's Integral	252
6.11 Elliptic Integrals and Jacobian Elliptic Functions	254
6.12 Hypergeometric Functions	263
7 Random Numbers	266
7.0 Introduction	266
7.1 Uniform Deviates	267

7.2 Transformation Method: Exponential and Normal Deviates	277
7.3 Rejection Method: Gamma, Poisson, Binomial Deviates	281
7.4 Generation of Random Bits	287
7.5 Random Sequences Based on Data Encryption	290
7.6 Simple Monte Carlo Integration	295
7.7 Quasi- (that is, Sub-) Random Sequences	299
7.8 Adaptive and Recursive Monte Carlo Methods	306
8 Sorting	320
8.0 Introduction	320
8.1 Straight Insertion and Shell's Method	321
8.2 Quicksort	323
8.3 Heapsort	327
8.4 Indexing and Ranking	329
8.5 Selecting the M th Largest	333
8.6 Determination of Equivalence Classes	337
9 Root Finding and Nonlinear Sets of Equations	340
9.0 Introduction	340
9.1 Bracketing and Bisection	343
9.2 Secant Method, False Position Method, and Ridders' Method	347
9.3 Van Wijngaarden–Dekker–Brent Method	352
9.4 Newton–Raphson Method Using Derivative	355
9.5 Roots of Polynomials	362
9.6 Newton–Raphson Method for Nonlinear Systems of Equations	372
9.7 Globally Convergent Methods for Nonlinear Systems of Equations	376
10 Minimization or Maximization of Functions	387
10.0 Introduction	387
10.1 Golden Section Search in One Dimension	390
10.2 Parabolic Interpolation and Brent's Method in One Dimension	395
10.3 One-Dimensional Search with First Derivatives	399
10.4 Downhill Simplex Method in Multidimensions	402
10.5 Direction Set (Powell's) Methods in Multidimensions	406
10.6 Conjugate Gradient Methods in Multidimensions	413
10.7 Variable Metric Methods in Multidimensions	418
10.8 Linear Programming and the Simplex Method	423
10.9 Simulated Annealing Methods	436
11 Eigensystems	449
11.0 Introduction	449
11.1 Jacobi Transformations of a Symmetric Matrix	456
11.2 Reduction of a Symmetric Matrix to Tridiagonal Form: Givens and Householder Reductions	462
11.3 Eigenvalues and Eigenvectors of a Tridiagonal Matrix	469
11.4 Hermitian Matrices	475
11.5 Reduction of a General Matrix to Hessenberg Form	476

11.6 The QR Algorithm for Real Hessenberg Matrices	480
11.7 Improving Eigenvalues and/or Finding Eigenvectors by Inverse Iteration	487
12 <i>Fast Fourier Transform</i>	490
12.0 Introduction	490
12.1 Fourier Transform of Discretely Sampled Data	494
12.2 Fast Fourier Transform (FFT)	498
12.3 FFT of Real Functions, Sine and Cosine Transforms	504
12.4 FFT in Two or More Dimensions	515
12.5 Fourier Transforms of Real Data in Two and Three Dimensions	519
12.6 External Storage or Memory-Local FFTs	525
13 <i>Fourier and Spectral Applications</i>	530
13.0 Introduction	530
13.1 Convolution and Deconvolution Using the FFT	531
13.2 Correlation and Autocorrelation Using the FFT	538
13.3 Optimal (Wiener) Filtering with the FFT	539
13.4 Power Spectrum Estimation Using the FFT	542
13.5 Digital Filtering in the Time Domain	551
13.6 Linear Prediction and Linear Predictive Coding	557
13.7 Power Spectrum Estimation by the Maximum Entropy (All Poles) Method	565
13.8 Spectral Analysis of Unevenly Sampled Data	569
13.9 Computing Fourier Integrals Using the FFT	577
13.10 Wavelet Transforms	584
13.11 Numerical Use of the Sampling Theorem	600
14 <i>Statistical Description of Data</i>	603
14.0 Introduction	603
14.1 Moments of a Distribution: Mean, Variance, Skewness, and So Forth	604
14.2 Do Two Distributions Have the Same Means or Variances?	609
14.3 Are Two Distributions Different?	614
14.4 Contingency Table Analysis of Two Distributions	622
14.5 Linear Correlation	630
14.6 Nonparametric or Rank Correlation	633
14.7 Do Two-Dimensional Distributions Differ?	640
14.8 Savitzky-Golay Smoothing Filters	644
15 <i>Modeling of Data</i>	650
15.0 Introduction	650
15.1 Least Squares as a Maximum Likelihood Estimator	651
15.2 Fitting Data to a Straight Line	655
15.3 Straight-Line Data with Errors in Both Coordinates	660
15.4 General Linear Least Squares	665
15.5 Nonlinear Models	675

15.6 Confidence Limits on Estimated Model Parameters	684
15.7 Robust Estimation	694
16 Integration of Ordinary Differential Equations	701
16.0 Introduction	701
16.1 Runge-Kutta Method	704
16.2 Adaptive Stepsize Control for Runge-Kutta	708
16.3 Modified Midpoint Method	716
16.4 Richardson Extrapolation and the Bulirsch-Stoer Method	718
16.5 Second-Order Conservative Equations	726
16.6 Stiff Sets of Equations	727
16.7 Multistep, Multivalue, and Predictor-Corrector Methods	740
17 Two Point Boundary Value Problems	745
17.0 Introduction	745
17.1 The Shooting Method	749
17.2 Shooting to a Fitting Point	751
17.3 Relaxation Methods	753
17.4 A Worked Example: Spheroidal Harmonics	764
17.5 Automated Allocation of Mesh Points	774
17.6 Handling Internal Boundary Conditions or Singular Points	775
18 Integral Equations and Inverse Theory	779
18.0 Introduction	779
18.1 Fredholm Equations of the Second Kind	782
18.2 Volterra Equations	786
18.3 Integral Equations with Singular Kernels	788
18.4 Inverse Problems and the Use of A Priori Information	795
18.5 Linear Regularization Methods	799
18.6 Backus-Gilbert Method	806
18.7 Maximum Entropy Image Restoration	809
19 Partial Differential Equations	818
19.0 Introduction	818
19.1 Flux-Conservative Initial Value Problems	825
19.2 Diffusive Initial Value Problems	838
19.3 Initial Value Problems in Multidimensions	844
19.4 Fourier and Cyclic Reduction Methods for Boundary Value Problems	848
19.5 Relaxation Methods for Boundary Value Problems	854
19.6 Multigrid Methods for Boundary Value Problems	862
20 Less-Numerical Algorithms	881
20.0 Introduction	881
20.1 Diagnosing Machine Parameters	881
20.2 Gray Codes	886

20.3 Cyclic Redundancy and Other Checksums	888
20.4 Huffman Coding and Compression of Data	896
20.5 Arithmetic Coding	902
20.6 Arithmetic at Arbitrary Precision	906

Plan of the Two-Volume Edition

Fortran, long the epitome of stability, is once again a language in flux. Fortran 90 is not just the long-awaited updating of traditional Fortran 77 to modern computing practices, but also demonstrates Fortran’s decisive bid to be the language of choice for parallel programming on multiprocessor computers.

At the same time, Fortran 90 is completely backwards-compatible with all Fortran 77 code. So, users with legacy code, or who choose to use only older language constructs, will still get the benefit of updated and actively maintained compilers.

As we, the authors of *Numerical Recipes*, watched the gestation and birth of Fortran 90 by its governing standards committee (an interesting process described by a leading Committee member, Michael Metcalf, in the Foreword to our Volume 2), it became clear to us that the right moment for moving Numerical Recipes from Fortran 77 to Fortran 90 was sooner, rather than later.

On the other hand, it was equally clear that Fortran-77-style programming — no matter whether with Fortran 77 or Fortran 90 compilers — is, and will continue for a long time to be, the “mother tongue” of a large population of active scientists, engineers, and other users of numerical computation. This is not a user base that we would willingly or knowingly abandon.

The solution was immediately clear: a two-volume edition of the Fortran *Numerical Recipes* consisting of Volume 1 (this one, a corrected reprinting of the previous one-volume edition), now retitled *Numerical Recipes in Fortran 77*, and a completely new Volume 2, titled *Numerical Recipes in Fortran 90: The Art of Parallel Scientific Computing*. Volume 2 begins with three chapters (21, 22, and 23) that extend the narrative of the first volume to the new subjects of Fortran 90 language features, parallel programming methodology, and the implementation of certain useful utility functions in Fortran 90. Then, in exact correspondence with Volume 1’s Chapters 1–20, are new chapters B1–B20, devoted principally to the listing and explanation of new Fortran 90 routines. With a few exceptions, each Fortran 77 routine in Volume 1 has a corresponding new Fortran 90 version in Volume 2. (The exceptions are a few new capabilities, notably in random number generation and in multigrid PDE solvers, that are unique to Volume 2’s Fortran 90.) Otherwise, there is no duplication between the volumes. The detailed explanation of the algorithms in this Volume 1 is intended to apply to, and be essential for, both volumes.

In other words: **You can use this Volume 1 without having Volume 2, but you can’t use Volume 2 without Volume 1.** We think that there is much to be gained by having and using *both* volumes: Fortran 90’s parallel language constructions are not only useful for present and future multiprocessor machines; they also allow for the elegant and concise formulation of many algorithms on ordinary single-processor computers. We think that essentially *all* Fortran programmers will want gradually to migrate into Fortran 90 and into a mode of “thinking parallel.” We have written Volume 2 specifically to help with this important transition.

Volume 2’s discussion of parallel programming is focused on those issues of direct relevance to the Fortran 90 programmer. Some more general aspects of parallel programming, such as communication costs, synchronization of multiple processors, etc., are touched on only briefly. We provide references to the extensive literature on these more specialized topics.

A special note to C programmers: Right now, there is no effort at producing a parallel version of C that is comparable to Fortran 90 in maturity, acceptance, and stability. We think, therefore, that C programmers will be well served by using Volume 2, either in conjunction with this Volume 1 or else in conjunction with the sister volume *Numerical Recipes in C: The Art of Scientific Computing*, for an educational excursion into Fortran 90, its parallel programming constructions, and the numerical algorithms that capitalize on them. C and C++ programming have not been far from our minds as we have written this two-volume version. We think you will find that time spent in absorbing the principal lessons of Volume 2's Chapters 21–23 will be amply repaid in the future, as C and C++ eventually develop standard parallel extensions.

Preface to the Second Edition

Our aim in writing the original edition of *Numerical Recipes* was to provide a book that combined general discussion, analytical mathematics, algorithmics, and actual working programs. The success of the first edition puts us now in a difficult, though hardly unenviable, position. We wanted, then and now, to write a book that is informal, fearlessly editorial, unesoteric, and above all useful. There is a danger that, if we are not careful, we might produce a second edition that is weighty, balanced, scholarly, and boring.

It is a mixed blessing that we know more now than we did six years ago. Then, we were making educated guesses, based on existing literature and our own research, about which numerical techniques were the most important and robust. Now, we have the benefit of direct feedback from a large reader community. Letters to our alter-ego enterprise, Numerical Recipes Software, are in the thousands per year. (Please, *don't telephone us.*) Our post office box has become a magnet for letters pointing out that we have omitted some particular technique, well known to be important in a particular field of science or engineering. We value such letters, and digest them carefully, especially when they point us to specific references in the literature.

The inevitable result of this input is that this Second Edition of *Numerical Recipes* is substantially larger than its predecessor, in fact about 50% larger both in words and number of included programs (the latter now numbering well over 300). “Don’t let the book grow in size,” is the advice that we received from several wise colleagues. We have tried to follow the intended spirit of that advice, even as we violate the letter of it. We have not lengthened, or increased in difficulty, the book’s principal discussions of mainstream topics. Many new topics are presented at this same accessible level. Some topics, both from the earlier edition and new to this one, are now set in smaller type that labels them as being “advanced.” The reader who ignores such advanced sections completely will not, we think, find any lack of continuity in the shorter volume that results.

Here are some highlights of the new material in this Second Edition:

- a new chapter on integral equations and inverse methods
- a detailed treatment of multigrid methods for solving elliptic partial differential equations
- routines for band diagonal linear systems
- improved routines for linear algebra on sparse matrices
- Cholesky and QR decomposition
- orthogonal polynomials and Gaussian quadratures for arbitrary weight functions
- methods for calculating numerical derivatives
- Padé approximants, and rational Chebyshev approximation
- Bessel functions, and modified Bessel functions, of fractional order; and several other new special functions
- improved random number routines
- quasi-random sequences
- routines for adaptive and recursive Monte Carlo integration in high-dimensional spaces
- globally convergent methods for sets of nonlinear equations

- simulated annealing minimization for continuous control spaces
- fast Fourier transform (FFT) for real data in two and three dimensions
- fast Fourier transform (FFT) using external storage
- improved fast cosine transform routines
- wavelet transforms
- Fourier integrals with upper and lower limits
- spectral analysis on unevenly sampled data
- Savitzky-Golay smoothing filters
- fitting straight line data with errors in both coordinates
- a two-dimensional Kolmogorov-Smirnov test
- the statistical bootstrap method
- embedded Runge-Kutta-Fehlberg methods for differential equations
- high-order methods for stiff differential equations
- a new chapter on “less-numerical” algorithms, including Huffman and arithmetic coding, arbitrary precision arithmetic, and several other topics.

Consult the Preface to the First Edition, following, or the Table of Contents, for a list of the more “basic” subjects treated.

Acknowledgments

It is not possible for us to list by name here all the readers who have made useful suggestions; we are grateful for these. In the text, we attempt to give specific attribution for ideas that appear to be original, and not known in the literature. We apologize in advance for any omissions.

Some readers and colleagues have been particularly generous in providing us with ideas, comments, suggestions, and programs for this Second Edition. We especially want to thank George Rybicki, Philip Pinto, Peter Lepage, Robert Lupton, Douglas Eardley, Ramesh Narayan, David Spergel, Alan Oppenheim, Sallie Baliunas, Scott Tremaine, Glennys Farrar, Steven Block, John Peacock, Thomas Loredo, Matthew Choptuik, Gregory Cook, L. Samuel Finn, P. Deufhard, Harold Lewis, Peter Weinberger, David Syer, Richard Ferch, Steven Ebstein, and William Gould. We have been helped by Nancy Lee Snyder’s mastery of a complicated *T_EX* manuscript. We express appreciation to our editors Lauren Cowles and Alan Harvey at Cambridge University Press, and to our production editor Russell Hahn. We remain, of course, grateful to the individuals acknowledged in the Preface to the First Edition.

Special acknowledgment is due to programming consultant Seth Finkelstein, who influenced many of the routines in this book, and wrote or rewrote many more routines in its C-language twin and the companion Example books. Our project has benefited enormously from Seth’s talent for detecting, and following the trail of, even very slight anomalies (often compiler bugs, but occasionally our errors), and from his good programming sense.

We prepared this book for publication on DEC and Sun workstations running the UNIX operating system, and on a 486/33 PC compatible running MS-DOS 5.0/Windows 3.0. (See §1.0 for a list of additional computers used in program tests.) We enthusiastically recommend the principal software used: GNU Emacs, *T_EX*, Perl, Adobe Illustrator, and PostScript. Also used were a variety of FORTRAN compilers — too numerous (and sometimes too buggy) for individual

acknowledgment. It is a sobering fact that our standard test suite (exercising all the routines in this book) has uncovered compiler bugs in a large majority of the compilers tried. When possible, we work with developers to see that such bugs get fixed; we encourage interested compiler developers to contact us about such arrangements.

WHP and SAT acknowledge the continued support of the U.S. National Science Foundation for their research on computational methods. D.A.R.P.A. support is acknowledged for §13.10 on wavelets.

Preface to the First Edition

We call this book *Numerical Recipes* for several reasons. In one sense, this book is indeed a “cookbook” on numerical computation. However there is an important distinction between a cookbook and a restaurant menu. The latter presents choices among complete dishes in each of which the individual flavors are blended and disguised. The former — and this book — reveals the individual ingredients and explains how they are prepared and combined.

Another purpose of the title is to connote an eclectic mixture of presentational techniques. This book is unique, we think, in offering, for each topic considered, a certain amount of general discussion, a certain amount of analytical mathematics, a certain amount of discussion of algorithmics, and (most important) actual implementations of these ideas in the form of working computer routines. Our task has been to find the right balance among these ingredients for each topic. You will find that for some topics we have tilted quite far to the analytic side; this where we have felt there to be gaps in the “standard” mathematical training. For other topics, where the mathematical prerequisites are universally held, we have tilted towards more in-depth discussion of the nature of the computational algorithms, or towards practical questions of implementation.

We admit, therefore, to some unevenness in the “level” of this book. About half of it is suitable for an advanced undergraduate course on numerical computation for science or engineering majors. The other half ranges from the level of a graduate course to that of a professional reference. Most cookbooks have, after all, recipes at varying levels of complexity. An attractive feature of this approach, we think, is that the reader can use the book at increasing levels of sophistication as his/her experience grows. Even inexperienced readers should be able to use our most advanced routines as black boxes. Having done so, we hope that these readers will subsequently go back and learn what secrets are inside.

If there is a single dominant theme in this book, it is that practical methods of numerical computation can be simultaneously efficient, clever, and — important — clear. The alternative viewpoint, that efficient computational methods must necessarily be so arcane and complex as to be useful only in “black box” form, we firmly reject.

Our purpose in this book is thus to open up a large number of computational black boxes to your scrutiny. We want to teach you to take apart these black boxes and to put them back together again, modifying them to suit your specific needs. We assume that you are mathematically literate, i.e., that you have the normal mathematical preparation associated with an undergraduate degree in a physical science, or engineering, or economics, or a quantitative social science. We assume that you know how to program a computer. We do not assume that you have any prior formal knowledge of numerical analysis or numerical methods.

The scope of *Numerical Recipes* is supposed to be “everything up to, but not including, partial differential equations.” We honor this in the breach: First, we *do* have one introductory chapter on methods for partial differential equations (Chapter 19). Second, we obviously cannot include *everything* else. All the so-called “standard” topics of a numerical analysis course have been included in this book:

linear equations (Chapter 2), interpolation and extrapolation (Chaper 3), integration (Chaper 4), nonlinear root-finding (Chapter 9), eigensystems (Chapter 11), and ordinary differential equations (Chapter 16). Most of these topics have been taken beyond their standard treatments into some advanced material which we have felt to be particularly important or useful.

Some other subjects that we cover in detail are not usually found in the standard numerical analysis texts. These include the evaluation of functions and of particular special functions of higher mathematics (Chapters 5 and 6); random numbers and Monte Carlo methods (Chapter 7); sorting (Chapter 8); optimization, including multidimensional methods (Chapter 10); Fourier transform methods, including FFT methods and other spectral methods (Chapters 12 and 13); two chapters on the statistical description and modeling of data (Chapters 14 and 15); and two-point boundary value problems, both shooting and relaxation methods (Chapter 17).

The programs in this book are included in ANSI-standard FORTRAN-77. Versions of the book in C, Pascal, and BASIC are available separately. We have more to say about the FORTRAN language, and the computational environment assumed by our routines, in §1.1 (Introduction).

Acknowledgments

Many colleagues have been generous in giving us the benefit of their numerical and computational experience, in providing us with programs, in commenting on the manuscript, or in general encouragement. We particularly wish to thank George Rybicki, Douglas Eardley, Philip Marcus, Stuart Shapiro, Paul Horowitz, Bruce Musicus, Irwin Shapiro, Stephen Wolfram, Henry Abarbanel, Larry Smarr, Richard Muller, John Bahcall, and A.G.W. Cameron.

We also wish to acknowledge two individuals whom we have never met: Forman Acton, whose 1970 textbook *Numerical Methods that Work* (New York: Harper and Row) has surely left its stylistic mark on us; and Donald Knuth, both for his series of books on *The Art of Computer Programming* (Reading, MA: Addison-Wesley), and for TeX, the computer typesetting language which immensely aided production of this book.

Research by the authors on computational methods was supported in part by the U.S. National Science Foundation.

October, 1985

License Information

Read this section if you want to use the programs in this book on a computer. You'll need to read the following Disclaimer of Warranty, get the programs onto your computer, and acquire a Numerical Recipes software license. (Without this license, which can be the free "immediate license" under terms described below, the book is intended as a text and reference book, for reading purposes only.)

Disclaimer of Warranty

We make no warranties, express or implied, that the programs contained in this volume are free of error, or are consistent with any particular standard of merchantability, or that they will meet your requirements for any particular application. They should not be relied on for solving a problem whose incorrect solution could result in injury to a person or loss of property. If you do use the programs in such a manner, it is at your own risk. The authors and publisher disclaim all liability for direct or consequential damages resulting from your use of the programs.

How to Get the Code onto Your Computer

Pick one of the following methods:

- You can type the programs from this book directly into your computer. In this case, the *only* kind of license available to you is the free "immediate license" (see below). You are not authorized to transfer or distribute a machine-readable copy to any other person, nor to have any other person type the programs into a computer on your behalf. We do not want to hear bug reports from you if you choose this option, because experience has shown that *virtually all* reported bugs in such cases are typing errors!
- You can download the Numerical Recipes programs electronically from the Numerical Recipes On-Line Software Store, located at our Web site (<http://www.nr.com>). They are packaged as a password-protected file, and you'll need to purchase a license to unpack them. You can get a single-screen license and password immediately, on-line, from the On-Line Store, with fees ranging from \$50 (PC, Macintosh, educational institutions' UNIX) to \$140 (general UNIX). Downloading the packaged software from the On-Line Store is also the way to start if you want to acquire a more general (multiscreen, site, or corporate) license.

- You can purchase media containing the programs from Cambridge University Press. Diskette versions are available in IBM-compatible format for machines running Windows 3.1, 95, or NT. CDROM versions in ISO-9660 format for PC, Macintosh, and UNIX systems are also available; these include both Fortran and C versions (as well as versions in Pascal and BASIC from the first edition) on a single CDROM. Diskettes purchased from Cambridge University Press include a single-screen license for PC or Macintosh only. The CDROM is available with a single-screen license for PC or Macintosh (order ISBN 0 521 576083), or (at a slightly higher price) with a single-screen license for UNIX workstations (order ISBN 0 521 576075). Orders for media from Cambridge University Press can be placed at 800 872-7423 (North America only) or by email to orders@cup.org (North America) or trade@cup.cam.ac.uk (rest of world). Or, visit the Web sites <http://www.cup.org> (North America) or <http://www.cup.cam.ac.uk> (rest of world).

Types of License Offered

Here are the types of licenses that we offer. Note that some types are automatically acquired with the purchase of media from Cambridge University Press, or of an unlocking password from the Numerical Recipes On-Line Software Store, while other types of licenses require that you communicate specifically with Numerical Recipes Software (email: orders@nr.com or fax: 781 863-1739). Our Web site <http://www.nr.com> has additional information.

- [“Immediate License”] If you are the individual owner of a copy of this book and you type one or more of its routines into your computer, we authorize you to use them on that computer for your own personal and noncommercial purposes. You are not authorized to transfer or distribute machine-readable copies to any other person, or to use the routines on more than one machine, or to distribute executable programs containing our routines. This is the only free license.
- [“Single-Screen License”] This is the most common type of low-cost license, with terms governed by our Single Screen (Shrinkwrap) License document (complete terms available through our Web site). Basically, this license lets you use Numerical Recipes routines on any one screen (PC, workstation, X-terminal, etc.). You may also, under this license, transfer pre-compiled, executable programs incorporating our routines to other, unlicensed, screens or computers, providing that (i) your application is noncommercial (i.e., does not involve the selling of your program for a fee), (ii) the programs were first developed, compiled, and successfully run on a licensed screen, and (iii) our routines are bound into the programs in such a manner that they cannot be accessed as individual routines and cannot practicably be unbound and used in other programs. That is, under this license, your program user must not be able to use our programs as part of a program library or “mix-and-match” workbench. Conditions for other types of commercial or noncommercial distribution may be found on our Web site (<http://www.nr.com>).

- [“Multi-Screen, Server, Site, and Corporate Licenses”] The terms of the Single Screen License can be extended to designated groups of machines, defined by number of screens, number of machines, locations, or ownership. Significant discounts from the corresponding single-screen prices are available when the estimated number of screens exceeds 40. Contact Numerical Recipes Software (email: orders@nr.com or fax: 781 863-1739) for details.
- [“Course Right-to-Copy License”] Instructors at accredited educational institutions who have adopted this book for a course, and who have already purchased a Single Screen License (either acquired with the purchase of media, or from the Numerical Recipes On-Line Software Store), may license the programs for use in that course as follows: Mail your name, title, and address; the course name, number, dates, and estimated enrollment; and advance payment of \$5 per (estimated) student to Numerical Recipes Software, at this address: P.O. Box 243, Cambridge, MA 02238 (USA). You will receive by return mail a license authorizing you to make copies of the programs for use by your students, and/or to transfer the programs to a machine accessible to your students (but only for the duration of the course).

About Copyrights on Computer Programs

Like artistic or literary compositions, computer programs are protected by copyright. Generally it is an infringement for you to copy into your computer a program from a copyrighted source. (It is also not a friendly thing to do, since it deprives the program’s author of compensation for his or her creative effort.) Under copyright law, all “derivative works” (modified versions, or translations into another computer language) also come under the same copyright as the original work.

Copyright does not protect ideas, but only the expression of those ideas in a particular form. In the case of a computer program, the ideas consist of the program’s methodology and algorithm, including the necessary sequence of steps adopted by the programmer. The expression of those ideas is the program source code (particularly any arbitrary or stylistic choices embodied in it), its derived object code, and any other derivative works.

If you analyze the ideas contained in a program, and then express those ideas in your own completely different implementation, then that new program implementation belongs to you. That is what we have done for those programs in this book that are not entirely of our own devising. When programs in this book are said to be “based” on programs published in copyright sources, we mean that the ideas are the same. The expression of these ideas as source code is our own. We believe that no material in this book infringes on an existing copyright.

Trademarks

Several registered trademarks appear within the text of this book: Sun is a trademark of Sun Microsystems, Inc. SPARC and SPARCstation are trademarks of SPARC International, Inc. Microsoft, Windows 95, Windows NT, PowerStation, and MS are trademarks of Microsoft Corporation. DEC, VMS, Alpha AXP, and

ULTRIX are trademarks of Digital Equipment Corporation. IBM is a trademark of International Business Machines Corporation. Apple and Macintosh are trademarks of Apple Computer, Inc. UNIX is a trademark licensed exclusively through X/Open Co. Ltd. IMSL is a trademark of Visual Numerics, Inc. NAG refers to proprietary computer software of Numerical Algorithms Group (USA) Inc. PostScript and Adobe Illustrator are trademarks of Adobe Systems Incorporated. Last, and no doubt least, Numerical Recipes (when identifying products) is a trademark of Numerical Recipes Software.

Attributions

The fact that ideas are legally “free as air” in no way supersedes the ethical requirement that ideas be credited to their known originators. When programs in this book are based on known sources, whether copyrighted or in the public domain, published or “handed-down,” we have attempted to give proper attribution. Unfortunately, the lineage of many programs in common circulation is often unclear. We would be grateful to readers for new or corrected information regarding attributions, which we will attempt to incorporate in subsequent printings.

Computer Programs by Chapter and Section

1.0	flmoon	calculate phases of the moon by date
1.1	julday	Julian Day number from calendar date
1.1	badluk	Friday the 13th when the moon is full
1.1	caldat	calendar date from Julian day number
2.1	gaussj	Gauss-Jordan matrix inversion and linear equation solution
2.3	ludcmp	linear equation solution, LU decomposition
2.3	lubksb	linear equation solution, backsubstitution
2.4	tridag	solution of tridiagonal systems
2.4	banmul	multiply vector by band diagonal matrix
2.4	bandec	band diagonal systems, decomposition
2.4	banbks	band diagonal systems, backsubstitution
2.5	mprove	linear equation solution, iterative improvement
2.6	svbksb	singular value backsubstitution
2.6	svdcmp	singular value decomposition of a matrix
2.6	pythag	calculate $(a^2 + b^2)^{1/2}$ without overflow
2.7	cyclic	solution of cyclic tridiagonal systems
2.7	sprsin	convert matrix to sparse format
2.7	sprsax	product of sparse matrix and vector
2.7	sprstx	product of transpose sparse matrix and vector
2.7	sprstp	transpose of sparse matrix
2.7	sprspm	pattern multiply two sparse matrices
2.7	sprstm	threshold multiply two sparse matrices
2.7	linbcg	biconjugate gradient solution of sparse systems
2.7	snrm	used by linbcg for vector norm
2.7	atimes	used by linbcg for sparse multiplication
2.7	asolve	used by linbcg for preconditioner
2.8	vander	solve Vandermonde systems
2.8	toeplz	solve Toeplitz systems
2.9	choldc	Cholesky decomposition
2.9	cholsl	Cholesky backsubstitution
2.10	qrdfcm	QR decomposition
2.10	qrsolv	QR backsubstitution
2.10	rsolv	right triangular backsubstitution
2.10	qrupdt	update a QR decomposition
2.10	rotate	Jacobi rotation used by qrupdt
3.1	polint	polynomial interpolation
3.2	ratint	rational function interpolation
3.3	spline	construct a cubic spline
3.3	splint	cubic spline interpolation
3.4	locate	search an ordered table by bisection

3.4	hunt	search a table when calls are correlated
3.5	polcoe	polynomial coefficients from table of values
3.5	polcof	polynomial coefficients from table of values
3.6	polin2	two-dimensional polynomial interpolation
3.6	bcucof	construct two-dimensional bicubic
3.6	bcuint	two-dimensional bicubic interpolation
3.6	splie2	construct two-dimensional spline
3.6	splin2	two-dimensional spline interpolation
4.2	trapzd	trapezoidal rule
4.2	qtrap	integrate using trapezoidal rule
4.2	qsimp	integrate using Simpson's rule
4.3	qromb	integrate using Romberg adaptive method
4.4	midpnt	extended midpoint rule
4.4	qromo	integrate using open Romberg adaptive method
4.4	midinf	integrate a function on a semi-infinite interval
4.4	midsql	integrate a function with lower square-root singularity
4.4	midsqu	integrate a function with upper square-root singularity
4.4	midexp	integrate a function that decreases exponentially
4.5	qgaus	integrate a function by Gaussian quadratures
4.5	gauleg	Gauss-Legendre weights and abscissas
4.5	gaulag	Gauss-Laguerre weights and abscissas
4.5	gauher	Gauss-Hermite weights and abscissas
4.5	gaujac	Gauss-Jacobi weights and abscissas
4.5	gaucof	quadrature weights from orthogonal polynomials
4.5	orthog	construct nonclassical orthogonal polynomials
4.6	quad3d	integrate a function over a three-dimensional space
5.1	eulsum	sum a series by Euler–van Wijngaarden algorithm
5.3	ddpoly	evaluate a polynomial and its derivatives
5.3	poldiv	divide one polynomial by another
5.3	ratval	evaluate a rational function
5.7	dfridr	numerical derivative by Ridders' method
5.8	chebft	fit a Chebyshev polynomial to a function
5.8	chebev	Chebyshev polynomial evaluation
5.9	chder	derivative of a function already Chebyshev fitted
5.9	chint	integrate a function already Chebyshev fitted
5.10	chebpc	polynomial coefficients from a Chebyshev fit
5.10	pcshft	polynomial coefficients of a shifted polynomial
5.11	pccheb	inverse of chebpc; use to economize power series
5.12	pade	Padé approximant from power series coefficients
5.13	ratlsq	rational fit by least-squares method
6.1	gammln	logarithm of gamma function
6.1	factrl	factorial function
6.1	bico	binomial coefficients function
6.1	factln	logarithm of factorial function

6.1	beta	beta function
6.2	gammp	incomplete gamma function
6.2	gammq	complement of incomplete gamma function
6.2	gser	series used by gammp and gammq
6.2	gcf	continued fraction used by gammp and gammq
6.2	erf	error function
6.2	erfc	complementary error function
6.2	erfcc	complementary error function, concise routine
6.3	expint	exponential integral E_n
6.3	ei	exponential integral Ei
6.4	betai	incomplete beta function
6.4	betacf	continued fraction used by betai
6.5	bessj0	Bessel function J_0
6.5	bessy0	Bessel function Y_0
6.5	bessj1	Bessel function J_1
6.5	bessy1	Bessel function Y_1
6.5	bessy	Bessel function Y of general integer order
6.5	bessj	Bessel function J of general integer order
6.6	bessi0	modified Bessel function I_0
6.6	bessk0	modified Bessel function K_0
6.6	bessi1	modified Bessel function I_1
6.6	bessk1	modified Bessel function K_1
6.6	bessk	modified Bessel function K of integer order
6.6	bessi	modified Bessel function I of integer order
6.7	bessjy	Bessel functions of fractional order
6.7	beschb	Chebyshev expansion used by bessjy
6.7	bessik	modified Bessel functions of fractional order
6.7	airy	Airy functions
6.7	sphbes	spherical Bessel functions j_n and y_n
6.8	plgndr	Legendre polynomials, associated (spherical harmonics)
6.9	frenel	Fresnel integrals $S(x)$ and $C(x)$
6.9	cisi	cosine and sine integrals Ci and Si
6.10	dawson	Dawson's integral
6.11	rf	Carlson's elliptic integral of the first kind
6.11	rd	Carlson's elliptic integral of the second kind
6.11	rj	Carlson's elliptic integral of the third kind
6.11	rc	Carlson's degenerate elliptic integral
6.11	ellf	Legendre elliptic integral of the first kind
6.11	elle	Legendre elliptic integral of the second kind
6.11	ellpi	Legendre elliptic integral of the third kind
6.11	sncndn	Jacobian elliptic functions
6.12	hypgeo	complex hypergeometric function
6.12	hypser	complex hypergeometric function, series evaluation
6.12	hypdrv	complex hypergeometric function, derivative of
7.1	ran0	random deviate by Park and Miller minimal standard
7.1	ran1	random deviate, minimal standard plus shuffle

7.1	ran2	random deviate by L'Ecuyer long period plus shuffle
7.1	ran3	random deviate by Knuth subtractive method
7.2	expdev	exponential random deviates
7.2	gasdev	normally distributed random deviates
7.3	gamdev	gamma-law distribution random deviates
7.3	poidev	Poisson distributed random deviates
7.3	bnldev	binomial distributed random deviates
7.4	irbit1	random bit sequence
7.4	irbit2	random bit sequence
7.5	psdes	"pseudo-DES" hashing of 64 bits
7.5	ran4	random deviates from DES-like hashing
7.7	sobseq	Sobol's quasi-random sequence
7.8	vegas	adaptive multidimensional Monte Carlo integration
7.8	rebin	sample rebinning used by vegas
7.8	miser	recursive multidimensional Monte Carlo integration
7.8	ranpt	get random point, used by miser
8.1	piksrt	sort an array by straight insertion
8.1	piksr2	sort two arrays by straight insertion
8.1	shell	sort an array by Shell's method
8.2	sort	sort an array by quicksort method
8.2	sort2	sort two arrays by quicksort method
8.3	hpsort	sort an array by heapsort method
8.4	indexx	construct an index for an array
8.4	sort3	sort, use an index to sort 3 or more arrays
8.4	rank	construct a rank table for an array
8.5	select	find the N th largest in an array
8.5	selip	find the N th largest, without altering an array
8.5	hpsel	find M largest values, without altering an array
8.6	eclass	determine equivalence classes from list
8.6	eclazz	determine equivalence classes from procedure
9.0	scrsho	graph a function to search for roots
9.1	zbrac	outward search for brackets on roots
9.1	zbrak	inward search for brackets on roots
9.1	rtbis	find root of a function by bisection
9.2	rtflsp	find root of a function by false-position
9.2	rtsec	find root of a function by secant method
9.2	zriddr	find root of a function by Ridders' method
9.3	zbrent	find root of a function by Brent's method
9.4	rtnewt	find root of a function by Newton-Raphson
9.4	rtsafe	find root of a function by Newton-Raphson and bisection
9.5	laguer	find a root of a polynomial by Laguerre's method
9.5	zroots	roots of a polynomial by Laguerre's method with deflation
9.5	zrhqr	roots of a polynomial by eigenvalue methods
9.5	qroot	complex or double root of a polynomial, Bairstow

9.6	mnewt	Newton's method for systems of equations
9.7	lnsrch	search along a line, used by newt
9.7	newt	globally convergent multi-dimensional Newton's method
9.7	fdjac	finite-difference Jacobian, used by newt
9.7	fmin	norm of a vector function, used by newt
9.7	broydn	secant method for systems of equations
10.1	mnbrak	bracket the minimum of a function
10.1	golden	find minimum of a function by golden section search
10.2	brent	find minimum of a function by Brent's method
10.3	dbrent	find minimum of a function using derivative information
10.4	amoeba	minimize in N -dimensions by downhill simplex method
10.4	amotry	evaluate a trial point, used by amoeba
10.5	powell	minimize in N -dimensions by Powell's method
10.5	linmin	minimum of a function along a ray in N -dimensions
10.5	f1dim	function used by linmin
10.6	frprmn	minimize in N -dimensions by conjugate gradient
10.6	df1dim	alternative function used by linmin
10.7	dfrm	minimize in N -dimensions by variable metric method
10.8	simplx	linear programming maximization of a linear function
10.8	simp1	linear programming, used by simplx
10.8	simp2	linear programming, used by simplx
10.8	simp3	linear programming, used by simplx
10.9	anneal	traveling salesman problem by simulated annealing
10.9	revcst	cost of a reversal, used by anneal
10.9	revers	do a reversal, used by anneal
10.9	trncst	cost of a transposition, used by anneal
10.9	trnspt	do a transposition, used by anneal
10.9	metrop	Metropolis algorithm, used by anneal
10.9	amebsa	simulated annealing in continuous spaces
10.9	amotsa	evaluate a trial point, used by amebsa
11.1	jacobi	eigenvalues and eigenvectors of a symmetric matrix
11.1	eigsrt	eigenvectors, sorts into order by eigenvalue
11.2	tred2	Householder reduction of a real, symmetric matrix
11.3	tqli	eigensolution of a symmetric tridiagonal matrix
11.5	balanc	balance a nonsymmetric matrix
11.5	elmhes	reduce a general matrix to Hessenberg form
11.6	hqr	eigenvalues of a Hessenberg matrix
12.2	four1	fast Fourier transform (FFT) in one dimension
12.3	twofft	fast Fourier transform of two real functions
12.3	realfft	fast Fourier transform of a single real function
12.3	sinf	fast sine transform
12.3	cosft1	fast cosine transform with endpoints
12.3	cosft2	"staggered" fast cosine transform
12.4	fourn	fast Fourier transform in multidimensions

12.5	r1fft3	FFT of real data in two or three dimensions
12.6	fourfs	FFT for huge data sets on external media
12.6	fourrew	rewind and permute files, used by fourfs
13.1	convlv	convolution or deconvolution of data using FFT
13.2	correl	correlation or autocorrelation of data using FFT
13.4	spctrm	power spectrum estimation using FFT
13.6	memcof	evaluate maximum entropy (MEM) coefficients
13.6	fixrts	reflect roots of a polynomial into unit circle
13.6	predic	linear prediction using MEM coefficients
13.7	evlmem	power spectral estimation from MEM coefficients
13.8	period	power spectrum of unevenly sampled data
13.8	fasper	power spectrum of unevenly sampled larger data sets
13.8	spread	extrapolate value into array, used by fasper
13.9	dftcor	compute endpoint corrections for Fourier integrals
13.9	dftint	high-accuracy Fourier integrals
13.10	wt1	one-dimensional discrete wavelet transform
13.10	daub4	Daubechies 4-coefficient wavelet filter
13.10	pwtset	initialize coefficients for pwt
13.10	pwt	partial wavelet transform
13.10	wtm	multidimensional discrete wavelet transform
14.1	moment	calculate moments of a data set
14.2	ttest	Student's <i>t</i> -test for difference of means
14.2	avevar	calculate mean and variance of a data set
14.2	tutest	Student's <i>t</i> -test for means, case of unequal variances
14.2	tptest	Student's <i>t</i> -test for means, case of paired data
14.2	ftest	<i>F</i> -test for difference of variances
14.3	chsone	chi-square test for difference between data and model
14.3	chstwo	chi-square test for difference between two data sets
14.3	ksone	Kolmogorov-Smirnov test of data against model
14.3	kstwo	Kolmogorov-Smirnov test between two data sets
14.3	probks	Kolmogorov-Smirnov probability function
14.4	cntab1	contingency table analysis using chi-square
14.4	cntab2	contingency table analysis using entropy measure
14.5	pearsn	Pearson's correlation between two data sets
14.6	spear	Spearman's rank correlation between two data sets
14.6	crank	replaces array elements by their rank
14.6	kend11	correlation between two data sets, Kendall's tau
14.6	kend12	contingency table analysis using Kendall's tau
14.7	ks2d1s	K-S test in two dimensions, data vs. model
14.7	quadct	count points by quadrants, used by ks2d1s
14.7	quadvl	quadrant probabilities, used by ks2d1s
14.7	ks2d2s	K-S test in two dimensions, data vs. data
14.8	savgol	Savitzky-Golay smoothing coefficients
15.2	fit	least-squares fit data to a straight line

15.3	fitexy	fit data to a straight line, errors in both x and y
15.3	chixy	used by fitexy to calculate a χ^2
15.4	lfit	general linear least-squares fit by normal equations
15.4	covsrt	rearrange covariance matrix, used by lfit
15.4	svdfit	linear least-squares fit by singular value decomposition
15.4	svdvar	variances from singular value decomposition
15.4	fpoly	fit a polynomial using lfit or svdfit
15.4	fleg	fit a Legendre polynomial using lfit or svdfit
15.5	mrqmin	nonlinear least-squares fit, Marquardt's method
15.5	mrqcof	used by mrqmin to evaluate coefficients
15.5	fgauss	fit a sum of Gaussians using mrqmin
15.7	medfit	fit data to a straight line robustly, least absolute deviation
15.7	rofunc	fit data robustly, used by medfit
16.1	rk4	integrate one step of ODEs, fourth-order Runge-Kutta
16.1	rkdumb	integrate ODEs by fourth-order Runge-Kutta
16.2	rkqs	integrate one step of ODEs with accuracy monitoring
16.2	rkck	Cash-Karp-Runge-Kutta step used by rkqs
16.2	odeint	integrate ODEs with accuracy monitoring
16.3	mmid	integrate ODEs by modified midpoint method
16.4	bsstep	integrate ODEs, Bulirsch-Stoer step
16.4	pzextr	polynomial extrapolation, used by bsstep
16.4	rzextr	rational function extrapolation, used by bsstep
16.5	stoerm	integrate conservative second-order ODEs
16.6	stiff	integrate stiff ODEs by fourth-order Rosenbrock
16.6	jacobn	sample Jacobian routine for stiff
16.6	derivs	sample derivatives routine for stiff
16.6	simpr	integrate stiff ODEs by semi-implicit midpoint rule
16.6	stifbs	integrate stiff ODEs, Bulirsch-Stoer step
17.1	shoot	solve two point boundary value problem by shooting
17.2	shootf	ditto, by shooting to a fitting point
17.3	solvde	two point boundary value problem, solve by relaxation
17.3	bksub	backsubstitution, used by solvde
17.3	pinvs	diagonalize a sub-block, used by solvde
17.3	red	reduce columns of a matrix, used by solvde
17.4	sfroid	spheroidal functions by method of solvde
17.4	difeq	spheroidal matrix coefficients, used by sfroid
17.4	sphoot	spheroidal functions by method of shoot
17.4	sphfpt	spheroidal functions by method of shootf
18.1	fred2	solve linear Fredholm equations of the second kind
18.1	fredin	interpolate solutions obtained with fred2
18.2	voltra	linear Volterra equations of the second kind
18.3	wwghts	quadrature weights for an arbitrarily singular kernel
18.3	kermom	sample routine for moments of a singular kernel
18.3	quadmx	sample routine for a quadrature matrix

18.3	fredex	example of solving a singular Fredholm equation
19.5	sor	elliptic PDE solved by successive overrelaxation method
19.6	mglin	linear elliptic PDE solved by multigrid method
19.6	rstrct	half-weighting restriction, used by mglin , mgfas
19.6	interp	bilinear prolongation, used by mglin , mgfas
19.6	addint	interpolate and add, used by mglin
19.6	slvsml	solve on coarsest grid, used by mglin
19.6	relax	Gauss-Seidel relaxation, used by mglin
19.6	resid	calculate residual, used by mglin
19.6	copy	utility used by mglin , mgfas
19.6	fill0	utility used by mglin
19.6	malloc	memory allocation utility used by mglin , mgfas
19.6	mgfas	nonlinear elliptic PDE solved by multigrid method
19.6	relax2	Gauss-Seidel relaxation, used by mgfas
19.6	slvsm2	solve on coarsest grid, used by mgfas
19.6	lop	applies nonlinear operator, used by mgfas
19.6	matadd	utility used by mgfas
19.6	matsub	utility used by mgfas
19.6	anorm2	utility used by mgfas
20.1	machar	diagnose computer's floating arithmetic
20.2	igray	Gray code and its inverse
20.3	icrc1	cyclic redundancy checksum, used by icrc
20.3	icrc	cyclic redundancy checksum
20.3	decchk	decimal check digit calculation or verification
20.4	hufmak	construct a Huffman code
20.4	hufapp	append bits to a Huffman code, used by hufmak
20.4	hufenc	use Huffman code to encode and compress a character
20.4	hufdec	use Huffman code to decode and decompress a character
20.5	arcmak	construct an arithmetic code
20.5	arcode	encode or decode a character using arithmetic coding
20.5	arcsum	add integer to byte string, used by arcde
20.6	mpops	multiple precision arithmetic, simpler operations
20.6	mpmul	multiple precision multiply, using FFT methods
20.6	mpinv	multiple precision reciprocal
20.6	mpdiv	multiple precision divide and remainder
20.6	mpsqrt	multiple precision square root
20.6	mp2dfr	multiple precision conversion to decimal base
20.6	mppi	multiple precision example, compute many digits of π

Chapter 1. Preliminaries

1.0 Introduction

This book, like its predecessor edition, is supposed to teach you methods of numerical computing that are practical, efficient, and (insofar as possible) elegant. We presume throughout this book that you, the reader, have particular tasks that you want to get done. We view our job as educating you on how to proceed. Occasionally we may try to reroute you briefly onto a particularly beautiful side road; but by and large, we will guide you along main highways that lead to practical destinations.

Throughout this book, you will find us fearlessly editorializing, telling you what you should and shouldn't do. This prescriptive tone results from a conscious decision on our part, and we hope that you will not find it irritating. We do not claim that our advice is infallible! Rather, we are reacting against a tendency, in the textbook literature of computation, to discuss every possible method that has ever been invented, without ever offering a practical judgment on relative merit. We do, therefore, offer you our practical judgments whenever we can. As you gain experience, you will form your own opinion of how reliable our advice is.

We presume that you are able to read computer programs in FORTRAN, that being the language of this version of *Numerical Recipes* (Second Edition). The book *Numerical Recipes in C* (Second Edition) is separately available, if you prefer to program in that language. Earlier editions of *Numerical Recipes in Pascal* and *Numerical Recipes Routines and Examples in BASIC* are also available; while not containing the additional material of the Second Edition versions in C and FORTRAN, these versions are perfectly serviceable if Pascal or BASIC is your language of choice.

When we include programs in the text, they look like this:

```
SUBROUTINE flmoon(n,nph,jd,frac)
INTEGER jd,n,nph
REAL frac,RAD
PARAMETER (RAD=3.14159265/180.)
```

Our programs begin with an introductory comment summarizing their purpose and explaining their calling sequence. This routine calculates the phases of the moon. Given an integer *n* and a code *nph* for the phase desired (*nph* = 0 for new moon, 1 for first quarter, 2 for full, 3 for last quarter), the routine returns the Julian Day Number *jd*, and the fractional part of a day *frac* to be added to it, of the *n*th such phase since January, 1900. Greenwich Mean Time is assumed.

```
INTEGER i
REAL am,as,c,t,t2,xtra
c=n+nph/4.
t=c/1236.85
t2=t**2
```

This is how we comment an individual line.

```

as=359.2242+29.105356*c          You aren't really intended to understand this al-
am=306.0253+385.816918*c+0.010730*t2      gorithm, but it does work!
jd=2415020+28*n+7*nph
xtra=0.75933+1.53058868*c+(1.178e-4-1.55e-7*t)*t2
if(nph.eq.0.or.nph.eq.2)then
  xtra=xtra+(0.1734-3.93e-4*t)*sin(RAD*as)-0.4068*sin(RAD*am)
else if(nph.eq.1.or.nph.eq.3)then
  xtra=xtra+(0.1721-4.e-4*t)*sin(RAD*as)-0.6280*sin(RAD*am)
else
  pause 'nph is unknown in flmoon' This is how we will indicate error conditions.
endif
if(xtra.ge.0.)then
  i=int(xtra)
else
  i=int(xtra-1.)
endif
jd=jd+i
frac=xtra-i
return
END

```

A few remarks about our typographical conventions and programming style are in order at this point:

- It is good programming practice to declare all variables and identifiers in explicit “type” statements (REAL, INTEGER, etc.), even though the implicit declaration rules of FORTRAN do not require this. We will always do so. (As an aside to non-FORTRAN programmers, the implicit declaration rules are that variables which begin with the letters `i,j,k,l,m,n` are implicitly declared to be type INTEGER, while all other variables are implicitly declared to be type REAL. Explicit declarations override these conventions.)
- In sympathy with modular and object-oriented programming practice, we separate, typographically, a routine’s “public” or “interface” section from its “private” or “implementation” section. We do this even though FORTRAN is by no means a modular or object-oriented language: the separation makes sense simply as good programming style.
- The *public* section contains the calling interface and declarations of its variables. We find it useful to consider PARAMETER statements, and their associated declarations, as also being in the public section, since a user may want to modify parameter values to suit a particular purpose. COMMON blocks are likewise usually part of the public section, since they involve communication between routines.
- As the last entry in the public section, we will, where applicable, put a standardized comment line with the word USES (not a FORTRAN keyword), followed by a list of all external subroutines and functions that the routine references, excluding built-in FORTRAN functions. (For examples, see the routines in §6.1.)
- An introductory comment, set in type as an indented paragraph, separates the public section from the private or implementation section.
- Within the introductory comments, as well as in the text, we will frequently use the notation `a(1:m)` to mean “the array elements `a(1), a(2), ..., a(m)`.” Likewise, notations like `b(2:7)` or `c(1:m,1:n)` are to be

interpreted as ranges of array indices. (This use of colon to denote ranges comes from FORTRAN-77's syntax for array declarators and character substrings.)

- The *implementation section* contains the declarations of variables that are used only internally in the routine, any necessary SAVE statements for static variables (variables that must be preserved between calls to the routine), and of course the routine's actual executable code.
- Case is not significant in FORTRAN, so it can be used to promote readability. Our convention is to use upper case for two different, nonconflicting, purposes. First, nonexecutable compiler keywords are in upper case (e.g., SUBROUTINE, REAL, COMMON); second, parameter identifiers are in upper case. The reason for capitalizing parameters is that, because their values are liable to be modified, the user often needs to scan the implementation section of code to see exactly how the parameters are used.
- For simplicity, we adopt the convention of handling all errors and exceptional cases by the pause statement. In general, we do not intend that you continue program execution after a pause occurs, but FORTRAN allows you to do so — if you want to see what kind of wrong answer or catastrophic error results. In many applications, you will want to modify our programs to do more sophisticated error handling, for example to return with an error flag set, or call an error-handling routine.
- In the printed form of this book, we take some special typographical liberties regarding statement labels, and do . . . continue constructions. These are described in §1.1. Note that no such liberties are taken in the machine-readable *Numerical Recipes* diskettes, where all routines are in standard ANSI FORTRAN-77.

Computational Environment and Program Validation

Our goal is that the programs in this book be as portable as possible, across different platforms (models of computer), across different operating systems, and across different FORTRAN compilers. As surrogates for the large number of possible combinations, we have tested all the programs in this book on the combinations of machines, operating systems, and compilers shown on the accompanying table. More generally, the programs should run without modification on any compiler that implements the ANSI FORTRAN-77 standard. At the time of writing, there are not enough installed implementations of the successor FORTRAN-90 standard to justify our using any of its more advanced features. Since FORTRAN-90 is backwards-compatible with FORTRAN-77, there should be no difficulty in using the programs in this book on FORTRAN-90 compilers, as they become available.

In validating the programs, we have taken the program source code directly from the machine-readable form of the book's manuscript, to decrease the chance of propagating typographical errors. “Driver” or demonstration programs that we used as part of our validations are available separately as the *Numerical Recipes Example Book (FORTRAN)*, as well as in machine-readable form. If you plan to use more than a few of the programs in this book, or if you plan to use programs in this book on more than one different computer, then you may find it useful to obtain a copy of these demonstration programs.

Tested Machines and Compilers		
Hardware	O/S Version	Compiler Version
IBM PC compatible 486/33	MS-DOS 5.0	Microsoft Fortran 5.1
IBM RS6000	AIX 3.0	IBM AIX XL FORTRAN Compiler/6000
IBM PC-RT	BSD UNIX 4.3	“UNIX Fortran 77”
DEC VAX 4000	VMS 5.4	VAX Fortran 5.4
DEC VAXstation 2000	BSD UNIX 4.3	Berkeley f77 2.0 (4.3 bsd, SCCS lev. 6)
DECstation 5000/200	ULTRIX 4.2	DEC Fortran for ULTRIX RISC 3.1
DECsystem 5400	ULTRIX 4.1	MIPS f77 2.10
Sun SPARCstation 2	SunOS 4.1	Sun Fortran 1.4 (SC 1.0)
Apple Macintosh	System 6.0.7 / MPW 3.2	Absoft Fortran 77 Compiler 3.1.2

Of course we would be foolish to claim that there are no bugs in our programs, and we do not make such a claim. We have been very careful, and have benefitted from the experience of the many readers who have written to us. If you find a new bug, please document it and tell us!

Compatibility with the First Edition

If you are accustomed to the *Numerical Recipes* routines of the First Edition, rest assured: almost all of them are still here, with the same names and functionalities, often with major improvements in the code itself. In addition, we hope that you will soon become equally familiar with the added capabilities of the more than 100 routines that are new to this edition.

We have retired a small number of First Edition routines, those that we believe to be clearly dominated by better methods implemented in this edition. A table, following, lists the retired routines and suggests replacements.

First Edition users should also be aware that some routines common to both editions have alterations in their calling interfaces, so are not directly “plug compatible.” A fairly complete list is: `chson`, `chstwo`, `covsrt`, `dfrm`, `laguer`, `lfit`, `memcof`, `mrqcof`, `mrqmin`, `pzextr`, `ran4`, `realft`, `rzextr`, `shoot`, `shootf`. There may be others (depending in part on which printing of the First Edition is taken for the comparison). If you have written software of any appreciable complexity that is dependent on First Edition routines, we do *not* recommend blindly replacing them by the corresponding routines in this book. We do recommend that any new programming efforts use the new routines.

About References

You will find references, and suggestions for further reading, listed at the end of most sections of this book. References are cited in the text by bracketed numbers like this [1].

Because computer algorithms often circulate informally for quite some time before appearing in a published form, the task of uncovering “primary literature”

Previous Routines Omitted from This Edition		
Name(s)	Replacement(s)	Comment
ADI	<code>mglin</code> or <code>mgfas</code>	better method
COSFT	<code>cosft1</code> or <code>cosft2</code>	choice of boundary conditions
CEL, EL2	<code>rf</code> , <code>rd</code> , <code>rj</code> , <code>rc</code>	better algorithms
DES, DESKS	<code>ran4</code> now uses <code>psdes</code>	was too slow
MDIAN1, MDIAN2	<code>select</code> , <code>selip</code>	more general
QCKSRT	<code>sort</code>	name change (<code>SORT</code> is now <code>hpsort</code>)
RKQC	<code>rkqs</code>	better method
SMOOFIT	use <code>convlv</code> with coefficients from <code>savgol</code>	
SPARSE	<code>linbcg</code>	more general

is sometimes quite difficult. We have not attempted this, and we do not pretend to any degree of bibliographical completeness in this book. For topics where a substantial secondary literature exists (discussion in textbooks, reviews, etc.) we have consciously limited our references to a few of the more useful secondary sources, especially those with good references to the primary literature. Where the existing secondary literature is insufficient, we give references to a few primary sources that are intended to serve as starting points for further reading, not as complete bibliographies for the field.

The order in which references are listed is not necessarily significant. It reflects a compromise between listing cited references in the order cited, and listing suggestions for further reading in a roughly prioritized order, with the most useful ones first.

The remaining two sections of this chapter review some basic concepts of programming (control structures, etc.) and of numerical analysis (roundoff error, etc.). Thereafter, we plunge into the substantive material of the book.

1.1 Program Organization and Control Structures

We sometimes like to point out the close analogies between computer programs, on the one hand, and written poetry or written musical scores, on the other. All three present themselves as visual media, symbols on a two-dimensional page or computer screen. Yet, in all three cases, the visual, two-dimensional, *frozen-in-time* representation communicates (or is supposed to communicate) something rather

different, namely a process that *unfolds in time*. A poem is meant to be read; music, played; a program, executed as a sequential series of computer instructions.

In all three cases, the target of the communication, in its visual form, is a human being. The goal is to transfer to him/her, as efficiently as can be accomplished, the greatest degree of understanding, in advance, of how the process *will* unfold in time. In poetry, this human target is the reader. In music, it is the performer. In programming, it is the program user.

Now, you may object that the target of communication of a program is not a human but a computer, that the program user is only an irrelevant intermediary, a lackey who feeds the machine. This is perhaps the case in the situation where the business executive pops a diskette into a desktop computer and feeds that computer a black-box program in binary executable form. The computer, in this case, doesn't much care whether that program was written with "good programming practice" or not.

We envision, however, that you, the readers of this book, are in quite a different situation. You need, or want, to know not just *what* a program does, but also *how* it does it, so that you can tinker with it and modify it to your particular application. You need others to be able to see what you have done, so that they can criticize or admire. In such cases, where the desired goal is *maintainable* or *reusable* code, the targets of a program's communication are surely human, not machine.

One key to achieving good programming practice is to recognize that programming, music, and poetry — all three being symbolic constructs of the human brain — are naturally structured into hierarchies that have many different nested levels. Sounds (phonemes) form small meaningful units (morphemes) which in turn form words; words group into phrases, which group into sentences; sentences make paragraphs, and these are organized into higher levels of meaning. Notes form musical phrases, which form themes, counterpoints, harmonies, etc.; which form movements, which form concertos, symphonies, and so on.

The structure in programs is equally hierarchical. Appropriately, good programming practice brings different techniques to bear on the different levels [1-3]. At a low level is the ascii character set. Then, constants, identifiers, operands, operators. Then program statements, like $a(j+1)=b+c/3.0$. Here, the best programming advice is simply *be clear*, or (correspondingly) *don't be too tricky*. You might momentarily be proud of yourself at writing the single line

```
k=(2-j)*(1+3*j)/2
```

if you want to permute cyclically one of the values $j = (0, 1, 2)$ into respectively $k = (1, 2, 0)$. You will regret it later, however, when you try to understand that line. Better, and likely also faster, is

```
k=j+1
if (k.eq.3) k=0
```

Many programming stylists would even argue for the ploddingly literal

```
if (j.eq.0) then
  k=1
else if (j.eq.1) then
  k=2
```

```

else if (j.eq.2) then
    k=0
else
    pause 'never get here'
endif

```

on the grounds that it is both clear and additionally safeguarded from wrong assumptions about the possible values of j . Our preference among the implementations is for the middle one.

In this simple example, we have in fact traversed several levels of hierarchy: Statements frequently come in “groups” or “blocks” which make sense only taken as a whole. The middle fragment above is one example. Another is

```

swap=a(j)
a(j)=b(j)
b(j)=swap

```

which makes immediate sense to any programmer as the exchange of two variables, while

```

sum=0.0
ans=0.0
n=1

```

is very likely to be an initialization of variables prior to some iterative process. This level of hierarchy in a program is usually evident to the eye. It is good programming practice to put in comments at this level, e.g., “initialize” or “exchange variables.”

The next level is that of *control structures*. These are things like the *if...then...else* clauses in the example above, do loops, and so on. This level is sufficiently important, and relevant to the hierarchical level of the routines in this book, that we will come back to it just below.

At still higher levels in the hierarchy, we have (in FORTRAN) subroutines, functions, and the whole “global” organization of the computational task to be done. In the musical analogy, we are now at the level of movements and complete works. At these levels, *modularization* and *encapsulation* become important programming concepts, the general idea being that program units should interact with one another only through clearly defined and narrowly circumscribed interfaces. Good modularization practice is an essential prerequisite to the success of large, complicated software projects, especially those employing the efforts of more than one programmer. It is also good practice (if not quite as essential) in the less massive programming tasks that an individual scientist, or reader of this book, encounters.

Some computer languages, such as Modula-2 and C++, promote good modularization with higher-level language constructs, absent in FORTRAN-77. In Modula-2, for example, subroutines, type definitions, and data structures can be encapsulated into “modules” that communicate through declared public interfaces and whose internal workings are hidden from the rest of the program [4]. In the C++ language, the key concept is “class,” a user-definable generalization of data type that provides for data hiding, automatic initialization of data, memory management, dynamic typing, and operator overloading (i.e., the user-definable extension of operators like + and * so as to be appropriate to operands in any particular class) [5]. Properly used in defining the data structures that are passed between program units, classes

can clarify and circumscribe these units' public interfaces, reducing the chances of programming error and also allowing a considerable degree of compile-time and run-time error checking.

Beyond modularization, though depending on it, lie the concepts of *object-oriented programming*. Here a programming language, such as C++ or Turbo Pascal 5.5 [6], allows a module's public interface to accept redefinitions of types or actions, and these redefinitions become shared all the way down through the module's hierarchy (so-called *polymorphism*). For example, a routine written to invert a matrix of real numbers could — dynamically, at run time — be made able to handle complex numbers by overloading complex data types and corresponding definitions of the arithmetic operations. Additional concepts of *inheritance* (the ability to define a data type that “inherits” all the structure of another type, plus additional structure of its own), and *object extensibility* (the ability to add functionality to a module without access to its source code, e.g., at run time), also come into play.

We have not attempted to modularize, or make objects out of, the routines in this book, for at least two reasons. First, the chosen language, FORTRAN-77, does not really make this possible. Second, we envision that you, the reader, might want to incorporate the algorithms in this book, a few at a time, into modules or objects with a structure of your own choosing. There does not exist, at present, a standard or accepted set of “classes” for scientific object-oriented computing. While we might have tried to invent such a set, doing so would have inevitably tied the algorithmic content of the book (which is its *raison d'être*) to some rather specific, and perhaps haphazard, set of choices regarding class definitions.

On the other hand, we are not unfriendly to the goals of modular and object-oriented programming. Within the limits of FORTRAN, we have therefore tried to structure our programs to be “object friendly,” principally via the clear delineation of interface vs. implementation (§1.0) and the explicit declaration of variables. Within our implementation sections, we have paid particular attention to the practices of *structured programming*, as we now discuss.

Control Structures

An executing program unfolds in time, but not strictly in the linear order in which the statements are written. Program statements that affect the order in which statements are executed, or that affect whether statements are executed, are called *control statements*. Control statements never make useful sense by themselves. They make sense only in the context of the groups or blocks of statements that they in turn control. If you think of those blocks as paragraphs containing sentences, then the control statements are perhaps best thought of as the indentation of the paragraph and the punctuation between the sentences, not the words within the sentences.

We can now say what the goal of structured programming is. It is *to make program control manifestly apparent in the visual presentation of the program*. You see that this goal has nothing at all to do with how the computer sees the program. As already remarked, computers don't care whether you use structured programming or not. Human readers, however, *do* care. You yourself will also care, once you discover how much easier it is to perfect and debug a well-structured program than one whose control structure is obscure.

You accomplish the goals of structured programming in two complementary ways. First, you acquaint yourself with the small number of essential control structures that occur over and over again in programming, and that are therefore given convenient representations in most programming languages. You should learn to think about your programming tasks, insofar as possible, exclusively in terms of these standard control structures. In writing programs, you should get into the habit of representing these standard control structures in consistent, conventional ways.

“Doesn’t this inhibit *creativity*?” our students sometimes ask. Yes, just as Mozart’s creativity was inhibited by the sonata form, or Shakespeare’s by the metrical requirements of the sonnet. The point is that creativity, when it is meant to communicate, does *well* under the inhibitions of appropriate restrictions on format.

Second, you *avoid*, insofar as possible, control statements whose controlled blocks or objects are difficult to discern at a glance. This means, in practice, that *you must try to avoid statement labels and goto’s*. It is not the *goto*’s that are dangerous (although they do interrupt one’s reading of a program); the statement labels are the hazard. In fact, whenever you encounter a statement label while reading a program, you will soon become conditioned to get a sinking feeling in the pit of your stomach. Why? Because the following questions will, by habit, immediately spring to mind: Where did control come *from* in a branch to this label? It could be anywhere in the routine! What circumstances resulted in a branch to this label? They could be anything! Certainty becomes uncertainty, understanding dissolves into a morass of possibilities.

Some older languages, notably 1966 FORTRAN and to a lesser extent FORTRAN-77, *require* statement labels in the construction of certain standard control structures. We will see this in more detail below. This is a demerit for these languages. In such cases, you must use labels as required. But you should never branch to them independently of the standard control structure. If you must branch, let it be to an additional label, one that is not masquerading as part of a standard control structure.

We call labels that are part of a standard construction and never otherwise branched to *tame labels*. They do not interfere with structured programming in any way, except possibly typographically as distractions to the eye.

Some examples are now in order to make these considerations more concrete (see Figure 1.1.1).

Catalog of Standard Structures

Iteration. In FORTRAN, simple iteration is performed with a do loop, for example

```
do 10 j=2,1000
      b(j)=a(j-1)
      a(j-1)=j
10  continue
```

Notice how we always indent the block of code that is acted upon by the control structure, leaving the structure itself unindented. The statement label 10 in this example is a tame label. The majority of modern implementations of FORTRAN-77 provide a nonstandard language extension that obviates the tame label. Originally

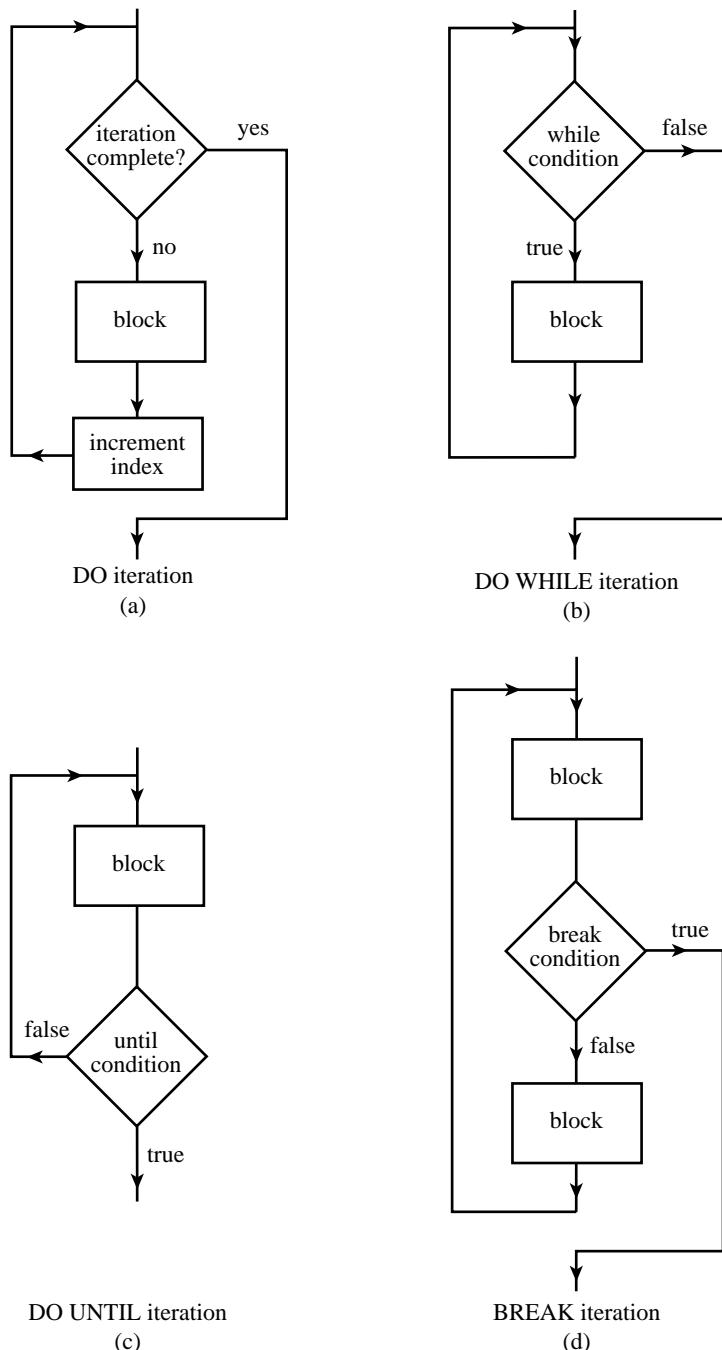

Figure 1.1.1. Standard control structures used in structured programming: (a) DO iteration; (b) DO WHILE iteration; (c) DO UNTIL iteration; (d) BREAK iteration; (e) IF structure; (f) obsolete form of DO iteration found in FORTRAN-66, where the block is executed once even if the iteration condition is initially not satisfied.

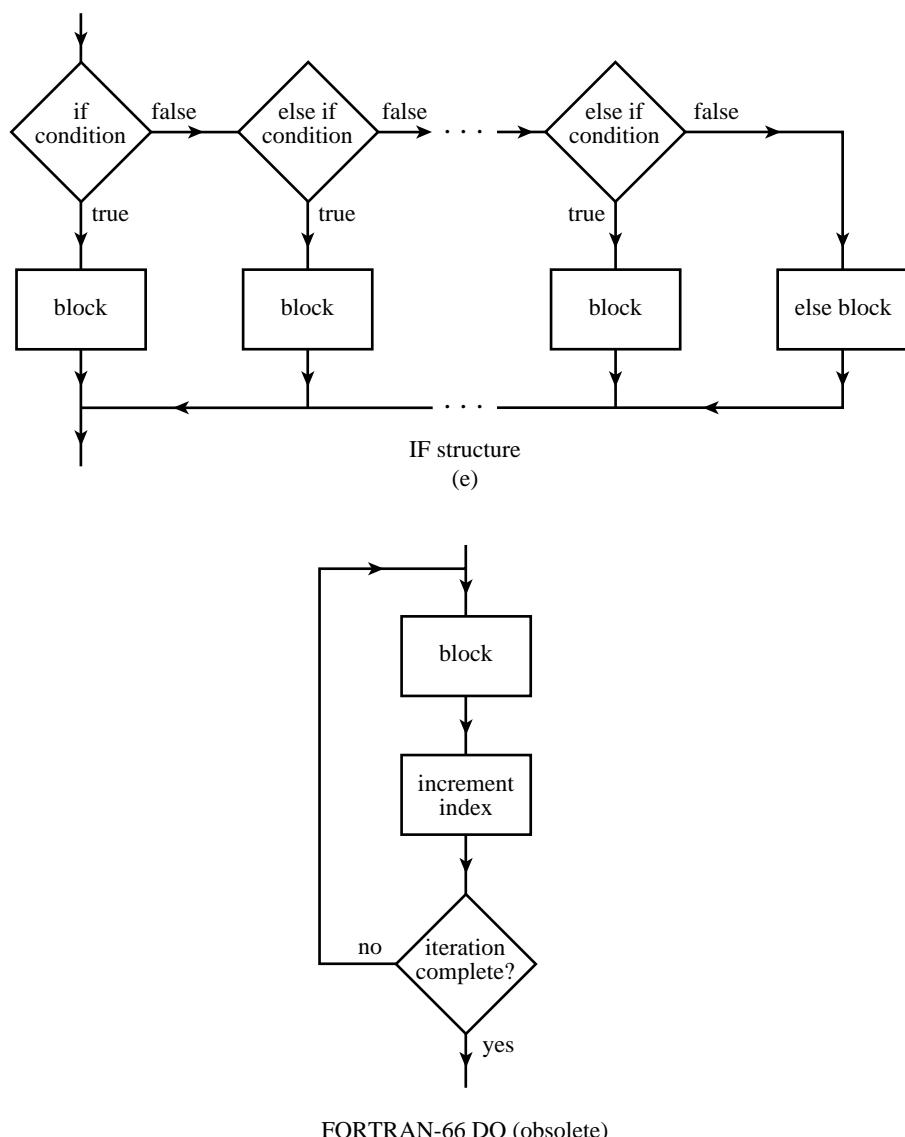

Figure 1.1.1. Standard control structures used in structured programming (see caption on previous page).

introduced in Digital Equipment Corporations's VAX-11 FORTRAN, the “`enddo`” statement is used as

```
do j=2,1000
    b(j)=a(j-1)
    a(j-1)=j
enddo
```

In fact, it was a terrible mistake that the American National Standard for FORTRAN-77 (ANSI X3.9-1978) failed to provide an `enddo` or equivalent construction. This mistake by the people who write standards, whoever they are, presents us now, more than 15 years later, with a painful quandary: Do we stick to the standard, and clutter our programs with tame labels? Or do we adopt a nonstandard (albeit widely implemented) FORTRAN construction like `enddo`?

We have adopted a compromise position. Standards, even imperfect standards, are terribly important and highly necessary in a time of rapid evolution in computers and their applications. Therefore, all machine-readable forms of our programs (e.g., the diskettes that you can order from the publisher — see back of this book) are strictly FORTRAN-77 compliant. (Well, *almost* strictly: there is a minor anomaly regarding bit manipulation functions, see below.) In particular, do blocks always end with labeled `continue` statements, as in the first example above.

In the printed version of this book, however, we make use of typography to mitigate the standard’s deficiencies. The statement label that follows the `do` is printed in small type — as a signal that it is a tame label that you can safely ignore. And, the word “`continue`” is printed as “`enddo`”, which you may regard as a *very* peculiar change of font! The example above, in our adopted typographical format, is

```
do 10 j=2,1000
    b(j)=a(j-1)
    a(j-1)=j
enddo 10
```

(Notice that we also take the typographical liberty of writing the tame label after the “`continue`” statement, rather than before.)

A nested `do` loop looks like this:

```
do 12 j=1,20
    s(j)=0.
    do 11 k=5,10
        s(j)=s(j)+a(j,k)
    enddo 11
enddo 12
```

Generally, the numerical values of the tame labels are chosen to put the `enddo`’s (labeled `continue`’s on the diskette) into ascending numerical order, hence the `do 12` before the `do 11` in the above example.

IF structure. In this structure the FORTRAN-77 standard is exemplary. Here is a working program that consists dominantly of `if` control statements:

```

FUNCTION julday(mm,id,iyyy)
INTEGER julday,id,iyyy,mm,IGREG
PARAMETER (IGREG=15+31*(10+12*1582))      Gregorian Calendar adopted Oct. 15, 1582.
In this routine julday returns the Julian Day Number that begins at noon of the calendar
date specified by month mm, day id, and year iyyy, all integer variables. Positive year
signifies A.D.; negative, B.C. Remember that the year after 1 B.C. was 1 A.D.
INTEGER ja,jm,jy
jy=iyyy
if (jy.eq.0) pause 'julday: there is no year zero'
if (jy.lt.0) jy=jy+1
if (mm.gt.2) then                                Here is an example of a block IF-structure.
  jm=mm+1
else
  jy=jy-1
  jm=mm+13
endif
julday=365*jy+int(0.25d0*jy+2000.d0)+int(30.6001d0*jm)+id+1718995
if (id+31*(mm+12*iyyy).ge.IGREG) then      Test whether to change to Gregorian Calen-
  ja=int(0.01d0*jy)                          dar.
  julday=julday+2-ja+int(0.25d0*ja)
endif
return
END

```

(Astronomers number each 24-hour period, starting and ending at *noon*, with a unique integer, the Julian Day Number [7]. Julian Day Zero was a very long time ago; a convenient reference point is that Julian Day 2440000 began at noon of May 23, 1968. If you know the Julian Day Number that begins at noon of a given calendar date, then the day of the week of that date is obtained by adding 1 and taking the result modulo base 7; a zero answer corresponds to Sunday, 1 to Monday, . . . , 6 to Saturday.)

Do-While iteration. Most good languages, except FORTRAN, provide for structures like the following C example:

```

while (n<1000) {
    n=2*n;
    j++;                         In C this has the meaning j=j+1.
}

```

In fact, many FORTRAN implementations have the nonstandard extension

```

do while (n.lt.1000)
    n=2*n
    j=j+1
enddo

```

Within the FORTRAN-77 standard, however, the structure requires a tame label:

```

17 if (n.lt.1000) then
    n=2*n
    j=j+1
  goto 17
endif

```

There are other ways of constructing a Do-While in FORTRAN, but we try to use the above format consistently. You will quickly get used to a statement like `17 if` as signaling this structure. Notice that the two final statements are not indented, since they are part of the control structure, not of the inside block.

Do-Until iteration. In Pascal, for example, this is rendered as

```
REPEAT
    n:=n DIV 2;           Pascal's integer divide is DIV.
    k:=k+1;
UNTIL (n=1);
```

In FORTRAN we write

```
19 continue
    n=n/2
    k=k+1
    if (n.ne.1) goto 19
```

Break. In this case, you have a loop that is repeated indefinitely until some condition *tested somewhere in the middle of the loop* (and possibly tested in more than one place) becomes true. At that point you wish to exit the loop and proceed with what comes after it. Standard FORTRAN does not make this structure accessible without labels. We will try to avoid using the structure when we can. Sometimes, however, it is plainly necessary. We do not have the patience to argue with the designers of computer languages over this point. In FORTRAN we write

```
13 continue
    [statements before the test]
    if (...) goto 14
    [statements after the test]
    goto 13
14 continue
```

Here is a program that uses several different iteration structures. One of us was once asked, for a scavenger hunt, to find the date of a Friday the 13th on which the moon was full. This is a program which accomplishes that task, giving incidentally all other Fridays the 13th as a by-product.

```
PROGRAM badluk
INTEGER ic,icon,idwk,ifrac,im,iybeg,iyend,iyyy,jd,jday,n,
*          julday
REAL TIMZON,frac
PARAMETER (TIMZON=-5./24.)           Time zone -5 is Eastern Standard Time.
DATA iybeg,iyend /1900,2000/         The range of dates to be searched.
C USES flmoon,julday
write (*,'(x,a,i5,a,i5)') 'Full moons on Friday the 13th from',
*          iybeg,' to ',iyend
do 12 iyyy=iybeg,iyend             Loop over each year,
   do 11 im=1,12                   and each month.
      jday=julday(im,13,iyyy)       Is the 13th a Friday?
      idwk=mod(jday+1,7)
      if(idwk.eq.5) then
         n=12.37*(iyyy-1900+(im-0.5)/12.)
         This value n is a first approximation to how many full moons have occurred
         since 1900. We will feed it into the phase routine and adjust it up or down until
```

we determine that our desired 13th was or was not a full moon. The variable icon signals the direction of adjustment.

```

1      icon=0
      call flmoon(n,2,jd,frac)      Get date of full moon n.
      ifrac=nint(24.* (frac+TZON)) Convert to hours in correct time zone.
      if(ifrac.lt.0)then           Convert from Julian Days beginning at noon
          jd=jd-1                  to civil days beginning at midnight.
          ifrac=ifrac+24
      endif
      if(ifrac.gt.12)then
          jd=jd+1
          ifrac=ifrac-12
      else
          ifrac=ifrac+12
      endif
      if(jd.eq.jday)then           Did we hit our target day?
          write (*,'(/1x,i2,a,i2,a,i4)') im,'/',13,'/',iyyy
          write (*,'(1x,a,i2,a)') 'Full moon ',ifrac,
          ' hrs after midnight (EST).'
*
*          Don't worry if you are unfamiliar with FORTRAN's esoteric input/output
*          statements; very few programs in this book do any input/output.
          goto 2                      Part of the break-structure, case of a match.
      else                           Didn't hit it.
          ic=isign(1,jday-jd)
          if(ic.eq.-icon) goto 2      Another break, case of no match.
          icon=ic
          n=n+ic
      endif
      goto 1
      continue
2      endif
      enddo 11
  enddo 12
END

```

If you are merely curious, there were (or will be) occurrences of a full moon on Friday the 13th (time zone GMT–5) on: 3/13/1903, 10/13/1905, 6/13/1919, 1/13/1922, 11/13/1970, 2/13/1987, 10/13/2000, 9/13/2019, and 8/13/2049.

Other “standard” structures. Our advice is to avoid them. Every programming language has some number of “goodies” that the designer just couldn’t resist throwing in. They seemed like a good idea at the time. Unfortunately they don’t stand the *test* of time! Your program becomes difficult to translate into other languages, and difficult to read (because rarely used structures are unfamiliar to the reader). You can almost always accomplish the supposed conveniences of these structures in other ways. Try to do so with the above standard structures, which really *are* standard. If you can’t, then use straightforward, unstructured, tests and goto’s. This will introduce real (not tame) statement labels, whose very existence will warn the reader to give special thought to the program’s control flow.

In FORTRAN we consider the ill-advised control structures to be

- assigned goto and assign statements
- computed goto statement
- arithmetic if statement

About “Advanced Topics”

Material set in smaller type, like this, signals an “advanced topic,” either one outside of the main argument of the chapter, or else one requiring of you more than the usual assumed mathematical background, or else (in a few cases) a discussion that is more speculative or an algorithm that is less well-tested. Nothing important will be lost if you skip the advanced topics on a first reading of the book.

You may have noticed that, by its looping over the months and years, the program `badluk` avoids using any algorithm for converting a Julian Day Number back into a calendar date. A routine for doing just this is not very interesting structurally, but it is occasionally useful:

```
SUBROUTINE caldat(julian,mm,id,iyyy)
INTEGER id,iyyy,julian,mm,IGREG
PARAMETER (IGREG=2299161)
    Inverse of the function julday given above. Here julian is input as a Julian Day Number,
    and the routine outputs mm,id, and iyyy as the month, day, and year on which the specified
    Julian Day started at noon.
    INTEGER ja,jalpha,jb,jc,jd,je
    if(julian.ge.IGREG)then
        Cross-over to Gregorian Calendar produces
        jalpha=int(((julian-1867216)-0.25d0)/36524.25d0)   this correction.
        ja=julian+1+jalpha-int(0.25d0*jalpha)
    else if(julian.lt.0)then
        ja=julian+36525*(1-julian/36525)
    else
        ja=julian
    endif
    jb=ja+1524
    jc=int(6680.0d0+((jb-2439870)-122.1d0)/365.25d0)
    jd=365*jc+int(0.25d0*jc)
    je=int((jb-jd)/30.6001d0)
    id=jb-jd-int(30.6001d0*je)
    mm=je-1
    if(mm.gt.12)mm=mm-12
    iyyy=jc-4715
    if(mm.gt.2)iyyy=iyyy-1
    if(iyyy.le.0)iyyy=iyyy-1
    if(julian.lt.0)iyyy=iyyy-100*(1-julian/36525)
    return
END
```

(For additional calendrical algorithms, applicable to various historical calendars, see [8].)

Some Habits and Assumed ANSI Extensions

Mentioning a few of our programming habits here will make it easier for you to read the programs in this book.

- We habitually use `m` and `n` to refer to the logical dimensions of a matrix, `mp` and `np` to refer to the physical dimensions. (These important concepts are detailed in §2.0 and Figure 2.0.1.)
- Often, when a subroutine or procedure is to be passed some integer `n`, it needs an internally preset value for the largest possible value that will be passed. We habitually call this `NMAX`, and set it in a `PARAMETER` statement. When we say in a comment, “largest value of `n`,” we do not mean to imply that the program will fail algorithmically for larger values, but only that `NMAX` must be altered.
- A number represented by `TINY`, usually a parameter, is supposed to be much smaller than any number of interest to you, but not so small that it underflows. Its use is usually prosaic, to prevent divide checks in some circumstances.

As a matter of typography, the printed FORTRAN programs in this book, if typed into a computer exactly as written, would violate the FORTRAN-77 standard in a few trivial ways. The anomalies, which are *not* present in the machine-readable program distributions, are as follows:

- As already discussed, we use `enddo` followed by the statement label instead of `continue` preceded by the label.
- Standard FORTRAN reads no more than 72 characters on a line and ignores input from column 73 onward. Longer statements are broken up onto “continuation lines.” In the printed programs in this book, some lines contain more than 72 characters. When the break to a continuation line is not shown explicitly, it should be inserted when you type the program into a computer.
- In standard FORTRAN, columns 1 through 6 on each line are used variously for (i) statement labels, (ii) signaling a comment line, and (iii) signaling a continuation line. We simplify the format slightly: To the left of the “program left margin,” an integer is a statement label (not a “tame label” as described above), an asterisk (*) indicates a continuation line, and a “C” indicates a comment line. Comment lines shown in this way are generally either USES statements (see §1.0), or else “commented-out program lines” that are separately explained in each instance.

A small number of routines in this book require the use of functions that act bitwise on integers, e.g., bitwise “and” or “exclusive or”. Unfortunately, although these functions are available in virtually all modern FORTRAN implementations, they are not a part of the FORTRAN-77 standard. Even more unfortunate is the fact that there are two different naming conventions in widespread use. We use the names `iand(i,j)`, `ior(i,j)`, `not(i)`, `ieor(i,j)`, and `ishft(i,j)`, for *and*, *or*, *not*, *exclusive-or*, and *left-shift*, respectively, as well as the subroutines `ibset(i,j)`, `ibclr(i,j)`, and the logical function `btest(i,j)` for *bit-set*, *bit-clear*, and *bit-test*. Some (mainly UNIX) FORTRAN compilers use a different set of names, with the following correspondences:

Us...	Them...
<code>iand(i,j)</code>	= <code>and(i,j)</code>
<code>ior(i,j)</code>	= <code>or(i,j)</code>
<code>not(i)</code>	= <code>not(i)</code>
<code>ieor(i,j)</code>	= <code>xor(i,j)</code>
<code>ishft(i,j)</code>	= <code>lshft(i,j)</code>
<code>ibset(i,j)</code>	= <code>bis(j,i)</code> Note reversed arguments!
<code>ibclr(i,j)</code>	= <code>bic(j,i)</code> Ditto!
<code>btest(i,j)</code>	= <code>bit(j,i)</code> Ditto!

If you are one of “Them,” you can either modify the small number of programs affected (e.g., by inserting FORTRAN statement function definitions at the beginning of the routines), or else link to an object file into which you have compiled the trivial functions that define “our” names in terms of “yours,” as in the above table. Standards really are important!

Hexadecimal constants, for which there is no standard notation in FORTRAN compilers, occur at three places in Chapter 7: a program fragment at the end of §7.1,

and routines `psdes` and `ran4` in §7.5. We use a notation like `Z'3F800000'`, which is consistent with the new FORTRAN-90 standard, but you may need to change this to, e.g., `x'3f800000'`, `'3F800000'X`, or even `16#3F800000`. In extremis, you can convert the hex values to decimal integers; but note that most compilers will require a *negative* decimal integer as the value of a hex constant with its high-order bit set.

As already mentioned in §1.0, the notation `a(1:m)`, in program comments and in the text, denotes the array element range `a(1), a(2), ..., a(m)`. Likewise, notations like `b(2:7)` or `c(1:m, 1:n)` are to be interpreted as denoting ranges of array indices.

1.2 Error, Accuracy, and Stability

Although we assume no prior training of the reader in formal numerical analysis, we will need to presume a common understanding of a few key concepts. We will define these briefly in this section.

Computers store numbers not with infinite precision but rather in some approximation that can be packed into a fixed number of *bits* (binary digits) or *bytes* (groups of 8 bits). Almost all computers allow the programmer a choice among several different such *representations* or *data types*. Data types can differ in the number of bits utilized (the *wordlength*), but also in the more fundamental respect of whether the stored number is represented in *fixed-point* (also called *integer*) or *floating-point* (also called *real*) format.

A number in integer representation is exact. Arithmetic between numbers in integer representation is also exact, with the provisos that (i) the answer is not outside the range of (usually, signed) integers that can be represented, and (ii) that division is interpreted as producing an integer result, throwing away any integer remainder.

and routines `psdes` and `ran4` in §7.5. We use a notation like `Z'3F800000'`, which is consistent with the new FORTRAN-90 standard, but you may need to change this to, e.g., `x'3f800000'`, `'3F800000'X`, or even `16#3F800000`. 1.2 Error, Accuracy, and Stability

Although we assume no prior training of the reader in formal numerical analysis, we will need to presume a common understanding of a few key concepts. We will define these briefly in this section.

Computers store numbers not with infinite precision but rather in some approximation that can be packed into a fixed number of *bits* (binary digits) or *bytes* (groups of 8 bits). Almost all computers allow the programmer a choice among several different such *representations* or *data types*. Data types can differ in the number of bits utilized (the *wordlength*), but also in the more fundamental respect of whether the stored number is represented in *fixed-point* (also called *integer*) or *floating-point* (also called *real*) format.

A number in integer representation is exact. Arithmetic between numbers in integer representation is also exact, with the provisos that (i) the answer is not outside the range of (usually, signed) integers that can be represented, and (ii) that division is interpreted as producing an integer result, throwing away any integer remainder.

Figure 1.2.1. Floating point representations of numbers in a typical 32-bit (4-byte) format. (a) The number $1/2$ (note the bias in the exponent); (b) the number 3 ; (c) the number $1/4$; (d) the number 10^{-7} , represented to machine accuracy; (e) the same number 10^{-7} , but shifted so as to have the same exponent as the number 3 ; with this shifting, all significance is lost and 10^{-7} becomes zero; shifting to a common exponent must occur before two numbers can be added; (f) sum of the numbers $3 + 10^{-7}$, which equals 3 to machine accuracy. Even though 10^{-7} can be represented accurately by itself, it cannot accurately be added to a much larger number.

In floating-point representation, a number is represented internally by a sign bit s (interpreted as plus or minus), an exact integer exponent e , and an exact positive integer mantissa M . Taken together these represent the number

$$s \times M \times B^{e-E} \quad (1.2.1)$$

where B is the base of the representation (usually $B = 2$, but sometimes $B = 16$), and E is the *bias* of the exponent, a fixed integer constant for any given machine and representation. An example is shown in Figure 1.2.1.

Several floating-point bit patterns can represent the same number. If $B = 2$, for example, a mantissa with leading (high-order) zero bits can be left-shifted, i.e., multiplied by a power of 2, if the exponent is decreased by a compensating amount. Bit patterns that are “as left-shifted as they can be” are termed *normalized*. Most computers always produce normalized results, since these don’t waste any bits of the mantissa and thus allow a greater accuracy of the representation. Since the high-order bit of a properly normalized mantissa (when $B = 2$) is *always* one, some computers don’t store this bit at all, giving one extra bit of significance.

Arithmetic among numbers in floating-point representation is not exact, even if the operands happen to be exactly represented (i.e., have exact values in the form of equation 1.2.1). For example, two floating numbers are added by first right-shifting (dividing by two) the mantissa of the smaller (in magnitude) one, simultaneously increasing its exponent, until the two operands have the same exponent. Low-order (least significant) bits of the smaller operand are lost by this shifting. If the two operands differ too greatly in magnitude, then the smaller operand is effectively replaced by zero, since it is right-shifted to oblivion.

The smallest (in magnitude) floating-point number which, when added to the floating-point number 1.0, produces a floating-point result different from 1.0 is termed the *machine accuracy* ϵ_m . A typical computer with $B = 2$ and a 32-bit wordlength has ϵ_m around 3×10^{-8} . (A more detailed discussion of machine

characteristics, and a program to determine them, is given in §20.1.) Roughly speaking, the machine accuracy ϵ_m is the fractional accuracy to which floating-point numbers are represented, corresponding to a change of one in the least significant bit of the mantissa. Pretty much any arithmetic operation among floating numbers should be thought of as introducing an additional fractional error of at least ϵ_m . This type of error is called *roundoff error*.

It is important to understand that ϵ_m is not the smallest floating-point number that can be represented on a machine. *That* number depends on how many bits there are in the exponent, while ϵ_m depends on how many bits there are in the mantissa.

Roundoff errors accumulate with increasing amounts of calculation. If, in the course of obtaining a calculated value, you perform N such arithmetic operations, you *might* be so lucky as to have a total roundoff error on the order of $\sqrt{N}\epsilon_m$, if the roundoff errors come in randomly up or down. (The square root comes from a random-walk.) However, this estimate can be very badly off the mark for two reasons:

(i) It very frequently happens that the regularities of your calculation, or the peculiarities of your computer, cause the roundoff errors to accumulate preferentially in one direction. In this case the total will be of order $N\epsilon_m$.

(ii) Some especially unfavorable occurrences can vastly increase the roundoff error of single operations. Generally these can be traced to the subtraction of two very nearly equal numbers, giving a result whose only significant bits are those (few) low-order ones in which the operands differed. You might think that such a “coincidental” subtraction is unlikely to occur. Not always so. Some mathematical expressions magnify its probability of occurrence tremendously. For example, in the familiar formula for the solution of a quadratic equation,

$$x = \frac{-b + \sqrt{b^2 - 4ac}}{2a} \quad (1.2.2)$$

the addition becomes delicate and roundoff-prone whenever $ac \ll b^2$. (In §5.6 we will learn how to avoid the problem in this particular case.)

Roundoff error is a characteristic of computer hardware. There is another, different, kind of error that is a characteristic of the program or algorithm used, independent of the hardware on which the program is executed. Many numerical algorithms compute “discrete” approximations to some desired “continuous” quantity. For example, an integral is evaluated numerically by computing a function at a discrete set of points, rather than at “every” point. Or, a function may be evaluated by summing a finite number of leading terms in its infinite series, rather than all infinity terms. In cases like this, there is an adjustable parameter, e.g., the number of points or of terms, such that the “true” answer is obtained only when that parameter goes to infinity. Any practical calculation is done with a finite, but sufficiently large, choice of that parameter.

The discrepancy between the true answer and the answer obtained in a practical calculation is called the *truncation error*. Truncation error would persist even on a hypothetical, “perfect” computer that had an infinitely accurate representation and no roundoff error. As a general rule there is not much that a programmer can do about roundoff error, other than to choose algorithms that do not magnify it unnecessarily (see discussion of “stability” below). Truncation error, on the other hand, is entirely under the programmer’s control. In fact, it is only a slight exaggeration to say

that clever minimization of truncation error is practically the entire content of the field of numerical analysis!

Most of the time, truncation error and roundoff error do not strongly interact with one another. A calculation can be imagined as having, first, the truncation error that it would have if run on an infinite-precision computer, “plus” the roundoff error associated with the number of operations performed.

Sometimes, however, an otherwise attractive method can be *unstable*. This means that any roundoff error that becomes “mixed into” the calculation at an early stage is successively magnified until it comes to swamp the true answer. An unstable method would be useful on a hypothetical, perfect computer; but in this imperfect world it is necessary for us to require that algorithms be stable — or if unstable that we use them with great caution.

Here is a simple, if somewhat artificial, example of an unstable algorithm: Suppose that it is desired to calculate all integer powers of the so-called “Golden Mean,” the number given by

$$\phi \equiv \frac{\sqrt{5} - 1}{2} \approx 0.61803398 \quad (1.2.3)$$

It turns out (you can easily verify) that the powers ϕ^n satisfy a simple recursion relation,

$$\phi^{n+1} = \phi^{n-1} - \phi^n \quad (1.2.4)$$

Thus, knowing the first two values $\phi^0 = 1$ and $\phi^1 = 0.61803398$, we can successively apply (1.2.4) performing only a single subtraction, rather than a slower multiplication by ϕ , at each stage.

Unfortunately, the recurrence (1.2.4) also has *another* solution, namely the value $-\frac{1}{2}(\sqrt{5} + 1)$. Since the recurrence is linear, and since this undesired solution has magnitude greater than unity, any small admixture of it introduced by roundoff errors will grow exponentially. On a typical machine with 32-bit wordlength, (1.2.4) starts to give completely wrong answers by about $n = 16$, at which point ϕ^n is down to only 10^{-4} . The recurrence (1.2.4) is *unstable*, and cannot be used for the purpose stated.

We will encounter the question of stability in many more sophisticated guises, later in this book.

Chapter 2. Solution of Linear Algebraic Equations

2.0 Introduction

A set of linear algebraic equations looks like this:

$$\begin{aligned} a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + \cdots + a_{1N}x_N &= b_1 \\ a_{21}x_1 + a_{22}x_2 + a_{23}x_3 + \cdots + a_{2N}x_N &= b_2 \\ a_{31}x_1 + a_{32}x_2 + a_{33}x_3 + \cdots + a_{3N}x_N &= b_3 \\ &\quad \dots \quad \dots \\ a_{M1}x_1 + a_{M2}x_2 + a_{M3}x_3 + \cdots + a_{MN}x_N &= b_M \end{aligned} \tag{2.0.1}$$

Here the N unknowns x_j , $j = 1, 2, \dots, N$ are related by M equations. The coefficients a_{ij} with $i = 1, 2, \dots, M$ and $j = 1, 2, \dots, N$ are known numbers, as are the *right-hand side* quantities b_i , $i = 1, 2, \dots, M$.

Nonsingular versus Singular Sets of Equations

If $N = M$ then there are as many equations as unknowns, and there is a good chance of solving for a unique solution set of x_j 's. Analytically, there can fail to be a unique solution if one or more of the M equations is a linear combination of the others, a condition called *row degeneracy*, or if all equations contain certain variables only in exactly the same linear combination, called *column degeneracy*. (For square matrices, a row degeneracy implies a column degeneracy, and vice versa.) A set of equations that is degenerate is called *singular*. We will consider singular matrices in some detail in §2.6.

Numerically, at least two additional things can go wrong:

- While not exact linear combinations of each other, some of the equations may be so close to linearly dependent that roundoff errors in the machine render them linearly dependent at some stage in the solution process. In this case your numerical procedure will fail, and it can tell you that it has failed.

- Accumulated roundoff errors in the solution process can swamp the true solution. This problem particularly emerges if N is too large. The numerical procedure does not fail algorithmically. However, it returns a set of x 's that are wrong, as can be discovered by direct substitution back into the original equations. The closer a set of equations is to being singular, the more likely this is to happen, since increasingly close cancellations will occur during the solution. In fact, the preceding item can be viewed as the special case where the loss of significance is unfortunately total.

Much of the sophistication of complicated “linear equation-solving packages” is devoted to the detection and/or correction of these two pathologies. As you work with large linear sets of equations, you will develop a feeling for when such sophistication is needed. It is difficult to give any firm guidelines, since there is no such thing as a “typical” linear problem. But here is a rough idea: Linear sets with N as large as 20 or 50 can be routinely solved in single precision (32 bit floating representations) without resorting to sophisticated methods, *if* the equations are not close to singular. With double precision (60 or 64 bits), this number can readily be extended to N as large as several hundred, after which point the limiting factor is generally machine time, not accuracy.

Even larger linear sets, N in the thousands or greater, can be solved when the coefficients are sparse (that is, mostly zero), by methods that take advantage of the sparseness. We discuss this further in §2.7.

At the other end of the spectrum, one seems just as often to encounter linear problems which, by their underlying nature, are close to singular. In this case, you *might* need to resort to sophisticated methods even for the case of $N = 10$ (though rarely for $N = 5$). Singular value decomposition (§2.6) is a technique that can sometimes turn singular problems into nonsingular ones, in which case additional sophistication becomes unnecessary.

Matrices

Equation (2.0.1) can be written in matrix form as

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (2.0.2)$$

Here the raised dot denotes matrix multiplication, \mathbf{A} is the matrix of coefficients, and \mathbf{b} is the right-hand side written as a column vector,

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \dots & a_{1N} \\ a_{21} & a_{22} & \dots & a_{2N} \\ \dots & & & \\ a_{M1} & a_{M2} & \dots & a_{MN} \end{bmatrix} \quad \mathbf{b} = \begin{bmatrix} b_1 \\ b_2 \\ \dots \\ b_M \end{bmatrix} \quad (2.0.3)$$

By convention, the first index on an element a_{ij} denotes its row, the second index its column. A computer will store the matrix \mathbf{A} as a two-dimensional array. However, computer memory is numbered sequentially by its address, and so is intrinsically one-dimensional. Therefore the two-dimensional array \mathbf{A} will, at the hardware level, either be *stored by columns* in the order

$$a_{11}, a_{21}, \dots, a_{M1}, a_{12}, a_{22}, \dots, a_{M2}, \dots, a_{1N}, a_{2N}, \dots, a_{MN}$$

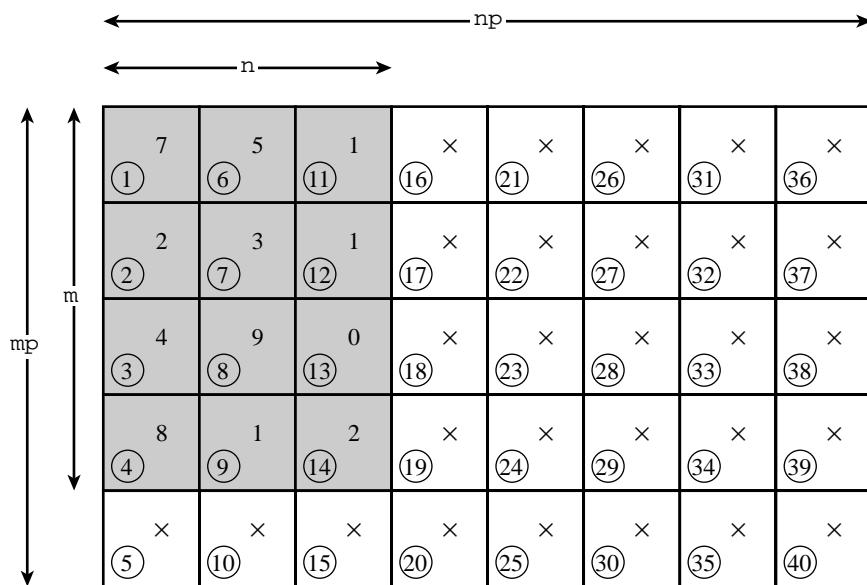

Figure 2.0.1. A matrix of logical dimension m by n is stored in an array of physical dimension mp by np . Locations marked by “ \times ” contain extraneous information which may be left over from some previous use of the physical array. Circled numbers show the actual ordering of the array in computer memory, not usually relevant to the programmer. Note, however, that the logical array does not occupy consecutive memory locations. To locate an (i, j) element correctly, a subroutine must be told mp and np , not just i and j .

or else *stored by rows* in the order

$$a_{11}, a_{12}, \dots, a_{1N}, a_{21}, a_{22}, \dots, a_{2N}, \dots, a_{M1}, a_{M2}, \dots, a_{MN}$$

FORTRAN always stores by columns, and user programs are generally allowed to exploit this fact to their advantage. By contrast, C, Pascal, and other languages generally store by rows. Note one confusing point in the terminology, that a matrix which is stored by columns (as in FORTRAN) has its *row* (i.e., first) index changing most rapidly as one goes linearly through memory, the opposite of a car’s odometer!

For most purposes you don’t *need* to know what the order of storage is, since you reference an element by its two-dimensional address: $a_{34} = a(3,4)$. It is, however, *essential* that you understand the difference between an array’s *physical dimensions* and its *logical dimensions*. When you pass an array to a subroutine, you must, in general, tell the subroutine *both* of these dimensions. The distinction between them is this: It may happen that you have a 4×4 matrix stored in an array dimensioned as 10×10 . This occurs most frequently in practice when you have dimensioned to the largest expected value of N , but are at the moment considering a value of N smaller than that largest possible one. In the example posed, the 16 elements of the matrix do not occupy 16 consecutive memory locations. Rather they are spread out among the 100 dimensioned locations of the array as if the whole 10×10 matrix were filled. Figure 2.0.1 shows an additional example.

If you have a subroutine to invert a matrix, its call might typically look like this:

```
call matinv(a,ai,n,np)
```

Here the subroutine has to be told both the logical size of the matrix that you want to invert (here $n = 4$), and the physical size of the array in which it is stored (here $np = 10$).

This seems like a trivial point, and we are sorry to belabor it. But it turns out that *most* reported failures of standard linear equation and matrix manipulation packages are due to user errors in passing inappropriate logical or physical dimensions!

Tasks of Computational Linear Algebra

We will consider the following tasks as falling in the general purview of this chapter:

- Solution of the matrix equation $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ for an unknown vector \mathbf{x} , where \mathbf{A} is a square matrix of coefficients, raised dot denotes matrix multiplication, and \mathbf{b} is a known right-hand side vector (§2.1–§2.10).
- Solution of more than one matrix equation $\mathbf{A} \cdot \mathbf{x}_j = \mathbf{b}_j$, for a set of vectors \mathbf{x}_j , $j = 1, 2, \dots$, each corresponding to a different, known right-hand side vector \mathbf{b}_j . In this task the key simplification is that the matrix \mathbf{A} is held constant, while the right-hand sides, the \mathbf{b} 's, are changed (§2.1–§2.10).
- Calculation of the matrix \mathbf{A}^{-1} which is the matrix inverse of a square matrix \mathbf{A} , i.e., $\mathbf{A} \cdot \mathbf{A}^{-1} = \mathbf{A}^{-1} \cdot \mathbf{A} = \mathbf{1}$, where $\mathbf{1}$ is the identity matrix (all zeros except for ones on the diagonal). This task is equivalent, for an $N \times N$ matrix \mathbf{A} , to the previous task with N different \mathbf{b}_j 's ($j = 1, 2, \dots, N$), namely the unit vectors (\mathbf{b}_j = all zero elements except for 1 in the j th component). The corresponding \mathbf{x} 's are then the columns of the matrix inverse of \mathbf{A} (§2.1 and §2.3).
- Calculation of the determinant of a square matrix \mathbf{A} (§2.3).

If $M < N$, or if $M = N$ but the equations are degenerate, then there are effectively fewer equations than unknowns. In this case there can be either no solution, or else more than one solution vector \mathbf{x} . In the latter event, the solution space consists of a particular solution \mathbf{x}_p added to any linear combination of (typically) $N - M$ vectors (which are said to be in the nullspace of the matrix \mathbf{A}). The task of finding the solution space of \mathbf{A} involves

- Singular value decomposition of a matrix \mathbf{A} .

This subject is treated in §2.6.

In the opposite case there are more equations than unknowns, $M > N$. When this occurs there is, in general, no solution vector \mathbf{x} to equation (2.0.1), and the set of equations is said to be *overdetermined*. It happens frequently, however, that the best “compromise” solution is sought, the one that comes closest to satisfying all equations simultaneously. If closeness is defined in the least-squares sense, i.e., that the sum of the squares of the differences between the left- and right-hand sides of equation (2.0.1) be minimized, then the overdetermined linear problem reduces to a

(usually) solvable linear problem, called the

- Linear least-squares problem.

The reduced set of equations to be solved can be written as the $N \times N$ set of equations

$$(\mathbf{A}^T \cdot \mathbf{A}) \cdot \mathbf{x} = (\mathbf{A}^T \cdot \mathbf{b}) \quad (2.0.4)$$

where \mathbf{A}^T denotes the transpose of the matrix \mathbf{A} . Equations (2.0.4) are called the *normal equations* of the linear least-squares problem. There is a close connection between singular value decomposition and the linear least-squares problem, and the latter is also discussed in §2.6. You should be warned that direct solution of the normal equations (2.0.4) is not generally the best way to find least-squares solutions.

Some other topics in this chapter include

- Iterative improvement of a solution (§2.5)
- Various special forms: symmetric positive-definite (§2.9), tridiagonal (§2.4), band diagonal (§2.4), Toeplitz (§2.8), Vandermonde (§2.8), sparse (§2.7)
- Strassen's "fast matrix inversion" (§2.11).

Standard Subroutine Packages

We cannot hope, in this chapter or in this book, to tell you everything there is to know about the tasks that have been defined above. In many cases you will have no alternative but to use sophisticated black-box program packages. Several good ones are available. LINPACK was developed at Argonne National Laboratories and deserves particular mention because it is published, documented, and available for free use. A successor to LINPACK, LAPACK, is now becoming available. Packages available commercially include those in the IMSL and NAG libraries.

You should keep in mind that the sophisticated packages are designed with very large linear systems in mind. They therefore go to great effort to minimize not only the number of operations, but also the required storage. Routines for the various tasks are usually provided in several versions, corresponding to several possible simplifications in the form of the input coefficient matrix: symmetric, triangular, banded, positive definite, etc. If you have a large matrix in one of these forms, you should certainly take advantage of the increased efficiency provided by these different routines, and not just use the form provided for general matrices.

There is also a great watershed dividing routines that are *direct* (i.e., execute in a predictable number of operations) from routines that are *iterative* (i.e., attempt to converge to the desired answer in however many steps are necessary). Iterative methods become preferable when the battle against loss of significance is in danger of being lost, either due to large N or because the problem is close to singular. We will treat iterative methods only incompletely in this book, in §2.7 and in Chapters 18 and 19. These methods are important, but mostly beyond our scope. We will, however, discuss in detail a technique which is on the borderline between direct and iterative methods, namely the iterative improvement of a solution that has been obtained by direct methods (§2.5).

2.1 Gauss-Jordan Elimination

For inverting a matrix, *Gauss-Jordan elimination* is about as efficient as any other method. For solving sets of linear equations, Gauss-Jordan elimination produces *both* the solution of the equations for one or more right-hand side vectors \mathbf{b} , and also the matrix inverse \mathbf{A}^{-1} . However, its principal weaknesses are (i) that it requires all the right-hand sides to be stored and manipulated at the same time, and (ii) that when the inverse matrix is *not* desired, Gauss-Jordan is three times slower than the best alternative technique for solving a single linear set (§2.3). The method's principal strength is that it is as stable as any other direct method, perhaps even a bit more stable when full pivoting is used (see below).

If you come along later with an additional right-hand side vector, you can multiply it by the inverse matrix, of course. This does give an answer, but one that is quite susceptible to roundoff error, not nearly as good as if the new vector had been included with the set of right-hand side vectors in the first instance.

For these reasons, Gauss-Jordan elimination should usually not be your method of first choice, either for solving linear equations or for matrix inversion. The decomposition methods in §2.3 are better. Why do we give you Gauss-Jordan at all? Because it is straightforward, understandable, solid as a rock, and an exceptionally good “psychological” backup for those times that something is going wrong and you think it *might* be your linear-equation solver.

Some people believe that the backup is more than psychological, that Gauss-Jordan elimination is an “independent” numerical method. This turns out to be mostly myth. Except for the relatively minor differences in pivoting, described below, the actual sequence of operations performed in Gauss-Jordan elimination is very closely related to that performed by the routines in the next two sections.

2.1 Gauss-Jordan Elimination

For inverting a matrix, *Gauss-Jordan elimination* is about as efficient as any other method. For solving sets of linear equations, Gauss-Jordan elimination produces *both* the solution of the equations for one or more right-hand side vectors \mathbf{b} , and also the matrix inverse \mathbf{A}^{-1} . However, its principal weaknesses are (i) that it requires all the right-hand sides to be stored and manipulated at the same time, and (ii) that when the inverse matrix is *not* desired, Gauss-Jordan is three times slower than the best alternative technique for solving a single linear set (§2.3). The method's principal strength is that it is as stable as any other direct method, perhaps even a bit more stable when full pivoting is used (see below).

If you come along later with an additional right-hand side vector, you can multiply it by the inverse matrix, of course. This does give an answer, but one that is quite susceptible to roundoff error, not nearly as good as if the new vector had been included with the set of right-hand side vectors in the first instance.

For these reasons, Gauss-Jordan elimination should usually not be your method of first choice, either for solving linear equations or for matrix inversion. The decomposition methods in §2.3 are better. Why do we give you Gauss-Jordan at all? Because it is straightforward, understandable, solid as a rock, and an exceptionally good “psychological” backup for those times that something is going wrong and you think it *might* be your linear-equation solver.

Some people believe that the backup is more than psychological, that Gauss-Jordan elimination is an “independent” numerical method. This turns out to be mostly myth. Except for the relatively minor differences in pivoting, described below, the actual sequence of operations performed in Gauss-Jordan elimination is very closely related to that performed by the routines in the next two sections.

For clarity, and to avoid writing endless ellipses (\cdots) we will write out equations only for the case of four equations and four unknowns, and with three different right-hand side vectors that are known in advance. You can write bigger matrices and extend the equations to the case of $N \times N$ matrices, with M sets of right-hand side vectors, in completely analogous fashion. The routine implemented below is, of course, general.

Elimination on Column-Augmented Matrices

Consider the linear matrix equation

$$\begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix} \cdot \left[\begin{pmatrix} x_{11} \\ x_{21} \\ x_{31} \\ x_{41} \end{pmatrix} \sqcup \begin{pmatrix} x_{12} \\ x_{22} \\ x_{32} \\ x_{42} \end{pmatrix} \sqcup \begin{pmatrix} x_{13} \\ x_{23} \\ x_{33} \\ x_{43} \end{pmatrix} \sqcup \begin{pmatrix} y_{11} & y_{12} & y_{13} & y_{14} \\ y_{21} & y_{22} & y_{23} & y_{24} \\ y_{31} & y_{32} & y_{33} & y_{34} \\ y_{41} & y_{42} & y_{43} & y_{44} \end{pmatrix} \right] \\ = \left[\begin{pmatrix} b_{11} \\ b_{21} \\ b_{31} \\ b_{41} \end{pmatrix} \sqcup \begin{pmatrix} b_{12} \\ b_{22} \\ b_{32} \\ b_{42} \end{pmatrix} \sqcup \begin{pmatrix} b_{13} \\ b_{23} \\ b_{33} \\ b_{43} \end{pmatrix} \sqcup \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix} \right] \quad (2.1.1)$$

Here the raised dot (\cdot) signifies matrix multiplication, while the operator \sqcup just signifies column augmentation, that is, removing the abutting parentheses and making a wider matrix out of the operands of the \sqcup operator.

It should not take you long to write out equation (2.1.1) and to see that it simply states that x_{ij} is the i th component ($i = 1, 2, 3, 4$) of the vector solution of the j th right-hand side ($j = 1, 2, 3$), the one whose coefficients are b_{ij} , $i = 1, 2, 3, 4$; and that the matrix of unknown coefficients y_{ij} is the inverse matrix of a_{ij} . In other words, the matrix solution of

$$[\mathbf{A}] \cdot [\mathbf{x}_1 \sqcup \mathbf{x}_2 \sqcup \mathbf{x}_3 \sqcup \mathbf{Y}] = [\mathbf{b}_1 \sqcup \mathbf{b}_2 \sqcup \mathbf{b}_3 \sqcup \mathbf{1}] \quad (2.1.2)$$

where \mathbf{A} and \mathbf{Y} are square matrices, the \mathbf{b}_i 's and \mathbf{x}_i 's are column vectors, and $\mathbf{1}$ is the identity matrix, simultaneously solves the linear sets

$$\mathbf{A} \cdot \mathbf{x}_1 = \mathbf{b}_1 \quad \mathbf{A} \cdot \mathbf{x}_2 = \mathbf{b}_2 \quad \mathbf{A} \cdot \mathbf{x}_3 = \mathbf{b}_3 \quad (2.1.3)$$

and

$$\mathbf{A} \cdot \mathbf{Y} = \mathbf{1} \quad (2.1.4)$$

Now it is also elementary to verify the following facts about (2.1.1):

- Interchanging any two *rows* of \mathbf{A} and the corresponding *rows* of the \mathbf{b} 's and of $\mathbf{1}$, does not change (or scramble in any way) the solution \mathbf{x} 's and \mathbf{Y} . Rather, it just corresponds to writing the same set of linear equations in a different order.
- Likewise, the solution set is unchanged and in no way scrambled if we replace any row in \mathbf{A} by a linear combination of itself and any other row, as long as we do the same linear combination of the rows of the \mathbf{b} 's and $\mathbf{1}$ (which then is no longer the identity matrix, of course).

- Interchanging any two *columns* of \mathbf{A} gives the same solution set only if we simultaneously interchange corresponding *rows* of the \mathbf{x} 's and of \mathbf{Y} . In other words, this interchange scrambles the order of the rows in the solution. If we do this, we will need to unscramble the solution by restoring the rows to their original order.

Gauss-Jordan elimination uses one or more of the above operations to reduce the matrix \mathbf{A} to the identity matrix. When this is accomplished, the right-hand side becomes the solution set, as one sees instantly from (2.1.2).

Pivoting

In “Gauss-Jordan elimination with no pivoting,” only the second operation in the above list is used. The first row is divided by the element a_{11} (this being a trivial linear combination of the first row with any other row — zero coefficient for the other row). Then the right amount of the first row is subtracted from each other row to make all the remaining a_{i1} 's zero. The first column of \mathbf{A} now agrees with the identity matrix. We move to the second column and divide the second row by a_{22} , then subtract the right amount of the second row from rows 1, 3, and 4, so as to make their entries in the second column zero. The second column is now reduced to the identity form. And so on for the third and fourth columns. As we do these operations to \mathbf{A} , we of course also do the corresponding operations to the \mathbf{b} 's and to $\mathbf{1}$ (which by now no longer resembles the identity matrix in any way!).

Obviously we will run into trouble if we ever encounter a zero element on the (then current) diagonal when we are going to divide by the diagonal element. (The element that we divide by, incidentally, is called the *pivot element* or *pivot*.) Not so obvious, but true, is the fact that Gauss-Jordan elimination with no pivoting (no use of the first or third procedures in the above list) is numerically unstable in the presence of any roundoff error, even when a zero pivot is not encountered. You must *never* do Gauss-Jordan elimination (or Gaussian elimination, see below) without pivoting!

So what *is* this magic pivoting? Nothing more than interchanging rows (*partial pivoting*) or rows and columns (*full pivoting*), so as to put a particularly desirable element in the diagonal position from which the pivot is about to be selected. Since we don't want to mess up the part of the identity matrix that we have already built up, we can choose among elements that are both (i) on rows below (or on) the one that is about to be normalized, and also (ii) on columns to the right (or on) the column we are about to eliminate. Partial pivoting is easier than full pivoting, because we don't have to keep track of the permutation of the solution vector. Partial pivoting makes available as pivots only the elements already in the correct column. It turns out that partial pivoting is “almost” as good as full pivoting, in a sense that can be made mathematically precise, but which need not concern us here (for discussion and references, see [1]). To show you both variants, we do full pivoting in the routine in this section, partial pivoting in §2.3.

We have to state how to recognize a particularly desirable pivot when we see one. The answer to this is not completely known theoretically. It is known, both theoretically and in practice, that simply picking the largest (in magnitude) available element as the pivot is a very good choice. A curiosity of this procedure, however, is that the choice of pivot will depend on the original scaling of the equations. If we take the third linear equation in our original set and multiply it by a factor of a million, it

is almost guaranteed that it will contribute the first pivot; yet the underlying solution of the equations is not changed by this multiplication! One therefore sometimes sees routines which choose as pivot that element which *would* have been largest if the original equations had all been scaled to have their largest coefficient normalized to unity. This is called *implicit pivoting*. There is some extra bookkeeping to keep track of the scale factors by which the rows would have been multiplied. (The routines in §2.3 include implicit pivoting, but the routine in this section does not.)

Finally, let us consider the storage requirements of the method. With a little reflection you will see that at every stage of the algorithm, *either* an element of \mathbf{A} is predictably a one or zero (if it is already in a part of the matrix that has been reduced to identity form) *or else* the exactly corresponding element of the matrix that started as **1** is predictably a one or zero (if its mate in \mathbf{A} has not been reduced to the identity form). Therefore the matrix **1** does not have to exist as separate storage: The matrix inverse of \mathbf{A} is gradually built up in \mathbf{A} as the original \mathbf{A} is destroyed. Likewise, the solution vectors \mathbf{x} can gradually replace the right-hand side vectors \mathbf{b} and share the same storage, since after each column in \mathbf{A} is reduced, the corresponding row entry in the \mathbf{b} 's is never again used.

Here is the routine for Gauss-Jordan elimination with full pivoting:

```
SUBROUTINE gaussj(a,n,np,b,m,mp)
INTEGER m,mp,n,np,NMAX
REAL a(np,np),b(np,mp)
PARAMETER (NMAX=50)
      Linear equation solution by Gauss-Jordan elimination, equation (2.1.1) above. a(1:n,1:n)
      is an input matrix stored in an array of physical dimensions np by np. b(1:n,1:m) is an
      input matrix containing the m right-hand side vectors, stored in an array of physical dimensions
      np by mp. On output, a(1:n,1:n) is replaced by its matrix inverse, and b(1:n,1:m) is
      replaced by the corresponding set of solution vectors.
      Parameter: NMAX is the largest anticipated value of n.
      INTEGER i,icol,irow,j,k,l,11,indx(NMAX),indxr(NMAX),
*          ipiv(NMAX)                                     The integer arrays ipiv, indx, and indx are used
      REAL big,dum,pivinv                                for bookkeeping on the pivoting.
      do 11 j=1,n
          ipiv(j)=0
      enddo 11
      do 22 i=1,n                                      This is the main loop over the columns to be re-
          big=0.                                         duced.
          do 13 j=1,n                                  This is the outer loop of the search for a pivot ele-
              if(ipiv(j).ne.1)then                      ment.
                  do 12 k=1,n
                      if (ipiv(k).eq.0) then
                          if (abs(a(j,k)).ge.big)then
                              big=abs(a(j,k))
                              irow=j
                              icol=k
                          endif
                      endif
                  enddo 12
              endif
          enddo 13
      ipiv(icol)=ipiv(icol)+1
      We now have the pivot element, so we interchange rows, if needed, to put the pivot
      element on the diagonal. The columns are not physically interchanged, only relabeled:
```

```

indx(i), the column of the ith pivot element, is the ith column that is reduced, while
indx(i) is the row in which that pivot element was originally located. If indx(i) ≠
indx(i) there is an implied column interchange. With this form of bookkeeping, the
solution b's will end up in the correct order, and the inverse matrix will be scrambled
by columns.

if (irow.ne.icol) then
    do 14 l=1,n
        dum=a(irow,l)
        a(irow,l)=a(icol,l)
        a(icol,l)=dum
    enddo 14
    do 15 l=1,m
        dum=b(irow,l)
        b(irow,l)=b(icol,l)
        b(icol,l)=dum
    enddo 15
endif
indx(i)=irow
indx(i)=icol
if (a(icol,icol).eq.0.) pause 'singular matrix in gaussj'
pivinv=1./a(icol,icol)
a(icol,icol)=1.
do 16 l=1,n
    a(icol,l)=a(icol,l)*pivinv
enddo 16
do 17 l=1,m
    b(icol,l)=b(icol,l)*pivinv
enddo 17
do 21 ll=1,n
    if(ll.ne.icol)then
        dum=a(ll,icol)
        a(ll,icol)=0.
        do 18 l=1,n
            a(ll,l)=a(ll,l)-a(icol,l)*dum
        enddo 18
        do 19 l=1,m
            b(ll,l)=b(ll,l)-b(icol,l)*dum
        enddo 19
    endif
enddo 21
enddo 22
do 24 l=n,1,-1
    if(indxr(l).ne.indxc(l))then
        do 23 k=1,n
            dum=a(k,indx(l))
            a(k,indx(l))=a(k,indxc(l))
            a(k,indxc(l))=dum
        enddo 23
    endif
enddo 24
return
END

```

We are now ready to divide the pivot row by the pivot element, located at irow and icol.

if (a(icol,icol).eq.0.) pause 'singular matrix in gaussj'

pivinv=1./a(icol,icol)

a(icol,icol)=1.

do 16 l=1,n

a(icol,l)=a(icol,l)*pivinv

enddo 16

do 17 l=1,m

b(icol,l)=b(icol,l)*pivinv

enddo 17

do 21 ll=1,n

if(ll.ne.icol)then

dum=a(ll,icol)

a(ll,icol)=0.

do 18 l=1,n

a(ll,l)=a(ll,l)-a(icol,l)*dum

enddo 18

do 19 l=1,m

b(ll,l)=b(ll,l)-b(icol,l)*dum

enddo 19

endif

endif

enddo 21

This is the end of the main loop over columns of the reduction.

It only remains to unscramble the solution in view

of the column interchanges. We do this by in-

terchanging pairs of columns in the reverse order

that the permutation was built up.

And we are done.

Row versus Column Elimination Strategies

The above discussion can be amplified by a modest amount of formalism. Row operations on a matrix \mathbf{A} correspond to pre- (that is, left-) multiplication by some simple

matrix \mathbf{R} . For example, the matrix \mathbf{R} with components

$$R_{ij} = \begin{cases} 1 & \text{if } i = j \text{ and } i \neq 2, 4 \\ 1 & \text{if } i = 2, j = 4 \\ 1 & \text{if } i = 4, j = 2 \\ 0 & \text{otherwise} \end{cases} \quad (2.1.5)$$

effects the interchange of rows 2 and 4. Gauss-Jordan elimination by row operations alone (including the possibility of *partial* pivoting) consists of a series of such left-multiplications, yielding successively

$$\begin{aligned} \mathbf{A} \cdot \mathbf{x} &= \mathbf{b} \\ (\cdots \mathbf{R}_3 \cdot \mathbf{R}_2 \cdot \mathbf{R}_1 \cdot \mathbf{A}) \cdot \mathbf{x} &= \cdots \mathbf{R}_3 \cdot \mathbf{R}_2 \cdot \mathbf{R}_1 \cdot \mathbf{b} \\ (\mathbf{1}) \cdot \mathbf{x} &= \cdots \mathbf{R}_3 \cdot \mathbf{R}_2 \cdot \mathbf{R}_1 \cdot \mathbf{b} \\ \mathbf{x} &= \cdots \mathbf{R}_3 \cdot \mathbf{R}_2 \cdot \mathbf{R}_1 \cdot \mathbf{b} \end{aligned} \quad (2.1.6)$$

The key point is that since the \mathbf{R} 's build from right to left, the right-hand side is simply transformed at each stage from one vector to another.

Column operations, on the other hand, correspond to post-, or right-, multiplications by simple matrices, call them \mathbf{C} . The matrix in equation (2.1.5), if right-multiplied onto a matrix \mathbf{A} , will interchange \mathbf{A} 's second and fourth *columns*. Elimination by column operations involves (conceptually) inserting a column operator, *and also its inverse*, between the matrix \mathbf{A} and the unknown vector \mathbf{x} :

$$\begin{aligned} \mathbf{A} \cdot \mathbf{x} &= \mathbf{b} \\ \mathbf{A} \cdot \mathbf{C}_1 \cdot \mathbf{C}_1^{-1} \cdot \mathbf{x} &= \mathbf{b} \\ \mathbf{A} \cdot \mathbf{C}_1 \cdot \mathbf{C}_2 \cdot \mathbf{C}_2^{-1} \cdot \mathbf{C}_1^{-1} \cdot \mathbf{x} &= \mathbf{b} \\ (\mathbf{A} \cdot \mathbf{C}_1 \cdot \mathbf{C}_2 \cdot \mathbf{C}_3 \cdots) \cdots \mathbf{C}_3^{-1} \cdot \mathbf{C}_2^{-1} \cdot \mathbf{C}_1^{-1} \cdot \mathbf{x} &= \mathbf{b} \\ (\mathbf{1}) \cdots \mathbf{C}_3^{-1} \cdot \mathbf{C}_2^{-1} \cdot \mathbf{C}_1^{-1} \cdot \mathbf{x} &= \mathbf{b} \end{aligned} \quad (2.1.7)$$

which (peeling off the \mathbf{C}^{-1} 's one at a time) implies a solution

$$\mathbf{x} = \mathbf{C}_1 \cdot \mathbf{C}_2 \cdot \mathbf{C}_3 \cdots \mathbf{b} \quad (2.1.8)$$

Notice the essential difference between equation (2.1.8) and equation (2.1.6). In the latter case, the \mathbf{C} 's must be applied to \mathbf{b} in the *reverse order* from that in which they become known. That is, they must all be stored along the way. This requirement greatly reduces the usefulness of column operations, generally restricting them to simple permutations, for example in support of full pivoting.

2.2 Gaussian Elimination with Backsubstitution

The usefulness of Gaussian elimination with backsubstitution is primarily pedagogical. It stands between full elimination schemes such as Gauss-Jordan, and triangular decomposition schemes such as will be discussed in the next section. Gaussian elimination reduces a matrix not all the way to the identity matrix, but only halfway, to a matrix whose components on the diagonal and above (say) remain nontrivial. Let us now see what advantages accrue.

Suppose that in doing Gauss-Jordan elimination, as described in §2.1, we at each stage subtract away rows only *below* the then-current pivot element. When a_{22} is the pivot element, for example, we divide the second row by its value (as before), but now use the pivot row to zero only a_{32} and a_{42} , not a_{12} (see equation 2.1.1). Suppose, also, that we do only partial pivoting, never interchanging columns, so that the order of the unknowns never needs to be modified.

Then, when we have done this for all the pivots, we will be left with a reduced equation that looks like this (in the case of a single right-hand side vector):

$$\begin{bmatrix} a'_{11} & a'_{12} & a'_{13} & a'_{14} \\ 0 & a'_{22} & a'_{23} & a'_{24} \\ 0 & 0 & a'_{33} & a'_{34} \\ 0 & 0 & 0 & a'_{44} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} b'_1 \\ b'_2 \\ b'_3 \\ b'_4 \end{bmatrix} \quad (2.2.1)$$

Here the primes signify that the a 's and b 's do not have their original numerical values, but have been modified by all the row operations in the elimination to this point. The procedure up to this point is termed *Gaussian elimination*.

Backsubstitution

But how do we solve for the x 's? The last x (x_4 in this example) is already isolated, namely

$$x_4 = b'_4 / a'_{44} \quad (2.2.2)$$

With the last x known we can move to the penultimate x ,

$$x_3 = \frac{1}{a'_{33}} [b'_3 - x_4 a'_{34}] \quad (2.2.3)$$

and then proceed with the x before that one. The typical step is

$$x_i = \frac{1}{a'_{ii}} \left[b'_i - \sum_{j=i+1}^N a'_{ij} x_j \right] \quad (2.2.4)$$

The procedure defined by equation (2.2.4) is called *backsubstitution*. The combination of Gaussian elimination and backsubstitution yields a solution to the set of equations.

2.2 Gaussian Elimination with Backsubstitution

The usefulness of Gaussian elimination with backsubstitution is primarily pedagogical. It stands between full elimination schemes such as Gauss-Jordan, and triangular decomposition schemes such as will be discussed in the next section. Gaussian elimination reduces a matrix not all the way to the identity matrix, but only halfway, to a matrix whose components on the diagonal and above (say) remain nontrivial. Let us now see what advantages accrue.

Suppose that in doing Gauss-Jordan elimination, as described in §2.1, we at each stage subtract away rows only *below* the then-current pivot element. When a_{22} is the pivot element, for example, we divide the second row by its value (as before), but now use the pivot row to zero only a_{32} and a_{42} , not a_{12} (see equation 2.1.1). Suppose, also, that we do only partial pivoting, never interchanging columns, so that the order of the unknowns never needs to be modified.

Then, when we have done this for all the pivots, we will be left with a reduced equation that looks like this (in the case of a single right-hand side vector):

$$\begin{bmatrix} a'_{11} & a'_{12} & a'_{13} & a'_{14} \\ 0 & a'_{22} & a'_{23} & a'_{24} \\ 0 & 0 & a'_{33} & a'_{34} \\ 0 & 0 & 0 & a'_{44} \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ x_3 \\ x_4 \end{bmatrix} = \begin{bmatrix} b'_1 \\ b'_2 \\ b'_3 \\ b'_4 \end{bmatrix} \quad (2.2.1)$$

Here the primes signify that the a 's and b 's do not have their original numerical values, but have been modified by all the row operations in the elimination to this point. The procedure up to this point is termed *Gaussian elimination*.

Backsubstitution

But how do we solve for the x 's? The last x (x_4 in this example) is already isolated, namely

$$x_4 = b'_4 / a'_{44} \quad (2.2.2)$$

With the last x known we can move to the penultimate x ,

$$x_3 = \frac{1}{a'_{33}} [b'_3 - x_4 a'_{34}] \quad (2.2.3)$$

and then proceed with the x before that one. The typical step is

$$x_i = \frac{1}{a'_{ii}} \left[b'_i - \sum_{j=i+1}^N a'_{ij} x_j \right] \quad (2.2.4)$$

The procedure defined by equation (2.2.4) is called *backsubstitution*. The combination of Gaussian elimination and backsubstitution yields a solution to the set of equations.

The advantage of Gaussian elimination and backsubstitution over Gauss-Jordan elimination is simply that the former is faster in raw operations count: The innermost loops of Gauss-Jordan elimination, each containing one subtraction and one multiplication, are executed N^3 and N^2M times (where there are N equations and M unknowns). The corresponding loops in Gaussian elimination are executed only $\frac{1}{3}N^3$ times (only half the matrix is reduced, and the increasing numbers of predictable zeros reduce the count to one-third), and $\frac{1}{2}N^2M$ times, respectively. Each backsubstitution of a right-hand side is $\frac{1}{2}N^2$ executions of a similar loop (one multiplication plus one subtraction). For $M \ll N$ (only a few right-hand sides) Gaussian elimination thus has about a factor three advantage over Gauss-Jordan. (We could reduce this advantage to a factor 1.5 by *not* computing the inverse matrix as part of the Gauss-Jordan scheme.)

For computing the inverse matrix (which we can view as the case of $M = N$ right-hand sides, namely the N unit vectors which are the columns of the identity matrix), Gaussian elimination and backsubstitution at first glance require $\frac{1}{3}N^3$ (matrix reduction) + $\frac{1}{2}N^3$ (right-hand side manipulations) + $\frac{1}{2}N^3$ (N backsubstitutions) = $\frac{4}{3}N^3$ loop executions, which is more than the N^3 for Gauss-Jordan. However, the unit vectors are quite special in containing all zeros except for one element. If this is taken into account, the right-side manipulations can be reduced to only $\frac{1}{6}N^3$ loop executions, and, for matrix inversion, the two methods have identical efficiencies.

Both Gaussian elimination and Gauss-Jordan elimination share the disadvantage that all right-hand sides must be known in advance. The *LU* decomposition method in the next section does not share that deficiency, and also has an equally small operations count, both for solution with any number of right-hand sides, and for matrix inversion. For this reason we will not implement the method of Gaussian elimination as a routine.

2.3 LU Decomposition and Its Applications

Suppose we are able to write the matrix \mathbf{A} as a product of two matrices,

$$\mathbf{L} \cdot \mathbf{U} = \mathbf{A} \quad (2.3.1)$$

where \mathbf{L} is *lower triangular* (has elements only on the diagonal and below) and \mathbf{U} is *upper triangular* (has elements only on the diagonal and above). For the case of

The advantage of Gaussian elimination and backsubstitution over Gauss-Jordan elimination is simply that the former is faster in raw operations count: The innermost loops of Gauss-Jordan elimination, each containing one subtraction and one multiplication, are executed N^3 and N^2M times (where there are N equations and M unknowns). 2.3 LU Decomposition and Its Applications

Suppose we are able to write the matrix \mathbf{A} as a product of two matrices,

$$\mathbf{L} \cdot \mathbf{U} = \mathbf{A} \quad (2.3.1)$$

where \mathbf{L} is *lower triangular* (has elements only on the diagonal and below) and \mathbf{U} is *upper triangular* (has elements only on the diagonal and above). For the case of

a 4×4 matrix \mathbf{A} , for example, equation (2.3.1) would look like this:

$$\begin{bmatrix} \alpha_{11} & 0 & 0 & 0 \\ \alpha_{21} & \alpha_{22} & 0 & 0 \\ \alpha_{31} & \alpha_{32} & \alpha_{33} & 0 \\ \alpha_{41} & \alpha_{42} & \alpha_{43} & \alpha_{44} \end{bmatrix} \cdot \begin{bmatrix} \beta_{11} & \beta_{12} & \beta_{13} & \beta_{14} \\ 0 & \beta_{22} & \beta_{23} & \beta_{24} \\ 0 & 0 & \beta_{33} & \beta_{34} \\ 0 & 0 & 0 & \beta_{44} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} & a_{13} & a_{14} \\ a_{21} & a_{22} & a_{23} & a_{24} \\ a_{31} & a_{32} & a_{33} & a_{34} \\ a_{41} & a_{42} & a_{43} & a_{44} \end{bmatrix} \quad (2.3.2)$$

We can use a decomposition such as (2.3.1) to solve the linear set

$$\mathbf{A} \cdot \mathbf{x} = (\mathbf{L} \cdot \mathbf{U}) \cdot \mathbf{x} = \mathbf{L} \cdot (\mathbf{U} \cdot \mathbf{x}) = \mathbf{b} \quad (2.3.3)$$

by first solving for the vector \mathbf{y} such that

$$\mathbf{L} \cdot \mathbf{y} = \mathbf{b} \quad (2.3.4)$$

and then solving

$$\mathbf{U} \cdot \mathbf{x} = \mathbf{y} \quad (2.3.5)$$

What is the advantage of breaking up one linear set into two successive ones? The advantage is that the solution of a triangular set of equations is quite trivial, as we have already seen in §2.2 (equation 2.2.4). Thus, equation (2.3.4) can be solved by *forward substitution* as follows,

$$\begin{aligned} y_1 &= \frac{b_1}{\alpha_{11}} \\ y_i &= \frac{1}{\alpha_{ii}} \left[b_i - \sum_{j=1}^{i-1} \alpha_{ij} y_j \right] \quad i = 2, 3, \dots, N \end{aligned} \quad (2.3.6)$$

while (2.3.5) can then be solved by *backsubstitution* exactly as in equations (2.2.2)–(2.2.4),

$$\begin{aligned} x_N &= \frac{y_N}{\beta_{NN}} \\ x_i &= \frac{1}{\beta_{ii}} \left[y_i - \sum_{j=i+1}^N \beta_{ij} x_j \right] \quad i = N-1, N-2, \dots, 1 \end{aligned} \quad (2.3.7)$$

Equations (2.3.6) and (2.3.7) total (for each right-hand side \mathbf{b}) N^2 executions of an inner loop containing one multiply and one add. If we have N right-hand sides which are the unit column vectors (which is the case when we are inverting a matrix), then taking into account the leading zeros reduces the total execution count of (2.3.6) from $\frac{1}{2}N^3$ to $\frac{1}{6}N^3$, while (2.3.7) is unchanged at $\frac{1}{2}N^3$.

Notice that, once we have the *LU* decomposition of \mathbf{A} , we can solve with as many right-hand sides as we then care to, one at a time. This is a distinct advantage over the methods of §2.1 and §2.2.

Performing the LU Decomposition

How then can we solve for \mathbf{L} and \mathbf{U} , given \mathbf{A} ? First, we write out the i, j th component of equation (2.3.1) or (2.3.2). That component always is a sum beginning with

$$\alpha_{i1}\beta_{1j} + \cdots = a_{ij}$$

The number of terms in the sum depends, however, on whether i or j is the smaller number. We have, in fact, the three cases,

$$i < j : \quad \alpha_{i1}\beta_{1j} + \alpha_{i2}\beta_{2j} + \cdots + \alpha_{ii}\beta_{ij} = a_{ij} \quad (2.3.8)$$

$$i = j : \quad \alpha_{i1}\beta_{1j} + \alpha_{i2}\beta_{2j} + \cdots + \alpha_{ii}\beta_{jj} = a_{ij} \quad (2.3.9)$$

$$i > j : \quad \alpha_{i1}\beta_{1j} + \alpha_{i2}\beta_{2j} + \cdots + \alpha_{ij}\beta_{jj} = a_{ij} \quad (2.3.10)$$

Equations (2.3.8)–(2.3.10) total N^2 equations for the $N^2 + N$ unknown α 's and β 's (the diagonal being represented twice). Since the number of unknowns is greater than the number of equations, we are invited to specify N of the unknowns arbitrarily and then try to solve for the others. In fact, as we shall see, it is always possible to take

$$\alpha_{ii} \equiv 1 \quad i = 1, \dots, N \quad (2.3.11)$$

A surprising procedure, now, is *Crout's algorithm*, which quite trivially solves the set of $N^2 + N$ equations (2.3.8)–(2.3.11) for all the α 's and β 's by just arranging the equations in a certain order! That order is as follows:

- Set $\alpha_{ii} = 1$, $i = 1, \dots, N$ (equation 2.3.11).
- For each $j = 1, 2, 3, \dots, N$ do these two procedures: First, for $i = 1, 2, \dots, j$, use (2.3.8), (2.3.9), and (2.3.11) to solve for β_{ij} , namely

$$\beta_{ij} = a_{ij} - \sum_{k=1}^{i-1} \alpha_{ik}\beta_{kj}. \quad (2.3.12)$$

(When $i = 1$ in 2.3.12 the summation term is taken to mean zero.) Second, for $i = j+1, j+2, \dots, N$ use (2.3.10) to solve for α_{ij} , namely

$$\alpha_{ij} = \frac{1}{\beta_{jj}} \left(a_{ij} - \sum_{k=1}^{j-1} \alpha_{ik}\beta_{kj} \right). \quad (2.3.13)$$

Be sure to do both procedures before going on to the next j .

If you work through a few iterations of the above procedure, you will see that the α 's and β 's that occur on the right-hand side of equations (2.3.12) and (2.3.13) are already determined by the time they are needed. You will also see that every a_{ij} is used only once and never again. This means that the corresponding α_{ij} or β_{ij} can be stored in the location that the a used to occupy: the decomposition is “in place.” [The diagonal unity elements α_{ii} (equation 2.3.11) are not stored at all.] In brief, Crout's method fills in the combined matrix of α 's and β 's,

$$\begin{bmatrix} \beta_{11} & \beta_{12} & \beta_{13} & \beta_{14} \\ \alpha_{21} & \beta_{22} & \beta_{23} & \beta_{24} \\ \alpha_{31} & \alpha_{32} & \beta_{33} & \beta_{34} \\ \alpha_{41} & \alpha_{42} & \alpha_{43} & \beta_{44} \end{bmatrix} \quad (2.3.14)$$

by columns from left to right, and within each column from top to bottom (see Figure 2.3.1).

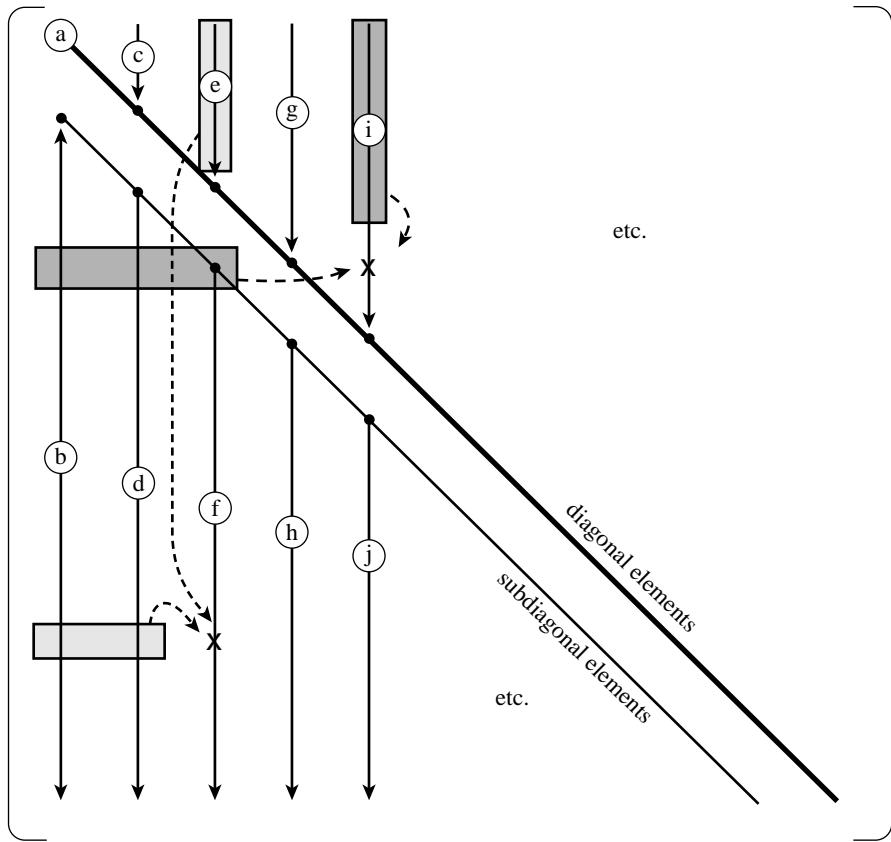

Figure 2.3.1. Crout's algorithm for LU decomposition of a matrix. Elements of the original matrix are modified in the order indicated by lower case letters: a, b, c, etc. Shaded boxes show the previously modified elements that are used in modifying two typical elements, each indicated by an "X".

What about pivoting? Pivoting (i.e., selection of a salubrious pivot element for the division in equation 2.3.13) is absolutely essential for the stability of Crout's method. Only partial pivoting (interchange of rows) can be implemented efficiently. However this is enough to make the method stable. This means, incidentally, that we don't actually decompose the matrix \mathbf{A} into LU form, but rather we decompose a rowwise permutation of \mathbf{A} . (If we keep track of what that permutation is, this decomposition is just as useful as the original one would have been.)

Pivoting is slightly subtle in Crout's algorithm. The key point to notice is that equation (2.3.12) in the case of $i = j$ (its final application) is *exactly the same* as equation (2.3.13) except for the division in the latter equation; in both cases the upper limit of the sum is $k = j - 1$ ($= i - 1$). This means that we don't have to commit ourselves as to whether the diagonal element β_{jj} is the one that happens to fall on the diagonal in the first instance, or whether one of the (undivided) α_{ij} 's below it in the column, $i = j + 1, \dots, N$, is to be "promoted" to become the diagonal β . This can be decided after all the candidates in the column are in hand. As you should be able to guess by now, we will choose the largest one as the diagonal β (pivot element), then do all the divisions by that element *en masse*. This is Crout's

method with partial pivoting. Our implementation has one additional wrinkle: It initially finds the largest element in each row, and subsequently (when it is looking for the maximal pivot element) scales the comparison *as if* we had initially scaled all the equations to make their maximum coefficient equal to unity; this is the *implicit pivoting* mentioned in §2.1.

```
SUBROUTINE ludcmp(a,n,np,indx,d)
INTEGER n,np,indx(n),NMAX
REAL d,a(np,np),TINY
PARAMETER (NMAX=500,TINY=1.0e-20) Largest expected n, and a small number.
Given a matrix a(1:n,1:n), with physical dimension np by np, this routine replaces it by
the LU decomposition of a rowwise permutation of itself. a and n are input. a is output,
arranged as in equation (2.3.14) above; indx(1:n) is an output vector that records the
row permutation effected by the partial pivoting; d is output as ±1 depending on whether
the number of row interchanges was even or odd, respectively. This routine is used in
combination with lubksb to solve linear equations or invert a matrix.
INTEGER i,imax,j,k
REAL aamax,dum,sum,vv(NMAX)           vv stores the implicit scaling of each row.
d=1.                                     No row interchanges yet.
do 12 i=1,n                           Loop over rows to get the implicit scaling information.
  aamax=0.
  do 11 j=1,n
    if (abs(a(i,j)).gt.aamax) aamax=abs(a(i,j))
  enddo 11
  if (aamax.eq.0.) pause 'singular matrix in ludcmp' No nonzero largest element.
  vv(i)=1./aamax                         Save the scaling.
enddo 12
do 19 j=1,n                           This is the loop over columns of Crout's method.
  do 14 i=1,j-1                         This is equation (2.3.12) except for i = j.
    sum=a(i,j)
    do 13 k=1,i-1
      sum=sum-a(i,k)*a(k,j)
    enddo 13
    a(i,j)=sum
  enddo 14
  aamax=0.                               Initialize for the search for largest pivot element.
  do 16 i=j,n                           This is i = j of equation (2.3.12) and i = j + 1 ... N
    sum=a(i,j)                          of equation (2.3.13).
    do 15 k=1,j-1
      sum=sum-a(i,k)*a(k,j)
    enddo 15
    a(i,j)=sum
    dum=vv(i)*abs(sum)                 Figure of merit for the pivot.
    if (dum.ge.aamax) then            Is it better than the best so far?
      imax=i
      aamax=dum
    endif
  enddo 16
  if (j.ne.imax)then                  Do we need to interchange rows?
    do 17 k=1,n                        Yes, do so...
      dum=a(imax,k)
      a(imax,k)=a(j,k)
      a(j,k)=dum
    enddo 17
    d=-d                                ...and change the parity of d.
    vv(imax)=vv(j)                      Also interchange the scale factor.
  endif
  indx(j)=imax
  if(a(j,j).eq.0.)a(j,j)=TINY
  If the pivot element is zero the matrix is singular (at least to the precision of the
  algorithm). For some applications on singular matrices, it is desirable to substitute TINY
  for zero.
```

```

if(j.ne.n)then           Now, finally, divide by the pivot element.
    dum=1./a(j,j)
    do 18 i=j+1,n
        a(i,j)=a(i,j)*dum
    enddo 18
endif
enddo 19               Go back for the next column in the reduction.
return
END

```

Here is the routine for forward substitution and backsubstitution, implementing equations (2.3.6) and (2.3.7).

```

SUBROUTINE lubksb(a,n,np,indx,b)
INTEGER n,np,indx(n)
REAL a(np,np),b(n)
Solves the set of n linear equations  $A \cdot X = B$ . Here a is input, not as the matrix  $A$  but rather as its  $LU$  decomposition, determined by the routine ludcmp. indx is input as the permutation vector returned by ludcmp. b(1:n) is input as the right-hand side vector  $B$ , and returns with the solution vector  $X$ . a, n, np, and indx are not modified by this routine and can be left in place for successive calls with different right-hand sides b. This routine takes into account the possibility that b will begin with many zero elements, so it is efficient for use in matrix inversion.
INTEGER i,ii,j,ll
REAL sum
ii=0
do 12 i=1,n
    ll=indx(i)
    sum=b(ll)
    b(ll)=b(i)
    if (ii.ne.0)then
        do 11 j=ii,i-1
            sum=sum-a(i,j)*b(j)
        enddo 11
    else if (sum.ne.0.) then
        ii=i
        endif
        b(i)=sum
    enddo 12
do 14 i=n,1,-1           When ii is set to a positive value, it will become the index of the first nonvanishing element of b. We now do the forward substitution, equation (2.3.6). The only new wrinkle is to unscramble the permutation as we go.
    sum=b(i)
    do 13 j=i+1,n
        sum=sum-a(i,j)*b(j)
    enddo 13
    b(i)=sum/a(i,i)         A nonzero element was encountered, so from now on we will have to do the sums in the loop above.
    enddo 14
return
END

```

The LU decomposition in ludcmp requires about $\frac{1}{3}N^3$ executions of the inner loops (each with one multiply and one add). This is thus the operation count for solving one (or a few) right-hand sides, and is a factor of 3 better than the Gauss-Jordan routine gaussj which was given in §2.1, and a factor of 1.5 better than a Gauss-Jordan routine (not given) that does not compute the inverse matrix. For inverting a matrix, the total count (including the forward and backsubstitution as discussed following equation 2.3.7 above) is $(\frac{1}{3} + \frac{1}{6} + \frac{1}{2})N^3 = N^3$, the same as gaussj.

To summarize, this is the preferred way to solve the linear set of equations $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$:

```
call ludcmp(a,n,np,indx,d)
call lubksb(a,n,np,indx,b)
```

The answer \mathbf{x} will be returned in \mathbf{b} . Your original matrix \mathbf{A} will have been destroyed.

If you subsequently want to solve a set of equations with the same \mathbf{A} but a different right-hand side \mathbf{b} , you repeat *only*

```
call lubksb(a,n,np,indx,b)
```

not, of course, with the original matrix \mathbf{A} , but with \mathbf{a} and \mathbf{indx} as were already returned from `ludcmp`.

Inverse of a Matrix

Using the above *LU* decomposition and backsubstitution routines, it is completely straightforward to find the inverse of a matrix column by column.

```
INTEGER np,indx(np)
REAL a(np,np),y(np,np)
...
do 12 i=1,n                      Set up identity matrix.
    do 11 j=1,n
        y(i,j)=0.
    enddo 11
    y(i,i)=1.
enddo 12
call ludcmp(a,n,np,indx,d)       Decompose the matrix just once.
do 13 j=1,n                      Find inverse by columns.
    call lubksb(a,n,np,indx,y(1,j))
        Note that FORTRAN stores two-dimensional matrices by column, so y(1,j) is the
        address of the jth column of y.
    enddo 13
```

The matrix \mathbf{y} will now contain the inverse of the original matrix \mathbf{a} , which will have been destroyed. Alternatively, there is nothing wrong with using a Gauss-Jordan routine like `gaussj` (§2.1) to invert a matrix in place, again destroying the original. Both methods have practically the same operations count.

Incidentally, if you ever have the need to compute $\mathbf{A}^{-1} \cdot \mathbf{B}$ from matrices \mathbf{A} and \mathbf{B} , you should *LU* decompose \mathbf{A} and then backsubstitute with the columns of \mathbf{B} instead of with the unit vectors that would give \mathbf{A} 's inverse. This saves a whole matrix multiplication, and is also more accurate.

Determinant of a Matrix

The determinant of an LU decomposed matrix is just the product of the diagonal elements,

$$\det = \prod_{j=1}^N \beta_{jj} \quad (2.3.15)$$

We don't, recall, compute the decomposition of the original matrix, but rather a decomposition of a rowwise permutation of it. Luckily, we have kept track of whether the number of row interchanges was even or odd, so we just preface the product by the corresponding sign. (You now finally know the purpose of returning d in the routine `ludcmp`.)

Calculation of a determinant thus requires one call to `ludcmp`, with *no* subsequent backsubstitutions by `lubksb`.

```
INTEGER np,indx(np)
REAL a(np,np)
...
call ludcmp(a,n,np,indx,d)           This returns d as ±1.
do ii j=1,n
    d=d*a(j,j)
enddo ii
```

The variable d now contains the determinant of the original matrix a , which will have been destroyed.

For a matrix of any substantial size, it is quite likely that the determinant will overflow or underflow your computer's floating-point dynamic range. In this case you can modify the loop of the above fragment and (e.g.) divide by powers of ten, to keep track of the scale separately, or (e.g.) accumulate the sum of logarithms of the absolute values of the factors and the sign separately.

Complex Systems of Equations

If your matrix A is real, but the right-hand side vector is complex, say $\mathbf{b} + i\mathbf{d}$, then (i) LU decompose A in the usual way, (ii) backsubstitute \mathbf{b} to get the real part of the solution vector, and (iii) backsubstitute \mathbf{d} to get the imaginary part of the solution vector.

If the matrix itself is complex, so that you want to solve the system

$$(A + iC) \cdot (x + iy) = (b + id) \quad (2.3.16)$$

then there are two possible ways to proceed. The best way is to rewrite `ludcmp` and `lubksb` as complex routines. Complex modulus substitutes for absolute value in the construction of the scaling vector vv and in the search for the largest pivot elements. Everything else goes through in the obvious way, with complex arithmetic used as needed.

A quick-and-dirty way to solve complex systems is to take the real and imaginary parts of (2.3.16), giving

$$\begin{aligned} A \cdot x - C \cdot y &= b \\ C \cdot x + A \cdot y &= d \end{aligned} \quad (2.3.17)$$

which can be written as a $2N \times 2N$ set of *real* equations,

$$\begin{pmatrix} A & -C \\ C & A \end{pmatrix} \cdot \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} b \\ d \end{pmatrix} \quad (2.3.18)$$

and then solved with `ludcmp` and `lubksb` in their present forms. This scheme is a factor of 2 inefficient in storage, since **A** and **C** are stored twice. It is also a factor of 2 inefficient in time, since the complex multiplies in a complexified version of the routines would each use 4 real multiplies, while the solution of a $2N \times 2N$ problem involves 8 times the work of an $N \times N$ one. If you can tolerate these factor-of-two inefficiencies, then equation (2.3.18) is an easy way to proceed.

2.4 Tridiagonal and Band Diagonal Systems of Equations

The special case of a system of linear equations that is *tridiagonal*, that is, has nonzero elements only on the diagonal plus or minus one column, is one that occurs frequently. Also common are systems that are *band diagonal*, with nonzero elements only along a few diagonal lines adjacent to the main diagonal (above and below).

For tridiagonal sets, the procedures of *LU* decomposition, forward- and back-substitution each take only $O(N)$ operations, and the whole solution can be encoded very concisely. The resulting routine `tridag` is one that we will use in later chapters.

Naturally, one does not reserve storage for the full $N \times N$ matrix, but only for the nonzero components, stored as three vectors. The set of equations to be solved is

$$\begin{bmatrix} b_1 & c_1 & 0 & \cdots \\ a_2 & b_2 & c_2 & \cdots \\ & \cdots & & \\ & \cdots & a_{N-1} & b_{N-1} & c_{N-1} \\ & \cdots & 0 & a_N & b_N \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_{N-1} \\ u_N \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ \vdots \\ r_{N-1} \\ r_N \end{bmatrix} \quad (2.4.1)$$

Notice that a_1 and c_N are undefined and are not referenced by the routine that follows.

and then solved with `ludcmp` and `lubksb` in their present forms. This scheme is a factor of 2 inefficient in storage, since **A** and **C** are stored twice. It is also a factor of 2 inefficient in time, since the complex multiplies in a complexified version of the routines would each use 4 real multiplies, while the solution of a $2N \times 2N$ problem involves 8 times the work of an $N \times N$ one. If you can tolerate these factor-of-two inefficiencies, then equation (2.3.18) is an easy way to proceed.

2.4 Tridiagonal and Band Diagonal Systems of Equations

The special case of a system of linear equations that is *tridiagonal*, that is, has nonzero elements only on the diagonal plus or minus one column, is one that occurs frequently. Also common are systems that are *band diagonal*, with nonzero elements only along a few diagonal lines adjacent to the main diagonal (above and below).

For tridiagonal sets, the procedures of *LU* decomposition, forward- and back-substitution each take only $O(N)$ operations, and the whole solution can be encoded very concisely. The resulting routine `tridag` is one that we will use in later chapters.

Naturally, one does not reserve storage for the full $N \times N$ matrix, but only for the nonzero components, stored as three vectors. The set of equations to be solved is

$$\begin{bmatrix} b_1 & c_1 & 0 & \cdots \\ a_2 & b_2 & c_2 & \cdots \\ & \cdots & & \\ & \cdots & a_{N-1} & b_{N-1} & c_{N-1} \\ & \cdots & 0 & a_N & b_N \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_2 \\ \vdots \\ u_{N-1} \\ u_N \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ \vdots \\ r_{N-1} \\ r_N \end{bmatrix} \quad (2.4.1)$$

Notice that a_1 and c_N are undefined and are not referenced by the routine that follows.

```

SUBROUTINE tridag(a,b,c,r,u,n)
INTEGER n,NMAX
REAL a(n),b(n),c(n),r(n),u(n)
PARAMETER (NMAX=500)
      Solves for a vector u(1:n) of length n the tridiagonal linear set given by equation (2.4.1).
      a(1:n), b(1:n), c(1:n), and r(1:n) are input vectors and are not modified.
      Parameter: NMAX is the maximum expected value of n.
INTEGER j
REAL bet,gam(NMAX)                               One vector of workspace, gam is needed.
if(b(1).eq.0.)pause 'tridag: rewrite equations'
      If this happens then you should rewrite your equations as a set of order N - 1, with  $u_2$ 
      trivially eliminated.
bet=b(1)
u(1)=r(1)/bet
do 11 j=2,n                                     Decomposition and forward substitution.
      gam(j)=c(j-1)/bet
      bet=b(j)-a(j)*gam(j)
      if(bet.eq.0.)pause 'tridag failed'        Algorithm fails; see below.
      u(j)=(r(j)-a(j)*u(j-1))/bet
11 enddo 11
do 12 j=n-1,1,-1                                Backsubstitution.
      u(j)=u(j)-gam(j+1)*u(j+1)
12 enddo 12
return
END

```

There is no pivoting in `tridag`. It is for this reason that `tridag` can fail (pause) even when the underlying matrix is nonsingular: A zero pivot can be encountered even for a nonsingular matrix. In practice, this is not something to lose sleep about. The kinds of problems that lead to tridiagonal linear sets usually have additional properties which guarantee that the algorithm in `tridag` will succeed. For example, if

$$|b_j| > |a_j| + |c_j| \quad j = 1, \dots, N \quad (2.4.2)$$

(called *diagonal dominance*) then it can be shown that the algorithm cannot encounter a zero pivot.

It is possible to construct special examples in which the lack of pivoting in the algorithm causes numerical instability. In practice, however, such instability is almost never encountered — unlike the general matrix problem where pivoting is essential.

The tridiagonal algorithm is the rare case of an algorithm that, in practice, is more robust than theory says it should be. Of course, should you ever encounter a problem for which `tridag` fails, you can instead use the more general method for band diagonal systems, now described (routines `bandec` and `banbks`).

Some other matrix forms consisting of tridiagonal with a small number of additional elements (e.g., upper right and lower left corners) also allow rapid solution; see §2.7.

Band Diagonal Systems

Where tridiagonal systems have nonzero elements only on the diagonal plus or minus one, band diagonal systems are slightly more general and have (say) $m_1 \geq 0$ nonzero elements immediately to the left of (below) the diagonal and $m_2 \geq 0$ nonzero elements immediately to its right (above it). Of course, this is only a useful classification if m_1 and m_2 are both $\ll N$. In that case, the solution of the linear system by *LU* decomposition can be accomplished much faster, and in much less storage, than for the general $N \times N$ case.

The precise definition of a band diagonal matrix with elements a_{ij} is that

$$a_{ij} = 0 \quad \text{when} \quad j > i + m_2 \quad \text{or} \quad i > j + m_1 \quad (2.4.3)$$

Band diagonal matrices are stored and manipulated in a so-called compact form, which results if the matrix is tilted 45° clockwise, so that its nonzero elements lie in a long, narrow matrix with $m_1 + 1 + m_2$ columns and N rows. This is best illustrated by an example: The band diagonal matrix

$$\begin{pmatrix} 3 & 1 & 0 & 0 & 0 & 0 & 0 \\ 4 & 1 & 5 & 0 & 0 & 0 & 0 \\ 9 & 2 & 6 & 5 & 0 & 0 & 0 \\ 0 & 3 & 5 & 8 & 9 & 0 & 0 \\ 0 & 0 & 7 & 9 & 3 & 2 & 0 \\ 0 & 0 & 0 & 3 & 8 & 4 & 6 \\ 0 & 0 & 0 & 0 & 2 & 4 & 4 \end{pmatrix} \quad (2.4.4)$$

which has $N = 7$, $m_1 = 2$, and $m_2 = 1$, is stored compactly as the 7×4 matrix,

$$\begin{pmatrix} x & x & 3 & 1 \\ x & 4 & 1 & 5 \\ 9 & 2 & 6 & 5 \\ 3 & 5 & 8 & 9 \\ 7 & 9 & 3 & 2 \\ 3 & 8 & 4 & 6 \\ 2 & 4 & 4 & x \end{pmatrix} \quad (2.4.5)$$

Here x denotes elements that are wasted space in the compact format; these will not be referenced by any manipulations and can have arbitrary values. Notice that the diagonal of the original matrix appears in column $m_1 + 1$, with subdiagonal elements to its left, superdiagonal elements to its right.

The simplest manipulation of a band diagonal matrix, stored compactly, is to multiply it by a vector to its right. Although this is algorithmically trivial, you might want to study the following routine carefully, as an example of how to pull nonzero elements a_{ij} out of the compact storage format in an orderly fashion. Notice that, as always, the logical and physical dimensions of a two-dimensional array can be different. Our convention is to pass N , m_1 , m_2 , and the *physical* dimensions $\text{np} \geq N$ and $\text{mp} \geq m_1 + 1 + m_2$.

```
SUBROUTINE banmul(a,n,m1,m2,np,mp,x,b)
INTEGER m1,m2,mp,n,np
REAL a(np,mp),b(n),x(n)

Matrix multiply b = A · x, where A is band diagonal with m1 rows below the diagonal
and m2 rows above. The input vector x and output vector b are stored as x(1:n) and
b(1:n), respectively. The array a(1:n,1:m1+m2+1) stores A as follows: The diagonal
elements are in a(1:n,m1+1). Subdiagonal elements are in a(j:n,1:m1) (with  $j > 1$ 
appropriate to the number of elements on each subdiagonal). Superdiagonal elements are
in a(1:j,m1+2:m1+m2+1) with  $j < n$  appropriate to the number of elements on each
superdiagonal.

INTEGER i,j,k
do 12 i=1,n
    b(i)=0.
    k=i-m1-1
    do 11 j=max(1,1-k),min(m1+m2+1,n-k)
        b(i)=b(i)+a(i,j)*x(j+k)
    enddo 11
12 do 13
    return
13 END
```

It is not possible to store the LU decomposition of a band diagonal matrix \mathbf{A} quite as compactly as the compact form of \mathbf{A} itself. The decomposition (essentially by Crout's method, see §2.3) produces additional nonzero "fill-ins." One straightforward storage scheme is to return the upper triangular factor (U) in the same space that \mathbf{A} previously occupied, and to return the lower triangular factor (L) in a separate compact matrix of size $N \times m_1$. The diagonal elements of U (whose product, times $d = \pm 1$, gives the determinant) are returned in the first column of \mathbf{A} 's storage space.

The following routine, `bandec`, is the band-diagonal analog of `ludcmp` in §2.3:

```
SUBROUTINE bandec(a,n,m1,m2,np,mp,al,mpl,indx,d)
INTEGER m1,m2,mp,mpl,n,np,indx(n)
REAL d,a(np,mp),al(np,mp1),TINY
PARAMETER (TINY=1.e-20)
```

Given an $n \times n$ band diagonal matrix \mathbf{A} with m_1 subdiagonal rows and m_2 superdiagonal rows, compactly stored in the array $a(1:n, 1:m_1+m_2+1)$ as described in the comment for routine `bammul`, this routine constructs an LU decomposition of a rowwise permutation of \mathbf{A} . The upper triangular matrix replaces \mathbf{a} , while the lower triangular matrix is returned in $al(1:n, 1:m_1)$. $indx(1:n)$ is an output vector which records the row permutation effected by the partial pivoting; d is output as ± 1 depending on whether the number of row interchanges was even or odd, respectively. This routine is used in combination with `banbks` to solve band-diagonal sets of equations.

```
INTEGER i,j,k,l,mm
REAL dum
mm=m1+m2+1
if(mm.gt.mp.or.m1.gt.mpl.or.n.gt,np) pause 'bad args in bandec'
l=m1
do 13 i=1,m1
    do 11 j=m1+2-i,mm
        a(i,j-1)=a(i,j)
    enddo 11
    l=l-1
    do 12 j=mm-l,mm
        a(i,j)=0.
    enddo 12
enddo 13
d=1.
l=m1
do 18 k=1,n
    dum=a(k,1)
    i=k
    if(l.lt.n)l=l+1
    do 14 j=k+1,l
        if(abs(a(j,1)).gt.abs(dum))then
            dum=a(j,1)
            i=j
        endif
    enddo 14
    indx(k)=i
    if(dum.eq.0.) a(k,1)=TINY
    Matrix is algorithmically singular, but proceed anyway with TINY pivot (desirable in some
    applications).
    if(i.ne.k)then
        Interchange rows.
        d=-d
        do 15 j=1,mm
            dum=a(k,j)
            a(k,j)=a(i,j)
            a(i,j)=dum
        enddo 15
    endif
    do 17 i=k+1,l
        dum=a(i,1)/a(k,1)
        al(k,i-k)=dum
    do 16 j=2,mm
        
```

```

        a(i,j-1)=a(i,j)-dum*a(k,j)
    enddo 16
    a(i,mm)=0.
  enddo 17
endo 18
return
END

```

Some pivoting is possible within the storage limitations of `bandec`, and the above routine does take advantage of the opportunity. In general, when TINY is returned as a diagonal element of U , then the original matrix (perhaps as modified by roundoff error) is in fact singular. In this regard, `bandec` is somewhat more robust than `tridag` above, which can fail algorithmically even for nonsingular matrices; `bandec` is thus also useful (with $m_1 = m_2 = 1$) for some ill-behaved tridiagonal systems.

Once the matrix \mathbf{A} has been decomposed, any number of right-hand sides can be solved in turn by repeated calls to `banbks`, the backsubstitution routine whose analog in §2.3 is `lubksb`.

```

SUBROUTINE banbks(a,n,m1,m2,np,mp,a1,mpl,indx,b)
INTEGER m1,m2,mp,mpl,n,np,indx(n)
REAL a(np,mp),a1(np,mp1),b(n)
Given the arrays a, a1, and indx as returned from bandec, and given a right-hand side
vector b(1:n), solves the band diagonal linear equations  $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ . The solution vector  $\mathbf{x}$ 
overwrites b(1:n). The other input arrays are not modified, and can be left in place for
successive calls with different right-hand sides.
INTEGER i,k,l,mm
REAL dum
mm=m1+m2+1
if(mm.gt.mp.or.m1.gt.mpl.or.n.gt,np) pause 'bad args in banbks'
l=m1
do 12 k=1,n
    i=indx(k)
    if(i.ne.k)then
        dum=b(k)
        b(k)=b(i)
        b(i)=dum
    endif
    if(l.lt.n)l=l+1
    do 11 i=k+1,l
        b(i)=b(i)-al(k,i-k)*b(k)
    enddo 11
  enddo 12
l=1
do 14 i=n,1,-1
    dum=b(i)
    do 13 k=2,l
        dum=dum-a(i,k)*b(k+i-1)
    enddo 13
    b(i)=dum/a(i,1)
    if(l.lt.mm) l=l+1
  enddo 14
return
END

```

The routines `bandec` and `banbks` are based on the Handbook routines `bandel1` and `bansol1` in [1].

2.5 Iterative Improvement of a Solution to Linear Equations

Obviously it is not easy to obtain greater precision for the solution of a linear set than the precision of your computer's floating-point word. Unfortunately, for large sets of linear equations, it is not always easy to obtain precision equal to, or even comparable to, the computer's limit. In direct methods of solution, roundoff errors accumulate, and they are magnified to the extent that your matrix is close to singular. You can easily lose two or three significant figures for matrices which (you thought) were *far* from singular.

If this happens to you, there is a neat trick to restore the full machine precision, called *iterative improvement* of the solution. The theory is very straightforward (see Figure 2.5.1): Suppose that a vector \mathbf{x} is the exact solution of the linear set

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (2.5.1)$$

You don't, however, know \mathbf{x} . You only know some slightly wrong solution $\mathbf{x} + \delta\mathbf{x}$, where $\delta\mathbf{x}$ is the unknown error. When multiplied by the matrix \mathbf{A} , your slightly wrong solution gives a product slightly discrepant from the desired right-hand side \mathbf{b} , namely

$$\mathbf{A} \cdot (\mathbf{x} + \delta\mathbf{x}) = \mathbf{b} + \delta\mathbf{b} \quad (2.5.2)$$

Subtracting (2.5.1) from (2.5.2) gives

$$\mathbf{A} \cdot \delta\mathbf{x} = \delta\mathbf{b} \quad (2.5.3)$$

But (2.5.2) can also be solved, trivially, for $\delta\mathbf{b}$. Substituting this into (2.5.3) gives

$$\mathbf{A} \cdot \delta\mathbf{x} = \mathbf{A} \cdot (\mathbf{x} + \delta\mathbf{x}) - \mathbf{b} \quad (2.5.4)$$

In this equation, the whole right-hand side is known, since $\mathbf{x} + \delta\mathbf{x}$ is the wrong solution that you want to improve. It is essential to calculate the right-hand side in double precision, since there will be a lot of cancellation in the subtraction of \mathbf{b} . Then, we need only solve (2.5.4) for the error $\delta\mathbf{x}$, then subtract this from the wrong solution to get an improved solution.

An important extra benefit occurs if we obtained the original solution by *LU* decomposition. In this case we already have the *LU* decomposed form of \mathbf{A} , and all we need do to solve (2.5.4) is compute the right-hand side and backsubstitute!

The code to do all this is concise and straightforward:

2.5 Iterative Improvement of a Solution to Linear Equations

Obviously it is not easy to obtain greater precision for the solution of a linear set than the precision of your computer's floating-point word. Unfortunately, for large sets of linear equations, it is not always easy to obtain precision equal to, or even comparable to, the computer's limit. In direct methods of solution, roundoff errors accumulate, and they are magnified to the extent that your matrix is close to singular. You can easily lose two or three significant figures for matrices which (you thought) were *far* from singular.

If this happens to you, there is a neat trick to restore the full machine precision, called *iterative improvement* of the solution. The theory is very straightforward (see Figure 2.5.1): Suppose that a vector \mathbf{x} is the exact solution of the linear set

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (2.5.1)$$

You don't, however, know \mathbf{x} . You only know some slightly wrong solution $\mathbf{x} + \delta\mathbf{x}$, where $\delta\mathbf{x}$ is the unknown error. When multiplied by the matrix \mathbf{A} , your slightly wrong solution gives a product slightly discrepant from the desired right-hand side \mathbf{b} , namely

$$\mathbf{A} \cdot (\mathbf{x} + \delta\mathbf{x}) = \mathbf{b} + \delta\mathbf{b} \quad (2.5.2)$$

Subtracting (2.5.1) from (2.5.2) gives

$$\mathbf{A} \cdot \delta\mathbf{x} = \delta\mathbf{b} \quad (2.5.3)$$

But (2.5.2) can also be solved, trivially, for $\delta\mathbf{b}$. Substituting this into (2.5.3) gives

$$\mathbf{A} \cdot \delta\mathbf{x} = \mathbf{A} \cdot (\mathbf{x} + \delta\mathbf{x}) - \mathbf{b} \quad (2.5.4)$$

In this equation, the whole right-hand side is known, since $\mathbf{x} + \delta\mathbf{x}$ is the wrong solution that you want to improve. It is essential to calculate the right-hand side in double precision, since there will be a lot of cancellation in the subtraction of \mathbf{b} . Then, we need only solve (2.5.4) for the error $\delta\mathbf{x}$, then subtract this from the wrong solution to get an improved solution.

An important extra benefit occurs if we obtained the original solution by *LU* decomposition. In this case we already have the *LU* decomposed form of \mathbf{A} , and all we need do to solve (2.5.4) is compute the right-hand side and backsubstitute!

The code to do all this is concise and straightforward:

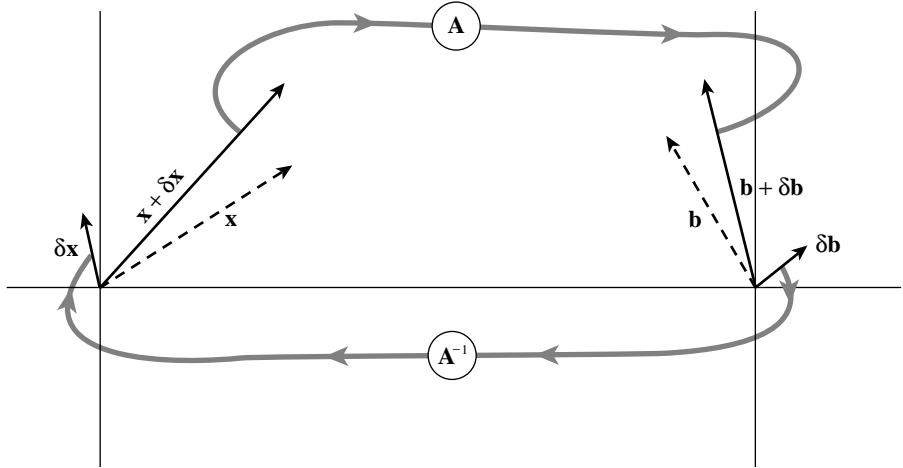

Figure 2.5.1. Iterative improvement of the solution to $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$. The first guess $\mathbf{x} + \delta\mathbf{x}$ is multiplied by \mathbf{A} to produce $\mathbf{b} + \delta\mathbf{b}$. The known vector \mathbf{b} is subtracted, giving $\delta\mathbf{b}$. The linear set with this right-hand side is inverted, giving $\delta\mathbf{x}$. This is subtracted from the first guess giving an improved solution \mathbf{x} .

```

SUBROUTINE mprove(a,alud,n,np,indx,b,x)
INTEGER n,np,indx(n),NMAX
REAL a(np,np),alud(np,np),b(n),x(n)
PARAMETER (NMAX=500)           Maximum anticipated value of n.
C USES lubksb
      Improves a solution vector x(1:n) of the linear set of equations  $A \cdot X = B$ . The matrix a(1:n,1:n), and the vectors b(1:n) and x(1:n) are input, as is the dimension n. Also input is alud, the LU decomposition of a as returned by ludcmp, and the vector indx also returned by that routine. On output, only x(1:n) is modified, to an improved set of values.
      INTEGER i,j
      REAL r(NMAX)
      DOUBLE PRECISION sdp
      do 12 i=1,n               Calculate the right-hand side, accumulating the residual
          sdp=-b(i)              in double precision.
          do 11 j=1,n
              sdp=sdp+dble(a(i,j))*dble(x(j))
          enddo 11
          r(i)=sdp
      enddo 12
      call lubksb(alud,n,np,indx,r)   Solve for the error term,
      do 13 i=1,n                  and subtract it from the old solution.
          x(i)=x(i)-r(i)
      enddo 13
      return
END

```

You should note that the routine `ludcmp` in §2.3 destroys the input matrix as its *LU* decomposes it. Since iterative improvement requires *both* the original matrix and its *LU* decomposition, you will need to copy \mathbf{A} before calling `ludcmp`. Likewise `lubksb` destroys \mathbf{b} in obtaining \mathbf{x} , so make a copy of \mathbf{b} also. If you don't mind this extra storage, iterative improvement is *highly* recommended: It is a process of order only N^2 operations (multiply vector by matrix, and backsubstitute — see discussion following equation 2.3.7); it never hurts; and it can really give you your money's worth if it saves an otherwise ruined solution on which you have already spent of order N^3 operations.

You can call `mprove` several times in succession if you want. Unless you are starting quite far from the true solution, one call is generally enough; but a second call to verify convergence can be reassuring.

More on Iterative Improvement

It is illuminating (and will be useful later in the book) to give a somewhat more solid analytical foundation for equation (2.5.4), and also to give some additional results. Implicit in the previous discussion was the notion that the solution vector $\mathbf{x} + \delta\mathbf{x}$ has an error term; but we neglected the fact that the *LU* decomposition of \mathbf{A} is itself not exact.

A different analytical approach starts with some matrix \mathbf{B}_0 that is assumed to be an *approximate* inverse of the matrix \mathbf{A} , so that $\mathbf{B}_0 \cdot \mathbf{A}$ is approximately the identity matrix $\mathbf{1}$. Define the *residual matrix* \mathbf{R} of \mathbf{B}_0 as

$$\mathbf{R} \equiv \mathbf{1} - \mathbf{B}_0 \cdot \mathbf{A} \quad (2.5.5)$$

which is supposed to be “small” (we will be more precise below). Note that therefore

$$\mathbf{B}_0 \cdot \mathbf{A} = \mathbf{1} - \mathbf{R} \quad (2.5.6)$$

Next consider the following formal manipulation:

$$\begin{aligned} \mathbf{A}^{-1} &= \mathbf{A}^{-1} \cdot (\mathbf{B}_0^{-1} \cdot \mathbf{B}_0) = (\mathbf{A}^{-1} \cdot \mathbf{B}_0^{-1}) \cdot \mathbf{B}_0 = (\mathbf{B}_0 \cdot \mathbf{A})^{-1} \cdot \mathbf{B}_0 \\ &= (\mathbf{1} - \mathbf{R})^{-1} \cdot \mathbf{B}_0 = (\mathbf{1} + \mathbf{R} + \mathbf{R}^2 + \mathbf{R}^3 + \dots) \cdot \mathbf{B}_0 \end{aligned} \quad (2.5.7)$$

We can define the n th partial sum of the last expression by

$$\mathbf{B}_n \equiv (\mathbf{1} + \mathbf{R} + \dots + \mathbf{R}^n) \cdot \mathbf{B}_0 \quad (2.5.8)$$

so that $\mathbf{B}_\infty \rightarrow \mathbf{A}^{-1}$, if the limit exists.

It now is straightforward to verify that equation (2.5.8) satisfies some interesting recurrence relations. As regards solving $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$, where \mathbf{x} and \mathbf{b} are vectors, define

$$\mathbf{x}_n \equiv \mathbf{B}_n \cdot \mathbf{b} \quad (2.5.9)$$

Then it is easy to show that

$$\mathbf{x}_{n+1} = \mathbf{x}_n + \mathbf{B}_0 \cdot (\mathbf{b} - \mathbf{A} \cdot \mathbf{x}_n) \quad (2.5.10)$$

This is immediately recognizable as equation (2.5.4), with $-\delta\mathbf{x} = \mathbf{x}_{n+1} - \mathbf{x}_n$, and with \mathbf{B}_0 taking the role of \mathbf{A}^{-1} . We see, therefore, that equation (2.5.4) does not require that the *LU* decomposition of \mathbf{A} be exact, but only that the implied residual \mathbf{R} be small. In rough terms, if the residual is smaller than the square root of your computer’s roundoff error, then after one application of equation (2.5.10) (that is, going from $\mathbf{x}_0 \equiv \mathbf{B}_0 \cdot \mathbf{b}$ to \mathbf{x}_1) the first neglected term, of order \mathbf{R}^2 , will be smaller than the roundoff error. Equation (2.5.10), like equation (2.5.4), moreover, can be applied more than once, since it uses only \mathbf{B}_0 , and not any of the higher \mathbf{B} ’s.

A much more surprising recurrence which follows from equation (2.5.8) is one that more than *doubles* the order n at each stage:

$$\mathbf{B}_{2n+1} = 2\mathbf{B}_n - \mathbf{B}_n \cdot \mathbf{A} \cdot \mathbf{B}_n \quad n = 0, 1, 3, 7, \dots \quad (2.5.11)$$

Repeated application of equation (2.5.11), from a suitable starting matrix \mathbf{B}_0 , converges *quadratically* to the unknown inverse matrix \mathbf{A}^{-1} (see §9.4 for the definition of “quadratically”). Equation (2.5.11) goes by various names, including *Schultz’s Method* and *Hotelling’s Method*; see Pan and Reif [1] for references. In fact, equation (2.5.11) is simply the iterative Newton-Raphson method of root-finding (§9.4) applied to matrix inversion.

Before you get too excited about equation (2.5.11), however, you should notice that it involves two full matrix multiplications at each iteration. Each matrix multiplication involves N^3 adds and multiplies. But we already saw in §§2.1–2.3 that direct inversion of \mathbf{A} requires only N^3 adds and N^3 multiplies *in toto*. Equation (2.5.11) is therefore practical only when special circumstances allow it to be evaluated much more rapidly than is the case for general matrices. We will meet such circumstances later, in §13.10.

In the spirit of delayed gratification, let us nevertheless pursue the two related issues: When does the series in equation (2.5.7) converge; and what is a suitable initial guess \mathbf{B}_0 (if, for example, an initial LU decomposition is not feasible)?

We can define the norm of a matrix as the largest amplification of length that it is able to induce on a vector,

$$\|\mathbf{R}\| \equiv \max_{\mathbf{v} \neq 0} \frac{|\mathbf{R} \cdot \mathbf{v}|}{|\mathbf{v}|} \quad (2.5.12)$$

If we let equation (2.5.7) act on some arbitrary right-hand side \mathbf{b} , as one wants a matrix inverse to do, it is obvious that a sufficient condition for convergence is

$$\|\mathbf{R}\| < 1 \quad (2.5.13)$$

Pan and Reif [1] point out that a suitable initial guess for \mathbf{B}_0 is any sufficiently small constant ϵ times the matrix transpose of \mathbf{A} , that is,

$$\mathbf{B}_0 = \epsilon \mathbf{A}^T \quad \text{or} \quad \mathbf{R} = \mathbf{I} - \epsilon \mathbf{A}^T \cdot \mathbf{A} \quad (2.5.14)$$

To see why this is so involves concepts from Chapter 11; we give here only the briefest sketch: $\mathbf{A}^T \cdot \mathbf{A}$ is a symmetric, positive definite matrix, so it has real, positive eigenvalues. In its diagonal representation, \mathbf{R} takes the form

$$\mathbf{R} = \text{diag}(1 - \epsilon \lambda_1, 1 - \epsilon \lambda_2, \dots, 1 - \epsilon \lambda_N) \quad (2.5.15)$$

where all the λ_i 's are positive. Evidently any ϵ satisfying $0 < \epsilon < 2/(\max_i \lambda_i)$ will give $\|\mathbf{R}\| < 1$. It is not difficult to show that the optimal choice for ϵ , giving the most rapid convergence for equation (2.5.11), is

$$\epsilon = 2 / (\max_i \lambda_i + \min_i \lambda_i) \quad (2.5.16)$$

Rarely does one know the eigenvalues of $\mathbf{A}^T \cdot \mathbf{A}$ in equation (2.5.16). Pan and Reif derive several interesting bounds, which are computable directly from \mathbf{A} . The following choices guarantee the convergence of \mathbf{B}_n as $n \rightarrow \infty$,

$$\epsilon \leq 1 / \left(\sum_{j,k} a_{jk}^2 \right) \quad \text{or} \quad \epsilon \leq 1 / \left(\left(\max_i \sum_j |a_{ij}| \times \max_j \sum_i |a_{ij}| \right) \right) \quad (2.5.17)$$

The latter expression is truly a remarkable formula, which Pan and Reif derive by noting that the vector norm in equation (2.5.12) need not be the usual L_2 norm, but can instead be either the L_∞ (max) norm, or the L_1 (absolute value) norm. See their work for details.

Another approach, with which we have had some success, is to estimate the largest eigenvalue statistically, by calculating $s_i \equiv |\mathbf{A} \cdot \mathbf{v}_i|^2$ for several unit vector \mathbf{v}_i 's with randomly chosen directions in N -space. The largest eigenvalue λ can then be bounded by the maximum of $2 \max s_i$ and $2N\text{Var}(s_i)/\mu(s_i)$, where Var and μ denote the sample variance and mean, respectively.

2.6 Singular Value Decomposition

There exists a very powerful set of techniques for dealing with sets of equations or matrices that are either singular or else numerically very close to singular. In many cases where Gaussian elimination and *LU* decomposition fail to give satisfactory results, this set of techniques, known as *singular value decomposition*, or *SVD*, will diagnose for you precisely what the problem is. In some cases, SVD will not only diagnose the problem, it will also solve it, in the sense of giving you a useful numerical answer, although, as we shall see, not necessarily “the” answer that you thought you should get.

SVD is also the method of choice for solving most *linear least-squares* problems. We will outline the relevant theory in this section, but defer detailed discussion of the use of SVD in this application to Chapter 15, whose subject is the parametric modeling of data.

SVD methods are based on the following theorem of linear algebra, whose proof is beyond our scope: Any $M \times N$ matrix \mathbf{A} whose number of rows M is greater than or equal to its number of columns N , can be written as the product of an $M \times N$ column-orthogonal matrix \mathbf{U} , an $N \times N$ diagonal matrix \mathbf{W} with positive or zero elements (the *singular values*), and the transpose of an $N \times N$ orthogonal matrix \mathbf{V} . The various shapes of these matrices will be made clearer by the following tableau:

$$\left(\begin{array}{c} \mathbf{A} \end{array} \right) = \left(\begin{array}{c} \mathbf{U} \end{array} \right) \cdot \left(\begin{array}{ccc} w_1 & & \\ & w_2 & \\ & & \ddots \\ & & & w_N \end{array} \right) \cdot \left(\begin{array}{c} \mathbf{V}^T \end{array} \right) \quad (2.6.1)$$

The matrices \mathbf{U} and \mathbf{V} are each orthogonal in the sense that their columns are orthonormal,

$$\sum_{i=1}^M U_{ik} U_{in} = \delta_{kn} \quad \begin{matrix} 1 \leq k \leq N \\ 1 \leq n \leq N \end{matrix} \quad (2.6.2)$$

$$\sum_{j=1}^N V_{jk} V_{jn} = \delta_{kn} \quad \begin{matrix} 1 \leq k \leq N \\ 1 \leq n \leq N \end{matrix} \quad (2.6.3)$$

2.6 Singular Value Decomposition

There exists a very powerful set of techniques for dealing with sets of equations or matrices that are either singular or else numerically very close to singular. In many cases where Gaussian elimination and *LU* decomposition fail to give satisfactory results, this set of techniques, known as *singular value decomposition*, or *SVD*, will diagnose for you precisely what the problem is. In some cases, SVD will not only diagnose the problem, it will also solve it, in the sense of giving you a useful numerical answer, although, as we shall see, not necessarily “the” answer that you thought you should get.

SVD is also the method of choice for solving most *linear least-squares* problems. We will outline the relevant theory in this section, but defer detailed discussion of the use of SVD in this application to Chapter 15, whose subject is the parametric modeling of data.

SVD methods are based on the following theorem of linear algebra, whose proof is beyond our scope: Any $M \times N$ matrix \mathbf{A} whose number of rows M is greater than or equal to its number of columns N , can be written as the product of an $M \times N$ column-orthogonal matrix \mathbf{U} , an $N \times N$ diagonal matrix \mathbf{W} with positive or zero elements (the *singular values*), and the transpose of an $N \times N$ orthogonal matrix \mathbf{V} . The various shapes of these matrices will be made clearer by the following tableau:

$$\left(\begin{array}{c} \mathbf{A} \end{array} \right) = \left(\begin{array}{c} \mathbf{U} \end{array} \right) \cdot \left(\begin{array}{ccc} w_1 & & \\ & w_2 & \\ & & \ddots \\ & & & w_N \end{array} \right) \cdot \left(\begin{array}{c} \mathbf{V}^T \end{array} \right) \quad (2.6.1)$$

The matrices \mathbf{U} and \mathbf{V} are each orthogonal in the sense that their columns are orthonormal,

$$\sum_{i=1}^M U_{ik} U_{in} = \delta_{kn} \quad \begin{matrix} 1 \leq k \leq N \\ 1 \leq n \leq N \end{matrix} \quad (2.6.2)$$

$$\sum_{j=1}^N V_{jk} V_{jn} = \delta_{kn} \quad \begin{matrix} 1 \leq k \leq N \\ 1 \leq n \leq N \end{matrix} \quad (2.6.3)$$

or as a tableau,

$$\begin{aligned} \left(\begin{array}{c} \mathbf{U}^T \\ \vdots \\ \mathbf{U}^T \end{array} \right) \cdot \left(\begin{array}{c} \mathbf{U} \\ \vdots \\ \mathbf{U} \end{array} \right) &= \left(\begin{array}{c} \mathbf{V}^T \\ \vdots \\ \mathbf{V}^T \end{array} \right) \cdot \left(\begin{array}{c} \mathbf{V} \\ \vdots \\ \mathbf{V} \end{array} \right) \\ &= \left(\begin{array}{c} \mathbf{1} \\ \vdots \\ \mathbf{1} \end{array} \right) \end{aligned} \tag{2.6.4}$$

Since \mathbf{V} is square, it is also row-orthonormal, $\mathbf{V} \cdot \mathbf{V}^T = \mathbf{I}$.

The SVD decomposition can also be carried out when $M < N$. In this case the singular values w_j for $j = M + 1, \dots, N$ are all zero, and the corresponding columns of \mathbf{U} are also zero. Equation (2.6.2) then holds only for $k, n \leq M$.

The decomposition (2.6.1) can always be done, no matter how singular the matrix is, and it is “almost” unique. That is to say, it is unique up to (i) making the same permutation of the columns of \mathbf{U} , elements of \mathbf{W} , and columns of \mathbf{V} (or rows of \mathbf{V}^T), or (ii) forming linear combinations of any columns of \mathbf{U} and \mathbf{V} whose corresponding elements of \mathbf{W} happen to be exactly equal. An important consequence of the permutation freedom is that for the case $M < N$, a numerical algorithm for the decomposition need not return zero w_j ’s for $j = M + 1, \dots, N$; the $N - M$ zero singular values can be scattered among all positions $j = 1, 2, \dots, N$.

At the end of this section, we give a routine, `svdcmp`, that performs SVD on an arbitrary matrix \mathbf{A} , replacing it by \mathbf{U} (they are the same shape) and returning \mathbf{W} and \mathbf{V} separately. The routine `svdcmp` is based on a routine by Forsythe et al. [1], which is in turn based on the original routine of Golub and Reinsch, found, in various forms, in [2-4] and elsewhere. These references include extensive discussion of the algorithm used. As much as we dislike the use of black-box routines, we are going to ask you to accept this one, since it would take us too far afield to cover its necessary background material here. Suffice it to say that the algorithm is very stable, and that it is very unusual for it ever to misbehave. Most of the concepts that enter the algorithm (Householder reduction to bidiagonal form, diagonalization by QR procedure with shifts) will be discussed further in Chapter 11.

If you are as suspicious of black boxes as we are, you will want to verify yourself that `svdcmp` does what we say it does. That is very easy to do: Generate an arbitrary matrix \mathbf{A} , call the routine, and then verify by matrix multiplication that (2.6.1) and (2.6.4) are satisfied. Since these two equations are the only defining requirements for SVD, this procedure is (for the chosen \mathbf{A}) a complete end-to-end check.

Now let us find out what SVD is good for.

SVD of a Square Matrix

If the matrix \mathbf{A} is square, $N \times N$ say, then \mathbf{U} , \mathbf{V} , and \mathbf{W} are all square matrices of the same size. Their inverses are also trivial to compute: \mathbf{U} and \mathbf{V} are orthogonal, so their inverses are equal to their transposes; \mathbf{W} is diagonal, so its inverse is the diagonal matrix whose elements are the reciprocals of the elements w_j . From (2.6.1) it now follows immediately that the inverse of \mathbf{A} is

$$\mathbf{A}^{-1} = \mathbf{V} \cdot [\text{diag}(1/w_j)] \cdot \mathbf{U}^T \quad (2.6.5)$$

The only thing that can go wrong with this construction is for one of the w_j 's to be zero, or (numerically) for it to be so small that its value is dominated by roundoff error and therefore unknowable. If more than one of the w_j 's have this problem, then the matrix is even more singular. So, first of all, SVD gives you a clear diagnosis of the situation.

Formally, the *condition number* of a matrix is defined as the ratio of the largest (in magnitude) of the w_j 's to the smallest of the w_j 's. A matrix is singular if its condition number is infinite, and it is *ill-conditioned* if its condition number is too large, that is, if its reciprocal approaches the machine's floating-point precision (for example, less than 10^{-6} for single precision or 10^{-12} for double).

For singular matrices, the concepts of *nullspace* and *range* are important. Consider the familiar set of simultaneous equations

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (2.6.6)$$

where \mathbf{A} is a square matrix, \mathbf{b} and \mathbf{x} are vectors. Equation (2.6.6) defines \mathbf{A} as a linear mapping from the vector space \mathbf{x} to the vector space \mathbf{b} . If \mathbf{A} is singular, then there is some subspace of \mathbf{x} , called the nullspace, that is mapped to zero, $\mathbf{A} \cdot \mathbf{x} = 0$. The dimension of the nullspace (the number of linearly independent vectors \mathbf{x} that can be found in it) is called the *nullity* of \mathbf{A} .

Now, there is also some subspace of \mathbf{b} that can be “reached” by \mathbf{A} , in the sense that there exists some \mathbf{x} which is mapped there. This subspace of \mathbf{b} is called the range of \mathbf{A} . The dimension of the range is called the *rank* of \mathbf{A} . If \mathbf{A} is nonsingular, then its range will be all of the vector space \mathbf{b} , so its rank is N . If \mathbf{A} is singular, then the rank will be less than N . In fact, the relevant theorem is “rank plus nullity equals N .”

What has this to do with SVD? SVD explicitly constructs orthonormal bases for the nullspace and range of a matrix. Specifically, the columns of \mathbf{U} whose same-numbered elements w_j are *nonzero* are an orthonormal set of basis vectors that span the range; the columns of \mathbf{V} whose same-numbered elements w_j are *zero* are an orthonormal basis for the nullspace.

Now let's have another look at solving the set of simultaneous linear equations (2.6.6) in the case that \mathbf{A} is singular. First, the set of *homogeneous* equations, where $\mathbf{b} = 0$, is solved immediately by SVD: Any column of \mathbf{V} whose corresponding w_j is zero yields a solution.

When the vector \mathbf{b} on the right-hand side is not zero, the important question is whether it lies in the range of \mathbf{A} or not. If it does, then the singular set of equations *does* have a solution \mathbf{x} ; in fact it has more than one solution, since any vector in the nullspace (any column of \mathbf{V} with a corresponding zero w_j) can be added to \mathbf{x} in any linear combination.

If we want to single out one particular member of this solution-set of vectors as a representative, we might want to pick the one with the smallest length $|\mathbf{x}|^2$. Here is how to find that vector using SVD: Simply replace $1/w_j$ by zero if $w_j = 0$. (It is not very often that one gets to set $\infty = 0$!) Then compute (working from right to left)

$$\mathbf{x} = \mathbf{V} \cdot [\text{diag}(1/w_j)] \cdot (\mathbf{U}^T \cdot \mathbf{b}) \quad (2.6.7)$$

This will be the solution vector of smallest length; the columns of \mathbf{V} that are in the nullspace complete the specification of the solution set.

Proof: Consider $|\mathbf{x} + \mathbf{x}'|$, where \mathbf{x}' lies in the nullspace. Then, if \mathbf{W}^{-1} denotes the modified inverse of \mathbf{W} with some elements zeroed,

$$\begin{aligned} |\mathbf{x} + \mathbf{x}'| &= |\mathbf{V} \cdot \mathbf{W}^{-1} \cdot \mathbf{U}^T \cdot \mathbf{b} + \mathbf{x}'| \\ &= |\mathbf{V} \cdot (\mathbf{W}^{-1} \cdot \mathbf{U}^T \cdot \mathbf{b} + \mathbf{V}^T \cdot \mathbf{x}')| \\ &= |\mathbf{W}^{-1} \cdot \mathbf{U}^T \cdot \mathbf{b} + \mathbf{V}^T \cdot \mathbf{x}'| \end{aligned} \quad (2.6.8)$$

Here the first equality follows from (2.6.7), the second and third from the orthonormality of \mathbf{V} . If you now examine the two terms that make up the sum on the right-hand side, you will see that the first one has nonzero j components only where $w_j \neq 0$, while the second one, since \mathbf{x}' is in the nullspace, has nonzero j components only where $w_j = 0$. Therefore the minimum length obtains for $\mathbf{x}' = 0$, q.e.d.

If \mathbf{b} is not in the range of the singular matrix \mathbf{A} , then the set of equations (2.6.6) has no solution. But here is some good news: If \mathbf{b} is not in the range of \mathbf{A} , then equation (2.6.7) can still be used to construct a “solution” vector \mathbf{x} . This vector \mathbf{x} will not exactly solve $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$. But, among all possible vectors \mathbf{x} , it will do the closest possible job in the least squares sense. In other words (2.6.7) finds

$$\mathbf{x} \text{ which minimizes } r \equiv |\mathbf{A} \cdot \mathbf{x} - \mathbf{b}| \quad (2.6.9)$$

The number r is called the *residual* of the solution.

The proof is similar to (2.6.8): Suppose we modify \mathbf{x} by adding some arbitrary \mathbf{x}' . Then $\mathbf{A} \cdot \mathbf{x} - \mathbf{b}$ is modified by adding some $\mathbf{b}' \equiv \mathbf{A} \cdot \mathbf{x}'$. Obviously \mathbf{b}' is in the range of \mathbf{A} . We then have

$$\begin{aligned} |\mathbf{A} \cdot \mathbf{x} - \mathbf{b} + \mathbf{b}'| &= |(\mathbf{U} \cdot \mathbf{W} \cdot \mathbf{V}^T) \cdot (\mathbf{V} \cdot \mathbf{W}^{-1} \cdot \mathbf{U}^T \cdot \mathbf{b}) - \mathbf{b} + \mathbf{b}'| \\ &= |(\mathbf{U} \cdot \mathbf{W} \cdot \mathbf{W}^{-1} \cdot \mathbf{U}^T - 1) \cdot \mathbf{b} + \mathbf{b}'| \\ &= |\mathbf{U} \cdot [(\mathbf{W} \cdot \mathbf{W}^{-1} - 1) \cdot \mathbf{U}^T \cdot \mathbf{b} + \mathbf{U}^T \cdot \mathbf{b}']| \\ &= |(\mathbf{W} \cdot \mathbf{W}^{-1} - 1) \cdot \mathbf{U}^T \cdot \mathbf{b} + \mathbf{U}^T \cdot \mathbf{b}'| \end{aligned} \quad (2.6.10)$$

Now, $(\mathbf{W} \cdot \mathbf{W}^{-1} - 1)$ is a diagonal matrix which has nonzero j components only for $w_j = 0$, while $\mathbf{U}^T \mathbf{b}'$ has nonzero j components only for $w_j \neq 0$, since \mathbf{b}' lies in the range of \mathbf{A} . Therefore the minimum obtains for $\mathbf{b}' = 0$, q.e.d.

Figure 2.6.1 summarizes our discussion of SVD thus far.

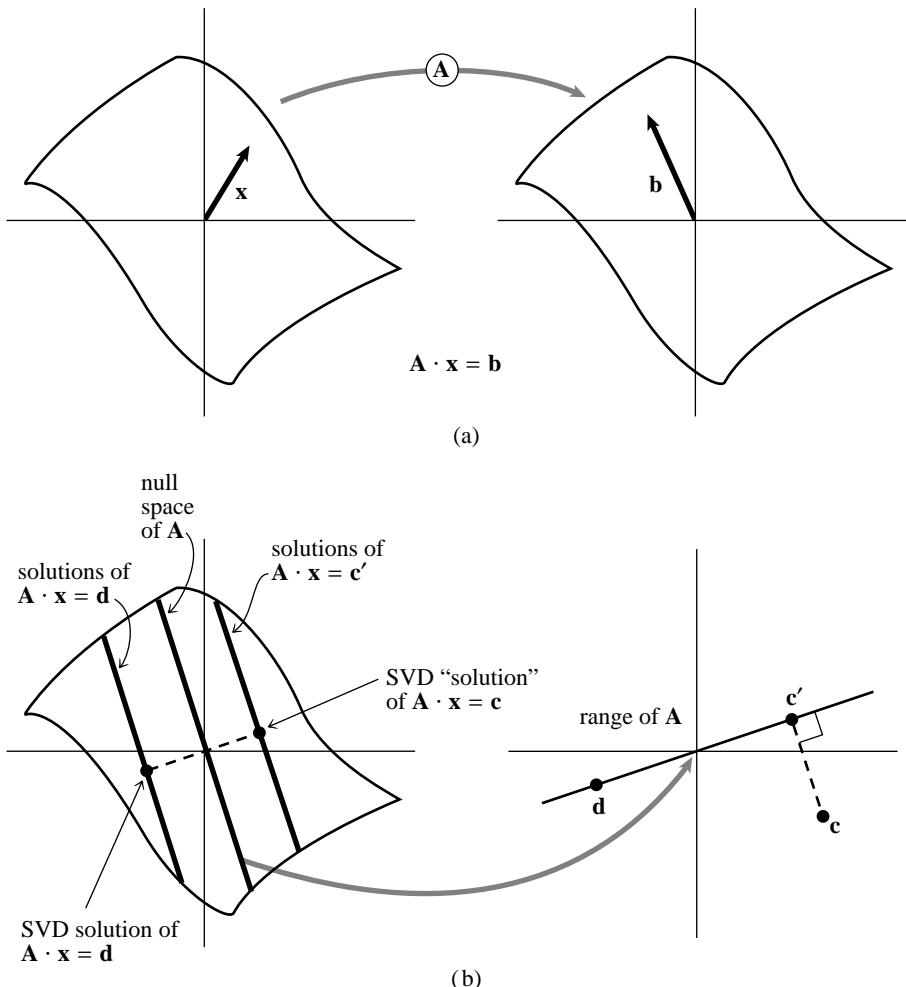

Figure 2.6.1. (a) A nonsingular matrix \mathbf{A} maps a vector space into one of the same dimension. The vector \mathbf{x} is mapped into \mathbf{b} , so that \mathbf{x} satisfies the equation $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$. (b) A singular matrix \mathbf{A} maps a vector space into one of lower dimensionality, here a plane into a line, called the “range” of \mathbf{A} . The “nullspace” of \mathbf{A} is mapped to zero. The solutions of $\mathbf{A} \cdot \mathbf{x} = \mathbf{d}$ consist of any one particular solution plus any vector in the nullspace, here forming a line parallel to the nullspace. Singular value decomposition (SVD) selects the particular solution closest to zero, as shown. The point \mathbf{c} lies outside of the range of \mathbf{A} , so $\mathbf{A} \cdot \mathbf{x} = \mathbf{c}$ has no solution. SVD finds the least-squares best compromise solution, namely a solution of $\mathbf{A} \cdot \mathbf{x} = \mathbf{c}'$, as shown.

In the discussion since equation (2.6.6), we have been pretending that a matrix either is singular or else isn’t. That is of course true analytically. Numerically, however, the far more common situation is that some of the w_j ’s are very small but nonzero, so that the matrix is ill-conditioned. In that case, the direct solution methods of LU decomposition or Gaussian elimination may actually give a formal solution to the set of equations (that is, a zero pivot may not be encountered); but the solution vector may have wildly large components whose algebraic cancellation, when multiplying by the matrix \mathbf{A} , may give a very poor approximation to the right-hand vector \mathbf{b} . In such cases, the solution vector \mathbf{x} obtained by zeroing the

small w_j 's and then using equation (2.6.7) is very often better (in the sense of the residual $|\mathbf{A} \cdot \mathbf{x} - \mathbf{b}|$ being smaller) than *both* the direct-method solution *and* the SVD solution where the small w_j 's are left nonzero.

It may seem paradoxical that this can be so, since zeroing a singular value corresponds to throwing away one linear combination of the set of equations that we are trying to solve. The resolution of the paradox is that we are throwing away precisely a combination of equations that is so corrupted by roundoff error as to be at best useless; usually it is worse than useless since it “pulls” the solution vector way off towards infinity along some direction that is almost a nullspace vector. In doing this, it compounds the roundoff problem and makes the residual $|\mathbf{A} \cdot \mathbf{x} - \mathbf{b}|$ larger.

SVD cannot be applied blindly, then. You have to exercise some discretion in deciding at what threshold to zero the small w_j 's, and/or you have to have some idea what size of computed residual $|\mathbf{A} \cdot \mathbf{x} - \mathbf{b}|$ is acceptable.

As an example, here is a “backsubstitution” routine `svbksb` for evaluating equation (2.6.7) and obtaining a solution vector \mathbf{x} from a right-hand side \mathbf{b} , given that the SVD of a matrix \mathbf{A} has already been calculated by a call to `svdcmp`. Note that this routine presumes that *you* have already zeroed the small w_j 's. It does not do this for you. If you *haven't* zeroed the small w_j 's, then this routine is just as ill-conditioned as any direct method, and you are misusing SVD.

```

SUBROUTINE svbksb(u,w,v,m,n,mp,np,b,x)
INTEGER m,mp,n,np,NMAX
REAL b(mp),u(mp,np),v(np,np),w(np),x(np)
PARAMETER (NMAX=500)           Maximum anticipated value of n.
Solves  $A \cdot X = B$  for a vector  $X$ , where  $A$  is specified by the arrays  $u$ ,  $w$ ,  $v$  as returned by
svdcmp.  $m$  and  $n$  are the logical dimensions of  $a$ , and will be equal for square matrices.  $mp$ 
and  $np$  are the physical dimensions of  $a$ .  $b(1:m)$  is the input right-hand side.  $x(1:n)$  is
the output solution vector. No input quantities are destroyed, so the routine may be called
sequentially with different  $b$ 's.
INTEGER i,j,jj
REAL s,tmp(NMAX)
do 12 j=1,n                  Calculate  $U^T B$ .
   s=0.
   if(w(j).ne.0.)then         Nonzero result only if  $w_j$  is nonzero.
      do 11 i=1,m
         s=s+u(i,j)*b(i)
      enddo 11
      s=s/w(j)                 This is the divide by  $w_j$ .
   endif
   tmp(j)=s
  enddo 12
do 14 j=1,n                  Matrix multiply by  $V$  to get answer.
   s=0.
   do 13 jj=1,n
      s=s+v(j,jj)*tmp(jj)
   enddo 13
   x(j)=s
  enddo 14
return
END

```

Note that a typical use of `svdcmp` and `svbksb` superficially resembles the typical use of `ludcmp` and `lubksb`: In both cases, you decompose the left-hand matrix \mathbf{A} just once, and then can use the decomposition either once or many times with different right-hand sides. The crucial difference is the “editing” of the singular

values before `svbksb` is called:

```

REAL a(np,np),u(np,np),w(np),v(np,np),b(np),x(np)
...
do 12 i=1,n
    do 11 j=1,n
        u(i,j)=a(i,j)
    enddo 11
endo 12
call svdcmp(u,n,n,np,np,w,v)          Copy a into u if you don't want it to be destroyed.
wmax=0.                                  SVD the square matrix a.
do 13 j=1,n                            Will be the maximum singular value obtained.
    if(w(j).gt.wmax)wmax=w(j)
endo 13
wmin=wmax*1.0e-6                      This is where we set the threshold for singular values
do 14 j=1,n                            allowed to be nonzero. The constant is typical,
    if(w(j).lt.wmin)w(j)=0.              but not universal. You have to experiment with
endo 14                                  your own application.
call svbksb(u,w,v,n,n,np,np,b,x)      Now we can backsubstitute.

```

SVD for Fewer Equations than Unknowns

If you have fewer linear equations M than unknowns N , then you are not expecting a unique solution. Usually there will be an $N - M$ dimensional family of solutions. If you want to find this whole solution space, then SVD can readily do the job.

The SVD decomposition will yield $N - M$ zero or negligible w_j 's, since $M < N$. There may be additional zero w_j 's from any degeneracies in your M equations. Be sure that you find this many small w_j 's, and zero them before calling `svbksb`, which will give you the particular solution vector \mathbf{x} . As before, the columns of \mathbf{V} corresponding to zeroed w_j 's are the basis vectors whose linear combinations, added to the particular solution, span the solution space.

SVD for More Equations than Unknowns

This situation will occur in Chapter 15, when we wish to find the least-squares solution to an overdetermined set of linear equations. In tableau, the equations to be solved are

$$\left(\begin{array}{c} \\ \\ \mathbf{A} \\ \end{array} \right) \cdot \left(\begin{array}{c} \\ \\ \mathbf{x} \\ \end{array} \right) = \left(\begin{array}{c} \\ \\ \mathbf{b} \\ \end{array} \right) \quad (2.6.11)$$

The proofs that we gave above for the square case apply without modification to the case of more equations than unknowns. The least-squares solution vector \mathbf{x} is

given by (2.6.7), which, with nonsquare matrices, looks like this,

$$\begin{pmatrix} \mathbf{x} \\ \vdots \\ \mathbf{v} \end{pmatrix} = \begin{pmatrix} & & \\ & \mathbf{V} & \\ & & \end{pmatrix} \cdot \begin{pmatrix} \text{diag}(1/w_j) \\ \vdots \\ \mathbf{U}^T \end{pmatrix} \cdot \begin{pmatrix} \mathbf{b} \\ \vdots \end{pmatrix} \quad (2.6.12)$$

In general, the matrix \mathbf{W} will not be singular, and no w_j 's will need to be set to zero. Occasionally, however, there might be column degeneracies in \mathbf{A} . In this case you will need to zero some small w_j values after all. The corresponding column in \mathbf{V} gives the linear combination of \mathbf{x} 's that is then ill-determined even by the supposedly overdetermined set.

Sometimes, although you do not need to zero any w_j 's for *computational* reasons, you may nevertheless want to take note of any that are unusually small: Their corresponding columns in \mathbf{V} are linear combinations of \mathbf{x} 's which are insensitive to your data. In fact, you may then wish to zero these w_j 's, to reduce the number of free parameters in the fit. These matters are discussed more fully in Chapter 15.

Constructing an Orthonormal Basis

Suppose that you have N vectors in an M -dimensional vector space, with $N \leq M$. Then the N vectors span some subspace of the full vector space. Often you want to construct an orthonormal set of N vectors that span the same subspace. The textbook way to do this is by Gram-Schmidt orthogonalization, starting with one vector and then expanding the subspace one dimension at a time. Numerically, however, because of the build-up of roundoff errors, naive Gram-Schmidt orthogonalization is *terrible*.

The right way to construct an orthonormal basis for a subspace is by SVD: Form an $M \times N$ matrix \mathbf{A} whose N columns are your vectors. Run the matrix through `svdcmp`. The columns of the matrix \mathbf{U} (which in fact replaces \mathbf{A} on output from `svdcmp`) are your desired orthonormal basis vectors.

You might also want to check the output w_j 's for zero values. If any occur, then the spanned subspace was not, in fact, N dimensional; the columns of \mathbf{U} corresponding to zero w_j 's should be discarded from the orthonormal basis set.

(QR factorization, discussed in §2.10, also constructs an orthonormal basis, see [5].)

Approximation of Matrices

Note that equation (2.6.1) can be rewritten to express any matrix A_{ij} as a sum of outer products of columns of \mathbf{U} and rows of \mathbf{V}^T , with the “weighting factors” being the singular values w_j ,

$$A_{ij} = \sum_{k=1}^N w_k U_{ik} V_{jk} \quad (2.6.13)$$

If you ever encounter a situation where *most* of the singular values w_j of a matrix \mathbf{A} are very small, then \mathbf{A} will be well-approximated by only a few terms in the sum (2.6.13). This means that you have to store only a few columns of \mathbf{U} and \mathbf{V} (the same k ones) and you will be able to recover, with good accuracy, the whole matrix.

Note also that it is very efficient to multiply such an approximated matrix by a vector \mathbf{x} : You just dot \mathbf{x} with each of the stored columns of \mathbf{V} , multiply the resulting scalar by the corresponding w_k , and accumulate that multiple of the corresponding column of \mathbf{U} . If your matrix is approximated by a small number K of singular values, then this computation of $\mathbf{A} \cdot \mathbf{x}$ takes only about $K(M + N)$ multiplications, instead of MN for the full matrix.

SVD Algorithm

Here is the algorithm for constructing the singular value decomposition of any matrix. See §11.2–§11.3, and also [4-5], for discussion relating to the underlying method.

```

SUBROUTINE svdcmp(a,m,n,mp,np,w,v)
INTEGER m,mp,n,np,NMAX
REAL a(mp,np),v(np,np),w(np)
PARAMETER (NMAX=500)                               Maximum anticipated value of n.
C USES pythag
Given a matrix a(1:m,1:n), with physical dimensions mp by np, this routine computes its
singular value decomposition,  $A = U \cdot W \cdot V^T$ . The matrix  $U$  replaces a on output. The
diagonal matrix of singular values  $W$  is output as a vector w(1:n). The matrix  $V$  (not the
transpose  $V^T$ ) is output as v(1:n,1:n).

2.7 Sparse Linear Systems

A system of linear equations is called *sparse* if only a relatively small number of its matrix elements a_{ij} are nonzero. It is wasteful to use general methods of linear algebra on such problems, because most of the $O(N^3)$ arithmetic operations devoted to solving the set of equations or inverting the matrix involve zero operands. Furthermore, you might wish to work problems so large as to tax your available memory space, and it is wasteful to reserve storage for unfruitful zero elements. Note that there are two distinct (and not always compatible) goals for any sparse matrix method: saving time and/or saving space.

We have already considered one archetypal sparse form in §2.4, the band diagonal matrix. In the tridiagonal case, e.g., we saw that it was possible to save

2.7 Sparse Linear Systems

A system of linear equations is called *sparse* if only a relatively small number of its matrix elements a_{ij} are nonzero. It is wasteful to use general methods of linear algebra on such problems, because most of the $O(N^3)$ arithmetic operations devoted to solving the set of equations or inverting the matrix involve zero operands. Furthermore, you might wish to work problems so large as to tax your available memory space, and it is wasteful to reserve storage for unfruitful zero elements. Note that there are two distinct (and not always compatible) goals for any sparse matrix method: saving time and/or saving space.

We have already considered one archetypal sparse form in §2.4, the band diagonal matrix. In the tridiagonal case, e.g., we saw that it was possible to save

both time (order N instead of N^3) and space (order N instead of N^2). The method of solution was not different in principle from the general method of *LU* decomposition; it was just applied cleverly, and with due attention to the bookkeeping of zero elements. Many practical schemes for dealing with sparse problems have this same character. They are fundamentally decomposition schemes, or else elimination schemes akin to Gauss-Jordan, but carefully optimized so as to minimize the number of so-called *fill-ins*, initially zero elements which must become nonzero during the solution process, and for which storage must be reserved.

Direct methods for solving sparse equations, then, depend crucially on the precise pattern of sparsity of the matrix. Patterns that occur frequently, or that are useful as way-stations in the reduction of more general forms, already have special names and special methods of solution. We do not have space here for any detailed review of these. References listed at the end of this section will furnish you with an “in” to the specialized literature, and the following list of buzz words (and Figure 2.7.1) will at least let you hold your own at cocktail parties:

- tridiagonal
- band diagonal (or banded) with bandwidth M
- band triangular
- block diagonal
- block tridiagonal
- block triangular
- cyclic banded
- singly (or doubly) bordered block diagonal
- singly (or doubly) bordered block triangular
- singly (or doubly) bordered band diagonal
- singly (or doubly) bordered band triangular
- other (!)

You should also be aware of some of the special sparse forms that occur in the solution of partial differential equations in two or more dimensions. See Chapter 19.

If your particular pattern of sparsity is not a simple one, then you may wish to try an *analyze/factorize/operate* package, which automates the procedure of figuring out how fill-ins are to be minimized. The *analyze* stage is done once only for each pattern of sparsity. The *factorize* stage is done once for each particular matrix that fits the pattern. The *operate* stage is performed once for each right-hand side to be used with the particular matrix. Consult [2,3] for references on this. The NAG library [4] has an *analyze/factorize/operate* capability. A substantial collection of routines for sparse matrix calculation is also available from IMSL [5] as the *Yale Sparse Matrix Package* [6].

You should be aware that the special order of interchanges and eliminations, prescribed by a sparse matrix method so as to minimize fill-ins and arithmetic operations, generally acts to decrease the method’s numerical stability as compared to, e.g., regular *LU* decomposition with pivoting. Scaling your problem so as to make its nonzero matrix elements have comparable magnitudes (if you can do it) will sometimes ameliorate this problem.

In the remainder of this section, we present some concepts which are applicable to some general classes of sparse matrices, and which do not necessarily depend on details of the pattern of sparsity.

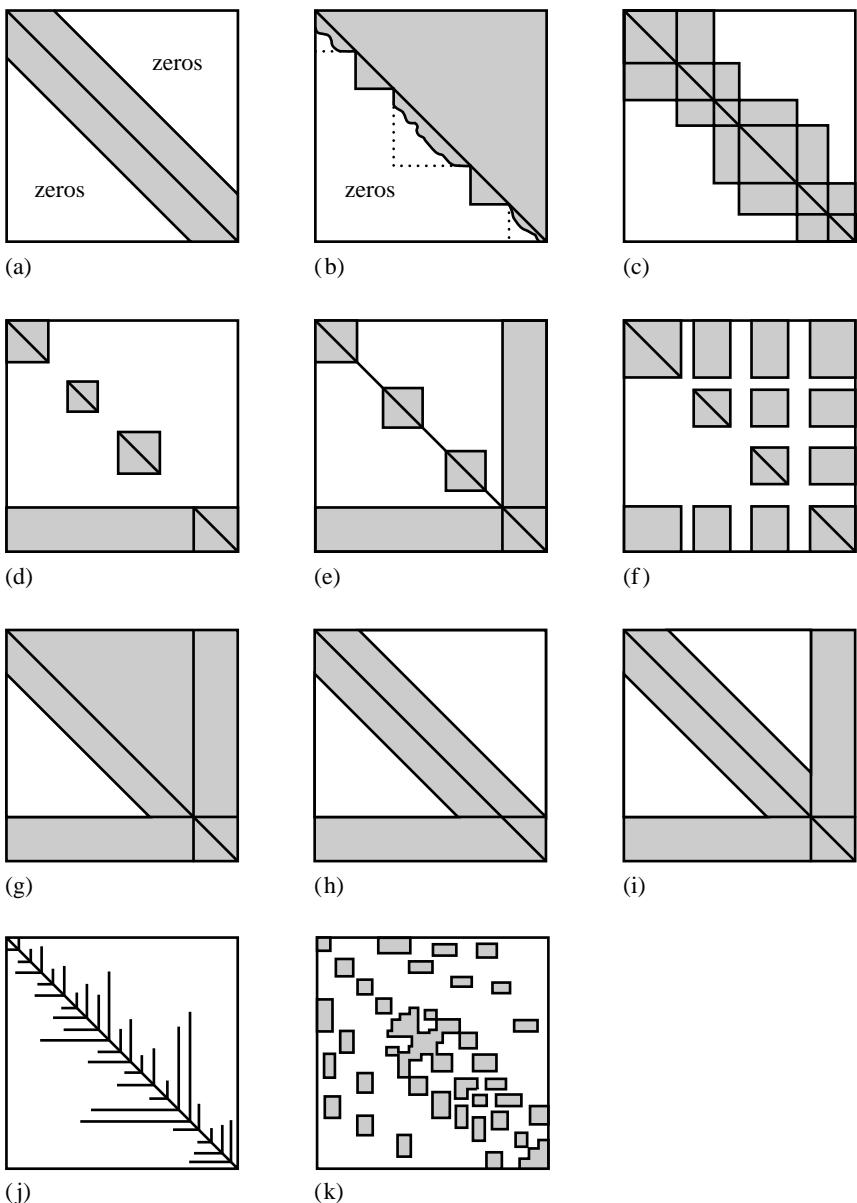

Figure 2.7.1. Some standard forms for sparse matrices. (a) Band diagonal; (b) block triangular; (c) block tridiagonal; (d) singly bordered block diagonal; (e) doubly bordered block diagonal; (f) singly bordered block triangular; (g) bordered band-triangular; (h) and (i) singly and doubly bordered band diagonal; (j) and (k) other! (after Tewarson [1].

Sherman-Morrison Formula

Suppose that you have already obtained, by herculean effort, the inverse matrix \mathbf{A}^{-1} of a square matrix \mathbf{A} . Now you want to make a “small” change in \mathbf{A} , for example change one element a_{ij} , or a few elements, or one row, or one column. Is there any way of calculating the corresponding change in \mathbf{A}^{-1} without repeating

your difficult labors? Yes, if your change is of the form

$$\mathbf{A} \rightarrow (\mathbf{A} + \mathbf{u} \otimes \mathbf{v}) \quad (2.7.1)$$

for some vectors \mathbf{u} and \mathbf{v} . If \mathbf{u} is a unit vector \mathbf{e}_i , then (2.7.1) adds the components of \mathbf{v} to the i th row. (Recall that $\mathbf{u} \otimes \mathbf{v}$ is a matrix whose i, j th element is the product of the i th component of \mathbf{u} and the j th component of \mathbf{v} .) If \mathbf{v} is a unit vector \mathbf{e}_j , then (2.7.1) adds the components of \mathbf{u} to the j th column. If both \mathbf{u} and \mathbf{v} are proportional to unit vectors \mathbf{e}_i and \mathbf{e}_j respectively, then a term is added only to the element a_{ij} .

The *Sherman-Morrison* formula gives the inverse $(\mathbf{A} + \mathbf{u} \otimes \mathbf{v})^{-1}$, and is derived briefly as follows:

$$\begin{aligned} (\mathbf{A} + \mathbf{u} \otimes \mathbf{v})^{-1} &= (\mathbf{1} + \mathbf{A}^{-1} \cdot \mathbf{u} \otimes \mathbf{v})^{-1} \cdot \mathbf{A}^{-1} \\ &= (\mathbf{1} - \mathbf{A}^{-1} \cdot \mathbf{u} \otimes \mathbf{v} + \mathbf{A}^{-1} \cdot \mathbf{u} \otimes \mathbf{v} \cdot \mathbf{A}^{-1} \cdot \mathbf{u} \otimes \mathbf{v} - \dots) \cdot \mathbf{A}^{-1} \\ &= \mathbf{A}^{-1} - \mathbf{A}^{-1} \cdot \mathbf{u} \otimes \mathbf{v} \cdot \mathbf{A}^{-1} (1 - \lambda + \lambda^2 - \dots) \\ &= \mathbf{A}^{-1} - \frac{(\mathbf{A}^{-1} \cdot \mathbf{u}) \otimes (\mathbf{v} \cdot \mathbf{A}^{-1})}{1 + \lambda} \end{aligned} \quad (2.7.2)$$

where

$$\lambda \equiv \mathbf{v} \cdot \mathbf{A}^{-1} \cdot \mathbf{u} \quad (2.7.3)$$

The second line of (2.7.2) is a formal power series expansion. In the third line, the associativity of outer and inner products is used to factor out the scalars λ .

The use of (2.7.2) is this: Given \mathbf{A}^{-1} and the vectors \mathbf{u} and \mathbf{v} , we need only perform two matrix multiplications and a vector dot product,

$$\mathbf{z} \equiv \mathbf{A}^{-1} \cdot \mathbf{u} \quad \mathbf{w} \equiv (\mathbf{A}^{-1})^T \cdot \mathbf{v} \quad \lambda = \mathbf{v} \cdot \mathbf{z} \quad (2.7.4)$$

to get the desired change in the inverse

$$\mathbf{A}^{-1} \rightarrow \mathbf{A}^{-1} - \frac{\mathbf{z} \otimes \mathbf{w}}{1 + \lambda} \quad (2.7.5)$$

The whole procedure requires only $3N^2$ multiplies and a like number of adds (an even smaller number if \mathbf{u} or \mathbf{v} is a unit vector).

The Sherman-Morrison formula can be directly applied to a class of sparse problems. If you already have a fast way of calculating the inverse of \mathbf{A} (e.g., a tridiagonal matrix, or some other standard sparse form), then (2.7.4)–(2.7.5) allow you to build up to your related but more complicated form, adding for example a row or column at a time. Notice that you can apply the Sherman-Morrison formula more than once successively, using at each stage the most recent update of \mathbf{A}^{-1} (equation 2.7.5). Of course, if you have to modify *every* row, then you are back to an N^3 method. The constant in front of the N^3 is only a few times worse than the better direct methods, but you have deprived yourself of the stabilizing advantages of pivoting — so be careful.

For some other sparse problems, the Sherman-Morrison formula cannot be directly applied for the simple reason that storage of the whole inverse matrix \mathbf{A}^{-1}

is not feasible. If you want to add only a single correction of the form $\mathbf{u} \otimes \mathbf{v}$, and solve the linear system

$$(\mathbf{A} + \mathbf{u} \otimes \mathbf{v}) \cdot \mathbf{x} = \mathbf{b} \quad (2.7.6)$$

then you proceed as follows. Using the fast method that is presumed available for the matrix \mathbf{A} , solve the two auxiliary problems

$$\mathbf{A} \cdot \mathbf{y} = \mathbf{b} \quad \mathbf{A} \cdot \mathbf{z} = \mathbf{u} \quad (2.7.7)$$

for the vectors \mathbf{y} and \mathbf{z} . In terms of these,

$$\mathbf{x} = \mathbf{y} - \left[\frac{\mathbf{v} \cdot \mathbf{y}}{1 + (\mathbf{v} \cdot \mathbf{z})} \right] \mathbf{z} \quad (2.7.8)$$

as we see by multiplying (2.7.2) on the right by \mathbf{b} .

Cyclic Tridiagonal Systems

So-called *cyclic tridiagonal systems* occur quite frequently, and are a good example of how to use the Sherman-Morrison formula in the manner just described. The equations have the form

$$\begin{bmatrix} b_1 & c_1 & 0 & \cdots & & \beta \\ a_2 & b_2 & c_2 & \cdots & & \\ & \cdots & & & & \\ & \cdots & a_{N-1} & b_{N-1} & c_{N-1} & \\ \alpha & \cdots & 0 & a_N & b_N & \end{bmatrix} \cdot \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_{N-1} \\ x_N \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ \vdots \\ r_{N-1} \\ r_N \end{bmatrix} \quad (2.7.9)$$

This is a tridiagonal system, except for the matrix elements α and β in the corners. Forms like this are typically generated by finite-differencing differential equations with periodic boundary conditions (§19.4).

We use the Sherman-Morrison formula, treating the system as tridiagonal plus a correction. In the notation of equation (2.7.6), define vectors \mathbf{u} and \mathbf{v} to be

$$\mathbf{u} = \begin{bmatrix} \gamma \\ 0 \\ \vdots \\ 0 \\ \alpha \end{bmatrix} \quad \mathbf{v} = \begin{bmatrix} 1 \\ 0 \\ \vdots \\ 0 \\ \beta/\gamma \end{bmatrix} \quad (2.7.10)$$

Here γ is arbitrary for the moment. Then the matrix \mathbf{A} is the tridiagonal part of the matrix in (2.7.9), with two terms modified:

$$b'_1 = b_1 - \gamma, \quad b'_N = b_N - \alpha\beta/\gamma \quad (2.7.11)$$

We now solve equations (2.7.7) with the standard tridiagonal algorithm, and then get the solution from equation (2.7.8).

The routine `cyclic` below implements this algorithm. We choose the arbitrary parameter $\gamma = -b_1$ to avoid loss of precision by subtraction in the first of equations (2.7.11). In the unlikely event that this causes loss of precision in the second of these equations, you can make a different choice.

```

SUBROUTINE cyclic(a,b,c,alpha,beta,r,x,n)
INTEGER n,NMAX
REAL alpha,beta,a(n),b(n),c(n),r(n),x(n)
PARAMETER (NMAX=500)
C USES tridag
      Solves for a vector x(1:n) the "cyclic" set of linear equations given by equation (2.7.9).
      a, b, c, and r are input vectors, while alpha and beta are the corner entries in the matrix.
      The input is not modified.
      INTEGER i
      REAL fact,gamma,bb(NMAX),u(NMAX),z(NMAX)
      if(n.le.2)pause 'n too small in cyclic'
      if(n.gt.NMAX)pause 'NMAX too small in cyclic'
      gamma=-b(1)           Avoid subtraction error in forming bb(1).
      bb(1)=b(1)-gamma      Set up the diagonal of the modified tridiagonal system.
      bb(n)=b(n)-alpha*beta/gamma
      do 11 i=2,n-1
         bb(i)=b(i)
      enddo 11
      call tridag(a,bb,c,r,x,n)      Solve A · x = r.
      u(1)=gamma                  Set up the vector u.
      u(n)=alpha
      do 12 i=2,n-1
         u(i)=0.
      enddo 12
      call tridag(a,bb,c,u,z,n)      Solve A · z = u.
      fact=(x(1)+beta*x(n)/gamma)/(1.+z(1)+beta*z(n)/gamma)      Form v · x/(1 + v · z).
      do 13 i=1,n
         x(i)=x(i)-fact*z(i)      Now get the solution vector x.
      enddo 13
      return
END

```

Woodbury Formula

If you want to add more than a single correction term, then you cannot use (2.7.8) repeatedly, since without storing a new \mathbf{A}^{-1} you will not be able to solve the auxiliary problems (2.7.7) efficiently after the first step. Instead, you need the *Woodbury formula*, which is the block-matrix version of the Sherman-Morrison formula,

$$\begin{aligned} & (\mathbf{A} + \mathbf{U} \cdot \mathbf{V}^T)^{-1} \\ &= \mathbf{A}^{-1} - \left[\mathbf{A}^{-1} \cdot \mathbf{U} \cdot \left(\mathbf{1} + \mathbf{V}^T \cdot \mathbf{A}^{-1} \cdot \mathbf{U} \right)^{-1} \cdot \mathbf{V}^T \cdot \mathbf{A}^{-1} \right] \end{aligned} \quad (2.7.12)$$

Here A is, as usual, an $N \times N$ matrix, while \mathbf{U} and \mathbf{V} are $N \times P$ matrices with $P < N$ and usually $P \ll N$. The inner piece of the correction term may become clearer if written as the tableau,

$$\left[\begin{array}{c} \mathbf{U} \end{array} \right] \cdot \left[\begin{array}{c} \mathbf{1} + \mathbf{V}^T \cdot \mathbf{A}^{-1} \cdot \mathbf{U} \end{array} \right]^{-1} \cdot \left[\begin{array}{c} \mathbf{V}^T \end{array} \right] \quad (2.7.13)$$

where you can see that the matrix whose inverse is needed is only $P \times P$ rather than $N \times N$.

The relation between the Woodbury formula and successive applications of the Sherman-Morrison formula is now clarified by noting that, if \mathbf{U} is the matrix formed by columns out of the P vectors $\mathbf{u}_1, \dots, \mathbf{u}_P$, and \mathbf{V} is the matrix formed by columns out of the P vectors $\mathbf{v}_1, \dots, \mathbf{v}_P$,

$$\mathbf{U} \equiv \begin{bmatrix} \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_P \end{bmatrix} \quad \mathbf{V} \equiv \begin{bmatrix} \mathbf{v}_1 \\ \vdots \\ \mathbf{v}_P \end{bmatrix} \quad (2.7.14)$$

then two ways of expressing the same correction to \mathbf{A} are

$$\left(\mathbf{A} + \sum_{k=1}^P \mathbf{u}_k \otimes \mathbf{v}_k \right) = (\mathbf{A} + \mathbf{U} \cdot \mathbf{V}^T) \quad (2.7.15)$$

(Note that the subscripts on \mathbf{u} and \mathbf{v} do *not* denote components, but rather distinguish the different column vectors.)

Equation (2.7.15) reveals that, if you have \mathbf{A}^{-1} in storage, then you can either make the P corrections in one fell swoop by using (2.7.12), inverting a $P \times P$ matrix, or else make them by applying (2.7.5) P successive times.

If you don't have storage for \mathbf{A}^{-1} , then you *must* use (2.7.12) in the following way: To solve the linear equation

$$\left(\mathbf{A} + \sum_{k=1}^P \mathbf{u}_k \otimes \mathbf{v}_k \right) \cdot \mathbf{x} = \mathbf{b} \quad (2.7.16)$$

first solve the P auxiliary problems

$$\begin{aligned} \mathbf{A} \cdot \mathbf{z}_1 &= \mathbf{u}_1 \\ \mathbf{A} \cdot \mathbf{z}_2 &= \mathbf{u}_2 \\ &\dots \\ \mathbf{A} \cdot \mathbf{z}_P &= \mathbf{u}_P \end{aligned} \quad (2.7.17)$$

and construct the matrix \mathbf{Z} by columns from the \mathbf{z} 's obtained,

$$\mathbf{Z} \equiv \begin{bmatrix} \mathbf{z}_1 \\ \vdots \\ \mathbf{z}_P \end{bmatrix} \quad (2.7.18)$$

Next, do the $P \times P$ matrix inversion

$$\mathbf{H} \equiv (\mathbf{1} + \mathbf{V}^T \cdot \mathbf{Z})^{-1} \quad (2.7.19)$$

Finally, solve the one further auxiliary problem

$$\mathbf{A} \cdot \mathbf{y} = \mathbf{b} \quad (2.7.20)$$

In terms of these quantities, the solution is given by

$$\mathbf{x} = \mathbf{y} - \mathbf{Z} \cdot [\mathbf{H} \cdot (\mathbf{V}^T \cdot \mathbf{y})] \quad (2.7.21)$$

Inversion by Partitioning

Once in a while, you will encounter a matrix (not even necessarily sparse) that can be inverted efficiently by partitioning. Suppose that the $N \times N$ matrix \mathbf{A} is partitioned into

$$\mathbf{A} = \begin{bmatrix} \mathbf{P} & \mathbf{Q} \\ \mathbf{R} & \mathbf{S} \end{bmatrix} \quad (2.7.22)$$

where \mathbf{P} and \mathbf{S} are square matrices of size $p \times p$ and $s \times s$ respectively ($p + s = N$). The matrices \mathbf{Q} and \mathbf{R} are not necessarily square, and have sizes $p \times s$ and $s \times p$, respectively.

If the inverse of \mathbf{A} is partitioned in the same manner,

$$\mathbf{A}^{-1} = \begin{bmatrix} \tilde{\mathbf{P}} & \tilde{\mathbf{Q}} \\ \tilde{\mathbf{R}} & \tilde{\mathbf{S}} \end{bmatrix} \quad (2.7.23)$$

then $\tilde{\mathbf{P}}$, $\tilde{\mathbf{Q}}$, $\tilde{\mathbf{R}}$, $\tilde{\mathbf{S}}$, which have the same sizes as \mathbf{P} , \mathbf{Q} , \mathbf{R} , \mathbf{S} , respectively, can be found by either the formulas

$$\begin{aligned} \tilde{\mathbf{P}} &= (\mathbf{P} - \mathbf{Q} \cdot \mathbf{S}^{-1} \cdot \mathbf{R})^{-1} \\ \tilde{\mathbf{Q}} &= -(\mathbf{P} - \mathbf{Q} \cdot \mathbf{S}^{-1} \cdot \mathbf{R})^{-1} \cdot (\mathbf{Q} \cdot \mathbf{S}^{-1}) \\ \tilde{\mathbf{R}} &= -(\mathbf{S}^{-1} \cdot \mathbf{R}) \cdot (\mathbf{P} - \mathbf{Q} \cdot \mathbf{S}^{-1} \cdot \mathbf{R})^{-1} \\ \tilde{\mathbf{S}} &= \mathbf{S}^{-1} + (\mathbf{S}^{-1} \cdot \mathbf{R}) \cdot (\mathbf{P} - \mathbf{Q} \cdot \mathbf{S}^{-1} \cdot \mathbf{R})^{-1} \cdot (\mathbf{Q} \cdot \mathbf{S}^{-1}) \end{aligned} \quad (2.7.24)$$

or else by the equivalent formulas

$$\begin{aligned} \tilde{\mathbf{P}} &= \mathbf{P}^{-1} + (\mathbf{P}^{-1} \cdot \mathbf{Q}) \cdot (\mathbf{S} - \mathbf{R} \cdot \mathbf{P}^{-1} \cdot \mathbf{Q})^{-1} \cdot (\mathbf{R} \cdot \mathbf{P}^{-1}) \\ \tilde{\mathbf{Q}} &= -(\mathbf{P}^{-1} \cdot \mathbf{Q}) \cdot (\mathbf{S} - \mathbf{R} \cdot \mathbf{P}^{-1} \cdot \mathbf{Q})^{-1} \\ \tilde{\mathbf{R}} &= -(\mathbf{S} - \mathbf{R} \cdot \mathbf{P}^{-1} \cdot \mathbf{Q})^{-1} \cdot (\mathbf{R} \cdot \mathbf{P}^{-1}) \\ \tilde{\mathbf{S}} &= (\mathbf{S} - \mathbf{R} \cdot \mathbf{P}^{-1} \cdot \mathbf{Q})^{-1} \end{aligned} \quad (2.7.25)$$

The parentheses in equations (2.7.24) and (2.7.25) highlight repeated factors that you may wish to compute only once. (Of course, by associativity, you can instead do the matrix multiplications in any order you like.) The choice between using equation (2.7.24) and (2.7.25) depends on whether you want $\tilde{\mathbf{P}}$ or $\tilde{\mathbf{S}}$ to have the simpler formula; or on whether the repeated expression $(\mathbf{S} - \mathbf{R} \cdot \mathbf{P}^{-1} \cdot \mathbf{Q})^{-1}$ is easier to calculate than the expression $(\mathbf{P} - \mathbf{Q} \cdot \mathbf{S}^{-1} \cdot \mathbf{R})^{-1}$; or on the relative sizes of \mathbf{P} and \mathbf{S} ; or on whether \mathbf{P}^{-1} or \mathbf{S}^{-1} is already known.

Another sometimes useful formula is for the determinant of the partitioned matrix,

$$\det \mathbf{A} = \det \mathbf{P} \det (\mathbf{S} - \mathbf{R} \cdot \mathbf{P}^{-1} \cdot \mathbf{Q}) = \det \mathbf{S} \det (\mathbf{P} - \mathbf{Q} \cdot \mathbf{S}^{-1} \cdot \mathbf{R}) \quad (2.7.26)$$

Indexed Storage of Sparse Matrices

We have already seen (§2.4) that tri- or band-diagonal matrices can be stored in a compact format that allocates storage only to elements which can be nonzero, plus perhaps a few wasted locations to make the bookkeeping easier. What about more general sparse matrices? When a sparse matrix of logical size $N \times N$ contains only a few times N nonzero elements (a typical case), it is surely inefficient — and often physically impossible — to allocate storage for all N^2 elements. Even if one did allocate such storage, it would be inefficient or prohibitive in machine time to loop over all of it in search of nonzero elements.

Obviously some kind of indexed storage scheme is required, one that stores only nonzero matrix elements, along with sufficient auxiliary information to determine where an element logically belongs and how the various elements can be looped over in common matrix operations. Unfortunately, there is no one standard scheme in general use. Knuth [7] describes one method. The Yale Sparse Matrix Package [6] and ITPACK [8] describe several other methods. For most applications, we favor the storage scheme used by PCGPACK [9], which is almost the same as that described by Bentley [10], and also similar to one of the Yale Sparse Matrix Package methods. The advantage of this scheme, which can be called *row-indexed sparse storage mode*, is that it requires storage of only about two times the number of nonzero matrix elements. (Other methods can require as much as three or five times.) For simplicity, we will treat only the case of square matrices, which occurs most frequently in practice.

To represent a matrix \mathbf{A} of logical size $N \times N$, the row-indexed scheme sets up two one-dimensional arrays, call them \mathbf{sa} and \mathbf{ija} . The first of these stores matrix element values in single or double precision as desired; the second stores integer values. The storage rules are:

- The first N locations of \mathbf{sa} store \mathbf{A} 's diagonal matrix elements, in order. (Note that diagonal elements are stored even if they are zero; this is at most a slight storage inefficiency, since diagonal elements are nonzero in most realistic applications.)
- Each of the first N locations of \mathbf{ija} stores the index of the array \mathbf{sa} that contains the first *off-diagonal* element of the corresponding row of the matrix. (If there are no off-diagonal elements for that row, it is one greater than the index in \mathbf{sa} of the most recently stored element of a previous row.)
- Location 1 of \mathbf{ija} is always equal to $N + 2$. (It can be read to determine N .)
- Location $N + 1$ of \mathbf{ija} is one greater than the index in \mathbf{sa} of the last off-diagonal element of the last row. (It can be read to determine the number of nonzero elements in the matrix, or the logical length of the arrays \mathbf{sa} and \mathbf{ija} .) Location $N + 1$ of \mathbf{sa} is not used and can be set arbitrarily.
- Entries in \mathbf{sa} at locations $\geq N + 2$ contain \mathbf{A} 's off-diagonal values, ordered by rows and, within each row, ordered by columns.
- Entries in \mathbf{ija} at locations $\geq N + 2$ contain the column number of the corresponding element in \mathbf{sa} .

While these rules seem arbitrary at first sight, they result in a rather elegant storage scheme. As an example, consider the matrix

$$\begin{bmatrix} 3. & 0. & 1. & 0. & 0. \\ 0. & 4. & 0. & 0. & 0. \\ 0. & 7. & 5. & 9. & 0. \\ 0. & 0. & 0. & 0. & 2. \\ 0. & 0. & 0. & 6. & 5. \end{bmatrix} \quad (2.7.27)$$

In row-indexed compact storage, matrix (2.7.27) is represented by the two arrays of length 11, as follows

index k	1	2	3	4	5	6	7	8	9	10	11
$\mathbf{ija}(k)$	7	8	8	10	11	12	3	2	4	5	4
$\mathbf{sa}(k)$	3.	4.	5.	0.	5.	x	1.	7.	9.	2.	6.

(2.7.28)

Here x is an arbitrary value. Notice that, according to the storage rules, the value of N (namely 5) is $\mathbf{ija}(1)-2$, and the length of each array is $\mathbf{ija}(\mathbf{ija}(1)-1)-1$, namely 11.

The diagonal element in row i is $\text{sa}(i)$, and the off-diagonal elements in that row are in $\text{sa}(k)$ where k loops from $\text{ija}(i)$ to $\text{ija}(i+1)-1$, if the upper limit is greater or equal to the lower one (as in FORTRAN do loops).

Here is a routine, `sprsin`, that converts a matrix from full storage mode into row-indexed sparse storage mode, throwing away any elements that are less than a specified threshold. Of course, the principal use of sparse storage mode is for matrices whose full storage mode won't fit into your machine at all; then you have to generate them directly into sparse format. Nevertheless `sprsin` is useful as a precise algorithmic definition of the storage scheme, for subscale testing of large problems, and for the case where execution time, rather than storage, furnishes the impetus to sparse storage.

```
SUBROUTINE sprsin(a,n,np,thresh,nmax,sa,ija)
INTEGER n,nmax,np,ija(nmax)
REAL thresh,a(np,np),sa(nmax)
    Converts a square matrix a(1:n,1:n) with physical dimension np into row-indexed sparse
    storage mode. Only elements of a with magnitude  $\geq$  thresh are retained. Output is in
    two linear arrays with physical dimension nmax (an input parameter): sa(1:) contains
    array values, indexed by ija(1:). The logical sizes of sa and ija on output are both
    ija(ija(1)-1)-1 (see text).
INTEGER i,j,k
do 11 j=1,n                      Store diagonal elements.
    sa(j)=a(j,j)
enddo 11
ija(1)=n+2                         Index to 1st row off-diagonal element, if any.
k=n+1
do 13 i=1,n                         Loop over rows.
    do 12 j=1,n                       Loop over columns.
        if(abs(a(i,j)).ge.thresh)then
            if(i.ne.j)then           Store off-diagonal elements and their columns.
                k=k+1
                if(k.gt.nmax)pause 'nmax too small in sprsin'
                sa(k)=a(i,j)
                ija(k)=j
            endif
        endif
    enddo 12
    ija(i+1)=k+1                     As each row is completed, store index to next.
enddo 13
return
END
```

The single most important use of a matrix in row-indexed sparse storage mode is to multiply a vector to its right. In fact, the storage mode is optimized for just this purpose. The following routine is thus very simple.

```
SUBROUTINE sprsax(sa,ija,x,b,n)
INTEGER n,ija(*)
REAL b(n),sa(*),x(n)
    Multiply a matrix in row-index sparse storage arrays sa and ija by a vector x(1:n), giving
    a vector b(1:n).
INTEGER i,k
if (ija(1).ne.n+2) pause 'mismatched vector and matrix in sprsax'
do 12 i=1,n
    b(i)=sa(i)*x(i)                  Start with diagonal term.
    do 11 k=ija(i),ija(i+1)-1        Loop over off-diagonal terms.
        b(i)=b(i)+sa(k)*x(ija(k))
    enddo 11
enddo 12
return
END
```

It is also simple to multiply the *transpose* of a matrix by a vector to its right. (We will use this operation later in this section.) Note that the transpose matrix is not actually constructed.

```
SUBROUTINE sprstx(sa,ija,x,b,n)
INTEGER n,ija(*)
REAL b(n),sa(*),x(n)
      Multiply the transpose of a matrix in row-index sparse storage arrays sa and ija by a
      vector x(1:n), giving a vector b(1:n).
INTEGER i,j,k
if (ija(1).ne.n+2) pause 'mismatched vector and matrix in sprstx'
do 11 i=1,n           Start with diagonal terms.
    b(i)=sa(i)*x(i)
  enddo 11
do 13 i=1,n           Loop over off-diagonal terms.
    do 12 k=ija(i),ija(i+1)-1
        j=ija(k)
        b(j)=b(j)+sa(k)*x(i)
    enddo 12
  enddo 13
return
END
```

(Double precision versions of **sprsx** and **sprstx**, named **dsprsx** and **dsprstx**, are used by the routine **atimes** later in this section. You can easily make the conversion, or else get the converted routines from the *Numerical Recipes* diskettes.)

In fact, because the choice of row-indexed storage treats rows and columns quite differently, it is quite an involved operation to construct the transpose of a matrix, given the matrix itself in row-indexed sparse storage mode. When the operation cannot be avoided, it is done as follows: An index of all off-diagonal elements by their columns is constructed (see §8.4). The elements are then written to the output array in column order. As each element is written, its row is determined and stored. Finally, the elements in each column are sorted by row.

```
SUBROUTINE sprstp(sa,ija,sb,ijb)
INTEGER ija(*),ijb(*)
REAL sa(*),sb(*)
C USES iindexx           Version of iindexx with all REAL variables changed to INTEGER.
      Construct the transpose of a sparse square matrix, from row-index sparse storage arrays sa
      and ija into arrays sb and ijb.
INTEGER j,jl,jm,jp,ju,k,m,n2,noff,inc,iv
REAL v
n2=ija(1)           Linear size of matrix plus 2.
do 11 j=1,n2-2     Diagonal elements.
    sb(j)=sa(j)
  enddo 11
call iindexx(ija(n2-1)-ija(1),ija(n2),ijb(n2))
      Index all off-diagonal elements by their columns.
jp=0
do 13 k=ija(1),ija(n2-1)-1   Loop over output off-diagonal elements.
    m=ijb(k)+n2-1           Use index table to store by (former) columns.
    sb(k)=sa(m)
    do 12 j=jp+1,ija(m)     Fill in the index to any omitted rows.
        ijbj(j)=k
    enddo 12
    jp=ija(m)               Use bisection to find which row element m is in and put that
    jl=1                     into ijbj(k).
    ju=n2-1
5     if (ju-jl.gt.1) then
        jm=(ju+jl)/2
        if(ija(jm).gt.m)then
            ju=jm
        else
```

```

        jl=jm
    endif
    goto 5
endif
ijb(k)=jl
enddo 13
do 14 j=jp+1,n2-1
    ijb(j)=ija(n2-1)
enddo 14
do 16 j=1,n2-2
    jl=ijb(j+1)-ijb(j)
    noff=ijb(j)-1
    inc=1
1    inc=3*inc+1
    if(inc.le.jl)goto 1
2    continue
    inc=inc/3
    do 15 k=noff+inc+1,noff+jl
        iv=ijb(k)
        v=sb(k)
        m=k
3    if(ijb(m-inc).gt.iv)then
        ijb(m)=ijb(m-inc)
        sb(m)=sb(m-inc)
        m=m-inc
        if(m-noff.le.inc)goto 4
        goto 3
    endif

```

The above routine embeds internally a sorting algorithm from §8.1, but calls the external routine `iindexx` to construct the initial column index. This routine is identical to `indexx`, as listed in §8.4, except that the latter's two `REAL` declarations should be changed to `integer`. (The *Numerical Recipes* diskettes include both `indexx` and `iindexx`.) In fact, you can often use `indexx` without making these changes, since many computers have the property that numerical values will sort correctly independently of whether they are interpreted as floating or integer values.

As final examples of the manipulation of sparse matrices, we give two routines for the multiplication of two sparse matrices. These are useful for techniques to be described in §13.10.

In general, the product of two sparse matrices is not itself sparse. One therefore wants to limit the size of the product matrix in one of two ways: either compute only those elements of the product that are specified in advance by a known pattern of sparsity, or else compute all nonzero elements, but store only those whose magnitude exceeds some threshold value. The former technique, when it can be used, is quite efficient. The pattern of sparsity is specified by furnishing an index array in row-index sparse storage format (e.g., `ija`). The program then constructs a corresponding value array (e.g., `sa`). The latter technique runs the danger of excessive compute times and unknown output sizes, so it must be used cautiously.

With row-index storage, it is much more natural to multiply a matrix (on the left) by the transpose of a matrix (on the right), so that one is crunching rows on rows, rather than rows on columns. Our routines therefore calculate $\mathbf{A} \cdot \mathbf{B}^T$, rather than $\mathbf{A} \cdot \mathbf{B}$. This means that you have to run your right-hand matrix through the transpose routine `sprstp` before sending it to the matrix multiply routine.

The two implementing routines, `sprspm` for “pattern multiply” and `sprstm` for “threshold multiply” are quite similar in structure. Both are complicated by the logic of the various

combinations of diagonal or off-diagonal elements for the two input streams and output stream.

```

SUBROUTINE sprspm(sa,ija,sb,ijb,sc,ijc)
INTEGER ija(*),ijb(*),ijc(*)
REAL sa(*),sb(*),sc(*)
      Matrix multiply  $\mathbf{A} \cdot \mathbf{B}^T$  where  $\mathbf{A}$  and  $\mathbf{B}$  are two sparse matrices in row-index storage mode,
      and  $\mathbf{B}^T$  is the transpose of  $\mathbf{B}$ . Here, sa and ija store the matrix  $\mathbf{A}$ ; sb and ijb store the
      matrix  $\mathbf{B}$ . This routine computes only those components of the matrix product that are pre-specified
      by the input index array ijc, which is not modified. On output, the arrays sc and
      ijc give the product matrix in row-index storage mode. For sparse matrix multiplication,
      this routine will often be preceded by a call to sprstp, so as to construct the transpose
      of a known matrix into sb, ijb.
      INTEGER i,ijma,ijmb,j,m,ma,mb,mbb,mn
      REAL sum
      if (ija(1).ne.ijb(1).or.ija(1).ne.ijc(1))

Conjugate Gradient Method for a Sparse System

So-called *conjugate gradient methods* provide a quite general means for solving the $N \times N$ linear system

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (2.7.29)$$

The attractiveness of these methods for large sparse systems is that they reference \mathbf{A} only through its multiplication of a vector, or the multiplication of its transpose and a vector. As we have seen, these operations can be very efficient for a properly stored sparse matrix. You, the “owner” of the matrix \mathbf{A} , can be asked to provide subroutines that perform these sparse matrix multiplications as efficiently as possible. We, the “grand strategists” supply the general routine, `linbcg` below, that solves the set of linear equations, (2.7.29), using your subroutines.

The simplest, “ordinary” conjugate gradient algorithm [11-13] solves (2.7.29) only in the case that \mathbf{A} is symmetric and positive definite. It is based on the idea of minimizing the function

$$f(\mathbf{x}) = \frac{1}{2} \mathbf{x} \cdot \mathbf{A} \cdot \mathbf{x} - \mathbf{b} \cdot \mathbf{x} \quad (2.7.30)$$

This function is minimized when its gradient

$$\nabla f = \mathbf{A} \cdot \mathbf{x} - \mathbf{b} \quad (2.7.31)$$

is zero, which is equivalent to (2.7.29). The minimization is carried out by generating a succession of search directions \mathbf{p}_k and improved minimizers \mathbf{x}_k . At each stage a quantity α_k is found that minimizes $f(\mathbf{x}_k + \alpha_k \mathbf{p}_k)$, and \mathbf{x}_{k+1} is set equal to the new point $\mathbf{x}_k + \alpha_k \mathbf{p}_k$. The \mathbf{p}_k and \mathbf{x}_k are built up in such a way that \mathbf{x}_{k+1} is also the minimizer of f over the whole vector space of directions already taken, $\{\mathbf{p}_1, \mathbf{p}_2, \dots, \mathbf{p}_k\}$. After N iterations you arrive at the minimizer over the entire vector space, i.e., the solution to (2.7.29).

Later, in §10.6, we will generalize this “ordinary” conjugate gradient algorithm to the minimization of arbitrary nonlinear functions. Here, where our interest is in solving linear, but not necessarily positive definite or symmetric, equations, a different generalization is important, the *biconjugate gradient method*. This method does not, in general, have a simple connection with function minimization. It constructs four sequences of vectors, \mathbf{r}_k , $\bar{\mathbf{r}}_k$, \mathbf{p}_k , $\bar{\mathbf{p}}_k$, $k = 1, 2, \dots$. You supply the initial vectors \mathbf{r}_1 and $\bar{\mathbf{r}}_1$, and set $\mathbf{p}_1 = \mathbf{r}_1$, $\bar{\mathbf{p}}_1 = \bar{\mathbf{r}}_1$. Then you carry out the following recurrence:

$$\begin{aligned} \alpha_k &= \frac{\bar{\mathbf{r}}_k \cdot \mathbf{r}_k}{\bar{\mathbf{p}}_k \cdot \mathbf{A} \cdot \mathbf{p}_k} \\ \mathbf{r}_{k+1} &= \mathbf{r}_k - \alpha_k \mathbf{A} \cdot \mathbf{p}_k \\ \bar{\mathbf{r}}_{k+1} &= \bar{\mathbf{r}}_k - \alpha_k \mathbf{A}^T \cdot \bar{\mathbf{p}}_k \\ \beta_k &= \frac{\bar{\mathbf{r}}_{k+1} \cdot \mathbf{r}_{k+1}}{\bar{\mathbf{r}}_k \cdot \mathbf{r}_k} \\ \mathbf{p}_{k+1} &= \mathbf{r}_{k+1} + \beta_k \mathbf{p}_k \\ \bar{\mathbf{p}}_{k+1} &= \bar{\mathbf{r}}_{k+1} + \beta_k \bar{\mathbf{p}}_k \end{aligned} \quad (2.7.32)$$

This sequence of vectors satisfies the *biorthogonality* condition

$$\bar{\mathbf{r}}_i \cdot \mathbf{r}_j = \mathbf{r}_i \cdot \bar{\mathbf{r}}_j = 0, \quad j < i \quad (2.7.33)$$

and the *biconjugacy* condition

$$\bar{\mathbf{p}}_i \cdot \mathbf{A} \cdot \mathbf{p}_j = \mathbf{p}_i \cdot \mathbf{A}^T \cdot \bar{\mathbf{p}}_j = 0, \quad j < i \quad (2.7.34)$$

There is also a mutual orthogonality,

$$\bar{\mathbf{r}}_i \cdot \mathbf{p}_j = \mathbf{r}_i \cdot \bar{\mathbf{p}}_j = 0, \quad j < i \quad (2.7.35)$$

The proof of these properties proceeds by straightforward induction [14]. As long as the recurrence does not break down earlier because one of the denominators is zero, it must

terminate after $m \leq N$ steps with $\mathbf{r}_{m+1} = \bar{\mathbf{r}}_{m+1} = 0$. This is basically because after at most N steps you run out of new orthogonal directions to the vectors you've already constructed.

To use the algorithm to solve the system (2.7.29), make an initial guess \mathbf{x}_1 for the solution. Choose \mathbf{r}_1 to be the *residual*

$$\mathbf{r}_1 = \mathbf{b} - \mathbf{A} \cdot \mathbf{x}_1 \quad (2.7.36)$$

and choose $\bar{\mathbf{r}}_1 = \mathbf{r}_1$. Then form the sequence of improved estimates

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \alpha_k \mathbf{p}_k \quad (2.7.37)$$

while carrying out the recurrence (2.7.32). Equation (2.7.37) guarantees that \mathbf{r}_{k+1} from the recurrence is in fact the residual $\mathbf{b} - \mathbf{A} \cdot \mathbf{x}_{k+1}$ corresponding to \mathbf{x}_{k+1} . Since $\mathbf{r}_{m+1} = 0$, \mathbf{x}_{m+1} is the solution to equation (2.7.29).

While there is no guarantee that this whole procedure will not break down or become unstable for general \mathbf{A} , in practice this is rare. More importantly, the exact termination in at most N iterations occurs only with exact arithmetic. Roundoff error means that you should regard the process as a genuinely iterative procedure, to be halted when some appropriate error criterion is met.

The ordinary conjugate gradient algorithm is the special case of the biconjugate gradient algorithm when \mathbf{A} is symmetric, and we choose $\bar{\mathbf{r}}_1 = \mathbf{r}_1$. Then $\bar{\mathbf{r}}_k = \mathbf{r}_k$ and $\bar{\mathbf{p}}_k = \mathbf{p}_k$ for all k ; you can omit computing them and halve the work of the algorithm. This conjugate gradient version has the interpretation of minimizing equation (2.7.30). If \mathbf{A} is positive definite as well as symmetric, the algorithm cannot break down (in theory!). The routine `linbcg` below indeed reduces to the ordinary conjugate gradient method if you input a symmetric \mathbf{A} , but it does all the redundant computations.

Another variant of the general algorithm corresponds to a symmetric but non-positive definite \mathbf{A} , with the choice $\bar{\mathbf{r}}_1 = \mathbf{A} \cdot \mathbf{r}_1$ instead of $\bar{\mathbf{r}}_1 = \mathbf{r}_1$. In this case $\bar{\mathbf{r}}_k = \mathbf{A} \cdot \mathbf{r}_k$ and $\bar{\mathbf{p}}_k = \mathbf{A} \cdot \mathbf{p}_k$ for all k . This algorithm is thus equivalent to the ordinary conjugate gradient algorithm, but with all dot products $\mathbf{a} \cdot \mathbf{b}$ replaced by $\mathbf{a} \cdot \mathbf{A} \cdot \mathbf{b}$. It is called the *minimum residual* algorithm, because it corresponds to successive minimizations of the function

$$\Phi(\mathbf{x}) = \frac{1}{2} \mathbf{r} \cdot \mathbf{r} = \frac{1}{2} |\mathbf{A} \cdot \mathbf{x} - \mathbf{b}|^2 \quad (2.7.38)$$

where the successive iterates \mathbf{x}_k minimize Φ over the same set of search directions \mathbf{p}_k generated in the conjugate gradient method. This algorithm has been generalized in various ways for unsymmetric matrices. The *generalized minimum residual* method (GMRES; see [9,15]) is probably the most robust of these methods.

Note that equation (2.7.38) gives

$$\nabla \Phi(\mathbf{x}) = \mathbf{A}^T \cdot (\mathbf{A} \cdot \mathbf{x} - \mathbf{b}) \quad (2.7.39)$$

For any nonsingular matrix \mathbf{A} , $\mathbf{A}^T \cdot \mathbf{A}$ is symmetric and positive definite. You might therefore be tempted to solve equation (2.7.29) by applying the ordinary conjugate gradient algorithm to the problem

$$(\mathbf{A}^T \cdot \mathbf{A}) \cdot \mathbf{x} = \mathbf{A}^T \cdot \mathbf{b} \quad (2.7.40)$$

Don't! The condition number of the matrix $\mathbf{A}^T \cdot \mathbf{A}$ is the square of the condition number of \mathbf{A} (see §2.6 for definition of condition number). A large condition number both increases the number of iterations required, and limits the accuracy to which a solution can be obtained. It is almost always better to apply the biconjugate gradient method to the original matrix \mathbf{A} .

So far we have said nothing about the *rate* of convergence of these methods. The ordinary conjugate gradient method works well for matrices that are well-conditioned, i.e., "close" to the identity matrix. This suggests applying these methods to the *preconditioned* form of equation (2.7.29),

$$(\tilde{\mathbf{A}}^{-1} \cdot \mathbf{A}) \cdot \mathbf{x} = \tilde{\mathbf{A}}^{-1} \cdot \mathbf{b} \quad (2.7.41)$$

The idea is that you might already be able to solve your linear system easily for some $\tilde{\mathbf{A}}$ close to \mathbf{A} , in which case $\tilde{\mathbf{A}}^{-1} \cdot \mathbf{A} \approx \mathbf{I}$, allowing the algorithm to converge in fewer steps. The

matrix $\tilde{\mathbf{A}}$ is called a *preconditioner* [11], and the overall scheme given here is known as the *preconditioned biconjugate gradient method* or *PBCG*.

For efficient implementation, the PBCG algorithm introduces an additional set of vectors \mathbf{z}_k and $\bar{\mathbf{z}}_k$ defined by

$$\tilde{\mathbf{A}} \cdot \mathbf{z}_k = \mathbf{r}_k \quad \text{and} \quad \tilde{\mathbf{A}}^T \cdot \bar{\mathbf{z}}_k = \bar{\mathbf{r}}_k \quad (2.7.42)$$

and modifies the definitions of α_k , β_k , \mathbf{p}_k , and $\bar{\mathbf{p}}_k$ in equation (2.7.32):

$$\begin{aligned} \alpha_k &= \frac{\bar{\mathbf{r}}_k \cdot \mathbf{z}_k}{\bar{\mathbf{p}}_k \cdot \mathbf{A} \cdot \mathbf{p}_k} \\ \beta_k &= \frac{\bar{\mathbf{r}}_{k+1} \cdot \mathbf{z}_{k+1}}{\bar{\mathbf{r}}_k \cdot \mathbf{z}_k} \\ \mathbf{p}_{k+1} &= \mathbf{z}_{k+1} + \beta_k \mathbf{p}_k \\ \bar{\mathbf{p}}_{k+1} &= \bar{\mathbf{z}}_{k+1} + \beta_k \bar{\mathbf{p}}_k \end{aligned} \quad (2.7.43)$$

For `linbcg`, below, we will ask you to supply routines that solve the auxiliary linear systems (2.7.42). If you have no idea what to use for the preconditioner $\tilde{\mathbf{A}}$, then use the diagonal part of \mathbf{A} , or even the identity matrix, in which case the burden of convergence will be entirely on the biconjugate gradient method itself.

The routine `linbcg`, below, is based on a program originally written by Anne Greenbaum. (See [13] for a different, less sophisticated, implementation.) There are a few wrinkles you should know about.

What constitutes “good” convergence is rather application dependent. The routine `linbcg` therefore provides for four possibilities, selected by setting the flag `itol` on input. If `itol=1`, iteration stops when the quantity $|\mathbf{A} \cdot \mathbf{x} - \mathbf{b}| / |\mathbf{b}|$ is less than the input quantity `tol`. If `itol=2`, the required criterion is

$$|\tilde{\mathbf{A}}^{-1} \cdot (\mathbf{A} \cdot \mathbf{x} - \mathbf{b})| / |\tilde{\mathbf{A}}^{-1} \cdot \mathbf{b}| < \text{tol} \quad (2.7.44)$$

If `itol=3`, the routine uses its own estimate of the error in \mathbf{x} , and requires its magnitude, divided by the magnitude of \mathbf{x} , to be less than `tol`. The setting `itol=4` is the same as `itol=3`, except that the largest (in absolute value) component of the error and largest component of \mathbf{x} are used instead of the vector magnitude (that is, the L_∞ norm instead of the L_2 norm). You may need to experiment to find which of these convergence criteria is best for your problem.

On output, `err` is the tolerance actually achieved. If the returned count `iter` does not indicate that the maximum number of allowed iterations `itmax` was exceeded, then `err` should be less than `tol`. If you want to do further iterations, leave all returned quantities as they are and call the routine again. The routine loses its memory of the spanned conjugate gradient subspace between calls, however, so you should not force it to return more often than about every N iterations.

Finally, note that `linbcg` is furnished in double precision, since it will be usually be used when N is quite large.

```
SUBROUTINE linbcg(n,b,x,itol,tol,itmax,iter,err)
INTEGER iter,itmax,itol,n,NMAX
DOUBLE PRECISION err,tol,b(*),x(*),EPS      Double precision is a good idea in this rou-
PARAMETER (NMAX=1024,EPS=1.d-14)              tine.
C USES atimes,asolve,snrm
      Solves  $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$  for  $\mathbf{x}(1:n)$ , given  $\mathbf{b}(1:n)$ , by the iterative biconjugate gradient method.
      On input  $\mathbf{x}(1:n)$  should be set to an initial guess of the solution (or all zeros); itol is
      1,2,3, or 4, specifying which convergence test is applied (see text); itmax is the maximum
      number of allowed iterations; and tol is the desired convergence tolerance. On output,
       $\mathbf{x}(1:n)$  is reset to the improved solution, iter is the number of iterations actually taken,
      and err is the estimated error. The matrix  $\mathbf{A}$  is referenced only through the user-supplied
      routines atimes, which computes the product of either  $\mathbf{A}$  or its transpose on a vector; and
      asolve, which solves  $\tilde{\mathbf{A}} \cdot \mathbf{x} = \mathbf{b}$  or  $\tilde{\mathbf{A}}^T \cdot \mathbf{x} = \mathbf{b}$  for some preconditioner matrix  $\tilde{\mathbf{A}}$  (possibly
      the trivial diagonal part of  $\mathbf{A}$ ).

else
    err=nr/bnrm
    goto 100
endif
endif
write (*,*) ' iter=' ,iter, ' err=' ,err
if(err.gt.tol) goto 100
endif
return
END

```

The routine linbcg uses this short utility for computing vector norms:

```

FUNCTION snrm(n,sx,itol)
INTEGER n,itol,i,isamax
DOUBLE PRECISION sx(n),snrm
Compute one of two norms for a vector sx(1:n), as signaled by itol. Used by linbcg.
if (itol.le.3)then
    snrm=0.
    do 11 i=1,n
        snrm=snrm+sx(i)**2
    enddo 11
    snrm=sqrt(snrm)
else
    isamax=1
    do 12 i=1,n
        if(abs(sx(i)).gt.abs(sx(isamax))) isamax=i
    enddo 12
    snrm=abs(sx(isamax))
endif
return
END

```

So that the specifications for the routines atimes and asolve are clear, we list here simple versions that assume a matrix A stored somewhere in row-index sparse format.

```

SUBROUTINE atimes(n,x,r,itrnsp)
INTEGER n,itrnsp,ija,NMAX
DOUBLE PRECISION x(n),r(n),sa
PARAMETER (NMAX=1000)
COMMON /mat/ sa(NMAX),ija(NMAX)
C USES dsprax,dsprstx
if (itrnsp.eq.0) then
    call dsprax(sa,ija,x,r,n)
else
    call dsprstx(sa,ija,x,r,n)
endif
return
END

```

The matrix is stored somewhere.
DOUBLE PRECISION versions of sprsax and sprstx.

```

SUBROUTINE asolve(n,b,x,itrnsp)
INTEGER n,itrnsp,ija,NMAX,i
DOUBLE PRECISION x(n),b(n),sa
PARAMETER (NMAX=1000)
COMMON /mat/ sa(NMAX),ija(NMAX)           The matrix is stored somewhere.
do :: i=1,n
    x(i)=b(i)/sa(i)
enddo :: i
return
END

```

The matrix \tilde{A} is the diagonal part of A , stored in the first n elements of sa . Since the transpose matrix has the same diagonal, the flag $itrnsp$ is not used.

2.8 Vandermonde Matrices and Toeplitz Matrices

In §2.4 the case of a tridiagonal matrix was treated specially, because that particular type of linear system admits a solution in only of order N operations, rather than of order N^3 for the general linear problem. When such particular types

exist, it is important to know about them. Your computational savings, should you ever happen to be working on a problem that involves the right kind of particular type, can be enormous.

This section treats two special types of matrices that can be solved in of order N^2 operations, not as good as tridiagonal, but a lot better than the general case. (Other than the operations count, these two types having nothing in common.) Matrices of the first type, termed *Vandermonde matrices*, occur in some problems having to do with the fitting of polynomials, the reconstruction of distributions from their moments, and also other contexts. In this book, for example, a Vandermonde problem crops up in §3.5. Matrices of the second type, termed *Toeplitz matrices*, tend to occur in problems involving deconvolution and signal processing. In this book, a Toeplitz problem is encountered in §13.7.

These are not the *only* special types of matrices worth knowing about. The *Hilbert matrices*, whose components are of the form $a_{ij} = 1/(i + j - 1)$, $i, j = 1, \dots, N$ can be inverted by an exact integer algorithm, and are very *difficult* to invert in any other way, since they are notoriously ill-conditioned (see [1] for details). The Sherman-Morrison and Woodbury formulas, discussed in §2.7, can sometimes be used to convert new special forms into old ones. Reference [2] gives some other special forms. We have not found these additional forms to arise as frequently as the two that we now discuss.

Vandermonde Matrices

A Vandermonde matrix of size $N \times N$ is completely determined by N arbitrary numbers x_1, x_2, \dots, x_N , in terms of which its N^2 components are the integer powers x_i^{j-1} , $i, j = 1, \dots, N$. Evidently there are two possible such forms, depending on whether we view the i 's as rows, j 's as columns, or vice versa. In the former case, we get a linear system of equations that looks like this,

$$\begin{bmatrix} 1 & x_1 & x_1^2 & \cdots & x_1^{N-1} \\ 1 & x_2 & x_2^2 & \cdots & x_2^{N-1} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_N & x_N^2 & \cdots & x_N^{N-1} \end{bmatrix} \cdot \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_N \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_N \end{bmatrix} \quad (2.8.1)$$

Performing the matrix multiplication, you will see that this equation solves for the unknown coefficients c_i which fit a polynomial to the N pairs of abscissas and ordinates (x_j, y_j) . Precisely this problem will arise in §3.5, and the routine given there will solve (2.8.1) by the method that we are about to describe.

The alternative identification of rows and columns leads to the set of equations

$$\begin{bmatrix} 1 & 1 & \cdots & 1 \\ x_1 & x_2 & \cdots & x_N \\ x_1^2 & x_2^2 & \cdots & x_N^2 \\ x_1^{N-1} & x_2^{N-1} & \cdots & x_N^{N-1} \end{bmatrix} \cdot \begin{bmatrix} w_1 \\ w_2 \\ w_3 \\ \vdots \\ w_N \end{bmatrix} = \begin{bmatrix} q_1 \\ q_2 \\ q_3 \\ \vdots \\ q_N \end{bmatrix} \quad (2.8.2)$$

Write this out and you will see that it relates to the *problem of moments*: Given the values of N points x_i , find the unknown weights w_i , assigned so as to match the given values q_j of the first N moments. (For more on this problem, consult [3].) The routine given in this section solves (2.8.2).

The method of solution of both (2.8.1) and (2.8.2) is closely related to Lagrange's polynomial interpolation formula, which we will not formally meet until §3.1 below. Notwithstanding, the following derivation should be comprehensible:

Let $P_j(x)$ be the polynomial of degree $N - 1$ defined by

$$P_j(x) = \prod_{\substack{n=1 \\ (n \neq j)}}^N \frac{x - x_n}{x_j - x_n} = \sum_{k=1}^N A_{jk} x^{k-1} \quad (2.8.3)$$

Here the meaning of the last equality is to define the components of the matrix A_{ij} as the coefficients that arise when the product is multiplied out and like terms collected.

The polynomial $P_j(x)$ is a function of x generally. But you will notice that it is specifically designed so that it takes on a value of zero at all x_i with $i \neq j$, and has a value of unity at $x = x_j$. In other words,

$$P_j(x_i) = \delta_{ij} = \sum_{k=1}^N A_{jk} x_i^{k-1} \quad (2.8.4)$$

But (2.8.4) says that A_{jk} is exactly the inverse of the matrix of components x_i^{k-1} , which appears in (2.8.2), with the subscript as the column index. Therefore the solution of (2.8.2) is just that matrix inverse times the right-hand side,

$$w_j = \sum_{k=1}^N A_{jk} q_k \quad (2.8.5)$$

As for the transpose problem (2.8.1), we can use the fact that the inverse of the transpose is the transpose of the inverse, so

$$c_j = \sum_{k=1}^N A_{kj} y_k \quad (2.8.6)$$

The routine in §3.5 implements this.

It remains to find a good way of multiplying out the monomial terms in (2.8.3), in order to get the components of A_{jk} . This is essentially a bookkeeping problem, and we will let you read the routine itself to see how it can be solved. One trick is to define a master $P(x)$ by

$$P(x) \equiv \prod_{n=1}^N (x - x_n) \quad (2.8.7)$$

work out its coefficients, and then obtain the numerators and denominators of the specific P_j 's via synthetic division by the one supernumerary term. (See §5.3 for more on synthetic division.) Since each such division is only a process of order N , the total procedure is of order N^2 .

You should be warned that Vandermonde systems are notoriously ill-conditioned, by their very nature. (As an aside anticipating §5.8, the reason is the same as that which makes Chebyshev fitting so impressively accurate: there exist high-order polynomials that are very good uniform fits to zero. Hence roundoff error can introduce rather substantial coefficients of the leading terms of these polynomials.) It is a good idea always to compute Vandermonde problems in double precision.

The routine for (2.8.2) which follows is due to G.B. Rybicki.

```
SUBROUTINE vander(x,w,q,n)
INTEGER n,NMAX
DOUBLE PRECISION q(n),w(n),x(n)
PARAMETER (NMAX=100)
Solves the Vandermonde linear system  $\sum_{i=1}^N x_i^{k-1} w_i = q_k$  ( $k = 1, \dots, N$ ). Input consists
of the vectors x(1:n) and q(1:n); the vector w(1:n) is output.
```

```

Parameters: NMAX is the maximum expected value of n.
INTEGER i,j,k
DOUBLE PRECISION b,s,t,xx,c(NMAX)
if(n.eq.1)then
  w(1)=q(1)
else
  do 11 i=1,n           Initialize array.
    c(i)=0.d0
  enddo 11
  c(n)=-x(1)           Coefficients of the master polynomial are found by recur-
  do 13 i=2,n           sion.
    xx=-x(i)
    do 12 j=n+1-i,n-1
      c(j)=c(j)+xx*c(j+1)
    enddo 12
    c(n)=c(n)+xx
  enddo 13
  do 15 i=1,n           Each subfactor in turn
    xx=x(i)
    t=1.d0
    b=1.d0
    s=q(n)
    do 14 k=n,2,-1       is synthetically divided,
      b=c(k)+xx*b
      s=s+q(k-1)*b
      t=xx*t+b
    enddo 14
    w(i)=s/t             matrix-multiplied by the right-hand side,
    and supplied with a denominator.
  enddo 15
endif
return
END

```

Toeplitz Matrices

An $N \times N$ Toeplitz matrix is specified by giving $2N - 1$ numbers R_k , $k = -N + 1, \dots, -1, 0, 1, \dots, N - 1$. Those numbers are then emplaced as matrix elements constant along the (upper-left to lower-right) diagonals of the matrix:

$$\begin{bmatrix} R_0 & R_{-1} & R_{-2} & \cdots & R_{-(N-2)} & R_{-(N-1)} \\ R_1 & R_0 & R_{-1} & \cdots & R_{-(N-3)} & R_{-(N-2)} \\ R_2 & R_1 & R_0 & \cdots & R_{-(N-4)} & R_{-(N-3)} \\ \vdots & & & \ddots & & \\ R_{N-2} & R_{N-3} & R_{N-4} & \cdots & R_0 & R_{-1} \\ R_{N-1} & R_{N-2} & R_{N-3} & \cdots & R_1 & R_0 \end{bmatrix} \quad (2.8.8)$$

The linear Toeplitz problem can thus be written as

$$\sum_{j=1}^N R_{i-j} x_j = y_i \quad (i = 1, \dots, N) \quad (2.8.9)$$

where the x_j 's, $j = 1, \dots, N$, are the unknowns to be solved for.

The Toeplitz matrix is symmetric if $R_k = R_{-k}$ for all k . Levinson [4] developed an algorithm for fast solution of the symmetric Toeplitz problem, by a *bordering method*, that is, a recursive procedure that solves the M -dimensional Toeplitz problem

$$\sum_{j=1}^M R_{i-j} x_j^{(M)} = y_i \quad (i = 1, \dots, M) \quad (2.8.10)$$

in turn for $M = 1, 2, \dots$ until $M = N$, the desired result, is finally reached. The vector $x_j^{(M)}$ is the result at the M th stage, and becomes the desired answer only when N is reached.

Levinson's method is well documented in standard texts (e.g., [5]). The useful fact that the method generalizes to the *nonsymmetric* case seems to be less well known. At some risk of excessive detail, we therefore give a derivation here, due to G.B. Rybicki.

In following a recursion from step M to step $M + 1$ we find that our developing solution $x^{(M)}$ changes in this way:

$$\sum_{j=1}^M R_{i-j} x_j^{(M)} = y_i \quad i = 1, \dots, M \quad (2.8.11)$$

becomes

$$\sum_{j=1}^M R_{i-j} x_j^{(M+1)} + R_{i-(M+1)} x_{M+1}^{(M+1)} = y_i \quad i = 1, \dots, M + 1 \quad (2.8.12)$$

By eliminating y_i we find

$$\sum_{j=1}^M R_{i-j} \left(\frac{x_j^{(M)} - x_j^{(M+1)}}{x_{M+1}^{(M+1)}} \right) = R_{i-(M+1)} \quad i = 1, \dots, M \quad (2.8.13)$$

or by letting $i \rightarrow M + 1 - i$ and $j \rightarrow M + 1 - j$,

$$\sum_{j=1}^M R_{j-i} G_j^{(M)} = R_{-i} \quad (2.8.14)$$

where

$$G_j^{(M)} \equiv \frac{x_{M+1-j}^{(M)} - x_{M+1-j}^{(M+1)}}{x_{M+1}^{(M+1)}} \quad (2.8.15)$$

To put this another way,

$$x_{M+1-j}^{(M+1)} = x_{M+1-j}^{(M)} - x_{M+1}^{(M+1)} G_j^{(M)} \quad j = 1, \dots, M \quad (2.8.16)$$

Thus, if we can use recursion to find the order M quantities $x^{(M)}$ and $G^{(M)}$ and the single order $M + 1$ quantity $x_{M+1}^{(M+1)}$, then all of the other $x_j^{(M+1)}$ will follow. Fortunately, the quantity $x_{M+1}^{(M+1)}$ follows from equation (2.8.12) with $i = M + 1$,

$$\sum_{j=1}^M R_{M+1-j} x_j^{(M+1)} + R_0 x_{M+1}^{(M+1)} = y_{M+1} \quad (2.8.17)$$

For the unknown order $M + 1$ quantities $x_j^{(M+1)}$ we can substitute the previous order quantities in G since

$$G_{M+1-j}^{(M)} = \frac{x_j^{(M)} - x_j^{(M+1)}}{x_{M+1}^{(M+1)}} \quad (2.8.18)$$

The result of this operation is

$$x_{M+1}^{(M+1)} = \frac{\sum_{j=1}^M R_{M+1-j} x_j^{(M)} - y_{M+1}}{\sum_{j=1}^M R_{M+1-j} G_{M+1-j}^{(M)} - R_0} \quad (2.8.19)$$

The only remaining problem is to develop a recursion relation for G . Before we do that, however, we should point out that there are actually two distinct sets of solutions to the original linear problem for a nonsymmetric matrix, namely right-hand solutions (which we

have been discussing) and left-hand solutions z_i . The formalism for the left-hand solutions differs only in that we deal with the equations

$$\sum_{j=1}^M R_{j-i} z_j^{(M)} = y_i \quad i = 1, \dots, M \quad (2.8.20)$$

Then, the same sequence of operations on this set leads to

$$\sum_{j=1}^M R_{i-j} H_j^{(M)} = R_i \quad (2.8.21)$$

where

$$H_j^{(M)} \equiv \frac{z_{M+1-j}^{(M)} - z_{M+1-j}^{(M+1)}}{z_{M+1}^{(M+1)}} \quad (2.8.22)$$

(compare with 2.8.14 – 2.8.15). The reason for mentioning the left-hand solutions now is that, by equation (2.8.21), the H_j satisfy exactly the same equation as the x_j except for the substitution $y_i \rightarrow R_i$ on the right-hand side. Therefore we can quickly deduce from equation (2.8.19) that

$$H_{M+1}^{(M+1)} = \frac{\sum_{j=1}^M R_{M+1-j} H_j^{(M)} - R_{M+1}}{\sum_{j=1}^M R_{M+1-j} G_{M+1-j}^{(M)} - R_0} \quad (2.8.23)$$

By the same token, G satisfies the same equation as z , except for the substitution $y_i \rightarrow R_{-i}$. This gives

$$G_{M+1}^{(M+1)} = \frac{\sum_{j=1}^M R_{j-M-1} G_j^{(M)} - R_{-M-1}}{\sum_{j=1}^M R_{j-M-1} H_{M+1-j}^{(M)} - R_0} \quad (2.8.24)$$

The same “morphism” also turns equation (2.8.16), and its partner for z , into the final equations

$$\begin{aligned} G_j^{(M+1)} &= G_j^{(M)} - G_{M+1}^{(M+1)} H_{M+1-j}^{(M)} \\ H_j^{(M+1)} &= H_j^{(M)} - H_{M+1}^{(M+1)} G_{M+1-j}^{(M)} \end{aligned} \quad (2.8.25)$$

Now, starting with the initial values

$$x_1^{(1)} = y_1/R_0 \quad G_1^{(1)} = R_{-1}/R_0 \quad H_1^{(1)} = R_1/R_0 \quad (2.8.26)$$

we can recurse away. At each stage M we use equations (2.8.23) and (2.8.24) to find $H_{M+1}^{(M+1)}$, $G_{M+1}^{(M+1)}$, and then equation (2.8.25) to find the other components of $H^{(M+1)}$, $G^{(M+1)}$. From there the vectors $x^{(M+1)}$ and/or $z^{(M+1)}$ are easily calculated.

The program below does this. It incorporates the second equation in (2.8.25) in the form

$$H_{M+1-j}^{(M+1)} = H_{M+1-j}^{(M)} - H_{M+1}^{(M+1)} G_j^{(M)} \quad (2.8.27)$$

so that the computation can be done “in place.”

Notice that the above algorithm fails if $R_0 = 0$. In fact, because the bordering method does not allow pivoting, the algorithm will fail if any of the diagonal principal minors of the original Toeplitz matrix vanish. (Compare with discussion of the tridiagonal algorithm in §2.4.) If the algorithm fails, your matrix is not necessarily singular — you might just have to solve your problem by a slower and more general algorithm such as *LU* decomposition with pivoting.

The routine that implements equations (2.8.23)–(2.8.27) is also due to Rybicki. Note that the routine’s $r(n+j)$ is equal to R_j above, so that subscripts on the r array vary from 1 to $2N - 1$.

```

SUBROUTINE toeplz(r,x,y,n)

If you are in the business of solving *very* large Toeplitz systems, you should find out about so-called “new, fast” algorithms, which require only on the order of $N(\log N)^2$ operations,

compared to N^2 for Levinson's method. These methods are too complicated to include here. Papers by Bunch [6] and de Hoog [7] will give entry to the literature.

2.9 Cholesky Decomposition

If a square matrix \mathbf{A} happens to be symmetric and positive definite, then it has a special, more efficient, triangular decomposition. *Symmetric* means that $a_{ij} = a_{ji}$ for $i, j = 1, \dots, N$, while *positive definite* means that

$$\mathbf{v} \cdot \mathbf{A} \cdot \mathbf{v} > 0 \quad \text{for all vectors } \mathbf{v} \quad (2.9.1)$$

(In Chapter 11 we will see that positive definite has the equivalent interpretation that \mathbf{A} has all positive eigenvalues.) While symmetric, positive definite matrices are rather special, they occur quite frequently in some applications, so their special factorization, called *Cholesky decomposition*, is good to know about. When you can use it, Cholesky decomposition is about a factor of two faster than alternative methods for solving linear equations.

Instead of seeking arbitrary lower and upper triangular factors \mathbf{L} and \mathbf{U} , Cholesky decomposition constructs a lower triangular matrix \mathbf{L} whose transpose \mathbf{L}^T can itself serve as the upper triangular part. In other words we replace equation (2.3.1) by

$$\mathbf{L} \cdot \mathbf{L}^T = \mathbf{A} \quad (2.9.2)$$

This factorization is sometimes referred to as “taking the square root” of the matrix \mathbf{A} . The components of \mathbf{L}^T are of course related to those of \mathbf{L} by

$$L_{ij}^T = L_{ji} \quad (2.9.3)$$

Writing out equation (2.9.2) in components, one readily obtains the analogs of equations (2.3.12)–(2.3.13),

$$L_{ii} = \left(a_{ii} - \sum_{k=1}^{i-1} L_{ik}^2 \right)^{1/2} \quad (2.9.4)$$

and

$$L_{ji} = \frac{1}{L_{ii}} \left(a_{ij} - \sum_{k=1}^{i-1} L_{ik} L_{jk} \right) \quad j = i+1, i+2, \dots, N \quad (2.9.5)$$

compared to N^2 for Levinson's method. These methods are too complicated to include here. Papers by Bunch [6] and de Hoog [7] will give entry to the literature.

2.9 Cholesky Decomposition

If a square matrix \mathbf{A} happens to be symmetric and positive definite, then it has a special, more efficient, triangular decomposition. *Symmetric* means that $a_{ij} = a_{ji}$ for $i, j = 1, \dots, N$, while *positive definite* means that

$$\mathbf{v} \cdot \mathbf{A} \cdot \mathbf{v} > 0 \quad \text{for all vectors } \mathbf{v} \quad (2.9.1)$$

(In Chapter 11 we will see that positive definite has the equivalent interpretation that \mathbf{A} has all positive eigenvalues.) While symmetric, positive definite matrices are rather special, they occur quite frequently in some applications, so their special factorization, called *Cholesky decomposition*, is good to know about. When you can use it, Cholesky decomposition is about a factor of two faster than alternative methods for solving linear equations.

Instead of seeking arbitrary lower and upper triangular factors \mathbf{L} and \mathbf{U} , Cholesky decomposition constructs a lower triangular matrix \mathbf{L} whose transpose \mathbf{L}^T can itself serve as the upper triangular part. In other words we replace equation (2.3.1) by

$$\mathbf{L} \cdot \mathbf{L}^T = \mathbf{A} \quad (2.9.2)$$

This factorization is sometimes referred to as “taking the square root” of the matrix \mathbf{A} . The components of \mathbf{L}^T are of course related to those of \mathbf{L} by

$$L_{ij}^T = L_{ji} \quad (2.9.3)$$

Writing out equation (2.9.2) in components, one readily obtains the analogs of equations (2.3.12)–(2.3.13),

$$L_{ii} = \left(a_{ii} - \sum_{k=1}^{i-1} L_{ik}^2 \right)^{1/2} \quad (2.9.4)$$

and

$$L_{ji} = \frac{1}{L_{ii}} \left(a_{ij} - \sum_{k=1}^{i-1} L_{ik} L_{jk} \right) \quad j = i+1, i+2, \dots, N \quad (2.9.5)$$

If you apply equations (2.9.4) and (2.9.5) in the order $i = 1, 2, \dots, N$, you will see that the L 's that occur on the right-hand side are already determined by the time they are needed. Also, only components a_{ij} with $j \geq i$ are referenced. (Since \mathbf{A} is symmetric, these have complete information.) It is convenient, then, to have the factor \mathbf{L} overwrite the subdiagonal (lower triangular but not including the diagonal) part of \mathbf{A} , preserving the input upper triangular values of \mathbf{A} . Only one extra vector of length N is needed to store the diagonal part of \mathbf{L} . The operations count is $N^3/6$ executions of the inner loop (consisting of one multiply and one subtract), with also N square roots. As already mentioned, this is about a factor 2 better than LU decomposition of \mathbf{A} (where its symmetry would be ignored).

A straightforward implementation is

```
SUBROUTINE choldc(a,n,np,p)
INTEGER n,np
REAL a(np,np),p(n)
      Given a positive-definite symmetric matrix a(1:n,1:n), with physical dimension np, this
      routine constructs its Cholesky decomposition,  $\mathbf{A} = \mathbf{L} \cdot \mathbf{L}^T$ . On input, only the upper triangle
      of a need be given; it is not modified. The Cholesky factor  $\mathbf{L}$  is returned in the lower triangle
      of a, except for its diagonal elements which are returned in p(1:n).
INTEGER i,j,k
REAL sum
do 13 i=1,n
  do 12 j=i,n
    sum=a(i,j)
    do 11 k=i-1,1,-1
      sum=sum-a(i,k)*a(j,k)
    enddo 11
    if(i.eq.j)then
      if(sum.le.0.)pause 'choldc failed'          a, with rounding errors, is not
      p(i)=sqrt(sum)                                positive definite.
    else
      a(j,i)=sum/p(i)
    endif
  enddo 12
enddo 13
return
END
```

You might at this point wonder about pivoting. The pleasant answer is that Cholesky decomposition is extremely stable numerically, without any pivoting at all. Failure of `choldc` simply indicates that the matrix \mathbf{A} (or, with roundoff error, another very nearby matrix) is not positive definite. In fact, `choldc` is an efficient way to test whether a symmetric matrix is positive definite. (In this application, you will want to replace the pause with some less drastic signaling method.)

Once your matrix is decomposed, the triangular factor can be used to solve a linear equation by backsubstitution. The straightforward implementation of this is

```
SUBROUTINE cholsl(a,n,np,p,b,x)
INTEGER n,np
REAL a(np,np),b(n),p(n),x(n)
      Solves the set of n linear equations  $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ , where a is a positive-definite symmetric
      matrix with physical dimension np. a and p are input as the output of the routine choldc.
      Only the lower triangle of a is accessed. b(1:n) is input as the right-hand side vector. The
      solution vector is returned in x(1:n). a, n, np, and p are not modified and can be left
      in place for successive calls with different right-hand sides b. b is not modified unless you
      identify b and x in the calling sequence, which is allowed.
INTEGER i,k
REAL sum
do 12 i=1,n                               Solve  $\mathbf{L} \cdot \mathbf{y} = \mathbf{b}$ , storing y in x.
  sum=b(i)
  do 11 k=i-1,1,-1
    sum=sum-a(i,k)*x(k)
```

```

    enddo 11
    x(i)=sum/p(i)
  enddo 12
do 14 i=n,1,-1           Solve  $\mathbf{L}^T \cdot \mathbf{x} = \mathbf{y}$ .
    sum=x(i)
    do 13 k=i+1,n
      sum=sum-a(k,i)*x(k)
    enddo 13
    x(i)=sum/p(i)
  enddo 14
  return
END

```

A typical use of `choldc` and `chols1` is in the inversion of covariance matrices describing the fit of data to a model; see, e.g., §15.6. In this, and many other applications, one often needs \mathbf{L}^{-1} . The lower triangle of this matrix can be efficiently found from the output of `choldc`:

```

do 13 i=1,n
  a(i,i)=1./p(i)
  do 12 j=i+1,n
    sum=0.
    do 11 k=i,j-1
      sum=sum-a(j,k)*a(k,i)
    enddo 11
    a(j,i)=sum/p(j)
  enddo 12
enddo 13

```

2.10 QR Decomposition

There is another matrix factorization that is sometimes very useful, the so-called *QR decomposition*,

$$\mathbf{A} = \mathbf{Q} \cdot \mathbf{R} \quad (2.10.1)$$

Here \mathbf{R} is upper triangular, while \mathbf{Q} is orthogonal, that is,

$$\mathbf{Q}^T \cdot \mathbf{Q} = \mathbf{I} \quad (2.10.2)$$

where \mathbf{Q}^T is the transpose matrix of \mathbf{Q} . Although the decomposition exists for a general rectangular matrix, we shall restrict our treatment to the case when all the matrices are square, with dimensions $N \times N$.

```

    enddo 11
    x(i)=sum/p(i)
  enddo 12
do 14 i=n,1,-1           Solve  $\mathbf{L}^T \cdot \mathbf{x} = \mathbf{y}$ .
    sum=x(i)
    do 13 k=i+1,n
      sum=sum-a(k,i)*x(k)
    enddo 13
    x(i)=sum/p(i)
  enddo 14
  return
END

```

A typical use of `choldc` and `chols1` is in the inversion of covariance matrices describing the fit of data to a model; see, e.g., §15.6. In this, and many other applications, one often needs \mathbf{L}^{-1} . The lower triangle of this matrix can be efficiently found from the output of `choldc`:

```

do 13 i=1,n
  a(i,i)=1./p(i)
  do 12 j=i+1,n
    sum=0.
    do 11 k=i,j-1
      sum=sum-a(j,k)*a(k,i)
    enddo 11
    a(j,i)=sum/p(j)
  enddo 12
enddo 13

```

2.10 QR Decomposition

There is another matrix factorization that is sometimes very useful, the so-called *QR decomposition*,

$$\mathbf{A} = \mathbf{Q} \cdot \mathbf{R} \quad (2.10.1)$$

Here \mathbf{R} is upper triangular, while \mathbf{Q} is orthogonal, that is,

$$\mathbf{Q}^T \cdot \mathbf{Q} = \mathbf{I} \quad (2.10.2)$$

where \mathbf{Q}^T is the transpose matrix of \mathbf{Q} . Although the decomposition exists for a general rectangular matrix, we shall restrict our treatment to the case when all the matrices are square, with dimensions $N \times N$.

Like the other matrix factorizations we have met (LU , SVD, Cholesky), QR decomposition can be used to solve systems of linear equations. To solve

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (2.10.3)$$

first form $\mathbf{Q}^T \cdot \mathbf{b}$ and then solve

$$\mathbf{R} \cdot \mathbf{x} = \mathbf{Q}^T \cdot \mathbf{b} \quad (2.10.4)$$

by backsubstitution. Since QR decomposition involves about twice as many operations as LU decomposition, it is not used for typical systems of linear equations. However, we will meet special cases where QR is the method of choice.

The standard algorithm for the QR decomposition involves successive Householder transformations (to be discussed later in §11.2). We write a Householder matrix in the form $\mathbf{1} - \mathbf{u} \otimes \mathbf{u}/c$ where $c = \frac{1}{2}\mathbf{u} \cdot \mathbf{u}$. An appropriate Householder matrix applied to a given matrix can zero all elements in a column of the matrix situated below a chosen element. Thus we arrange for the first Householder matrix \mathbf{Q}_1 to zero all elements in the first column of \mathbf{A} below the first element. Similarly \mathbf{Q}_2 zeroes all elements in the second column below the second element, and so on up to \mathbf{Q}_{n-1} . Thus

$$\mathbf{R} = \mathbf{Q}_{n-1} \cdots \mathbf{Q}_1 \cdot \mathbf{A} \quad (2.10.5)$$

Since the Householder matrices are orthogonal,

$$\mathbf{Q} = (\mathbf{Q}_{n-1} \cdots \mathbf{Q}_1)^{-1} = \mathbf{Q}_1 \cdots \mathbf{Q}_{n-1} \quad (2.10.6)$$

In most applications we don't need to form \mathbf{Q} explicitly; we instead store it in the factored form (2.10.6). Pivoting is not usually necessary unless the matrix \mathbf{A} is very close to singular. A general QR algorithm for rectangular matrices including pivoting is given in [1]. For square matrices, an implementation is the following:

```
SUBROUTINE qrdfmp(a,n,np,c,d,sing)
INTEGER n,np
REAL a(np,np),c(n),d(n)
LOGICAL sing
Constructs the QR decomposition of a(1:n,1:n), with physical dimension np. The upper
triangular matrix R is returned in the upper triangle of a, except for the diagonal elements
of R which are returned in d(1:n). The orthogonal matrix Q is represented as a product of
n - 1 Householder matrices Q_1 ... Q_{n-1}, where Q_j = 1 - u_j ⊗ u_j/c_j. The i-th component
of u_j is zero for i = 1, ..., j - 1 while the nonzero components are returned in a(i,j) for
i = j, ..., n. sing returns as true if singularity is encountered during the decomposition,
but the decomposition is still completed in this case.
INTEGER i,j,k
REAL scale,sigma,sum,tau
sing=.false.
do 17 k=1,n-1
    scale=0.
    do 11 i=k,n
        scale=max(scale,abs(a(i,k)))
    enddo 11
    if(scale.eq.0.)then           Singular case.
        sing=.true.
        c(k)=0.
        d(k)=0.
    else                           Form Q_k and Q_k · A.
        do 12 i=k,n
            a(i,k)=a(i,k)/scale
        enddo 12
        sum=0.
        do 13 i=k,n
            sum=sum+a(i,k)**2
        enddo 13
        sigma=sign(sqrt(sum),a(k,k))
        a(k,k)=a(k,k)+sigma
    endif 17
```

```

c(k)=sigma*a(k,k)
d(k)=-scale*sigma
do 16 j=k+1,n
    sum=0.
    do 14 i=k,n
        sum=sum+a(i,k)*a(i,j)
    enddo 14
    tau=sum/c(k)
    do 15 i=k,n
        a(i,j)=a(i,j)-tau*a(i,k)
    enddo 15
enddo 16
endif
enddo 17
d(n)=a(n,n)
if(d(n).eq.0.)sing=.true.
return
END

```

The next routine, `qrsolv`, is used to solve linear systems. In many applications only the part (2.10.4) of the algorithm is needed, so we separate it off into its own routine `rsolv`.

```

SUBROUTINE qrsolv(a,n,np,c,d,b)
INTEGER n,np
REAL a(np,np),b(n),c(n),d(n)
C USES rsolv
      Solves the set of n linear equations  $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ , where  $\mathbf{a}$  is a matrix with physical dimension np.
       $\mathbf{a}$ ,  $\mathbf{c}$ , and  $\mathbf{d}$  are input as the output of the routine qrdcmp and are not modified.  $\mathbf{b}(1:n)$ 
      is input as the right-hand side vector, and is overwritten with the solution vector on output.
      INTEGER i,j
      REAL sum,tau
      do 13 j=1,n-1
          sum=0.
          do 11 i=j,n
              sum=sum+a(i,j)*b(i)
          enddo 11
          tau=sum/c(j)
          do 12 i=j,n
              b(i)=b(i)-tau*a(i,j)
          enddo 12
      enddo 13
      call rsolv(a,n,np,d,b)           Form  $\mathbf{Q}^T \cdot \mathbf{b}$ .
      return                                Solve  $\mathbf{R} \cdot \mathbf{x} = \mathbf{Q}^T \cdot \mathbf{b}$ .
      END

```

```

SUBROUTINE rsolv(a,n,np,d,b)
INTEGER n,np
REAL a(np,np),b(n),d(n)
      Solves the set of n linear equations  $\mathbf{R} \cdot \mathbf{x} = \mathbf{b}$ , where  $\mathbf{R}$  is an upper triangular matrix stored
      in  $\mathbf{a}$  and  $\mathbf{d}$ .  $\mathbf{a}$  and  $\mathbf{d}$  are input as the output of the routine qrdcmp and are not modified.
       $\mathbf{b}(1:n)$  is input as the right-hand side vector, and is overwritten with the solution vector
      on output.
      INTEGER i,j
      REAL sum
      b(n)=b(n)/d(n)
      do 12 i=n-1,1,-1
          sum=0.
          do 11 j=i+1,n
              sum=sum+a(i,j)*b(j)
          enddo 11

See [2] for details on how to use *QR* decomposition for constructing orthogonal bases, and for solving least-squares problems. (We prefer to use SVD, §2.6, for these purposes, because of its greater diagnostic capability in pathological cases.)

Updating a QR decomposition

Some numerical algorithms involve solving a succession of linear systems each of which differs only slightly from its predecessor. Instead of doing $O(N^3)$ operations each time to solve the equations from scratch, one can often update a matrix factorization in $O(N^2)$ operations and use the new factorization to solve the next set of linear equations. The LU decomposition is complicated to update because of pivoting. However, QR turns out to be quite simple for a very common kind of update,

$$\mathbf{A} \rightarrow \mathbf{A} + \mathbf{s} \otimes \mathbf{t} \quad (2.10.7)$$

(compare equation 2.7.1). In practice it is more convenient to work with the equivalent form

$$\mathbf{A} = \mathbf{Q} \cdot \mathbf{R} \quad \rightarrow \quad \mathbf{A}' = \mathbf{Q}' \cdot \mathbf{R}' = \mathbf{Q} \cdot (\mathbf{R} + \mathbf{u} \otimes \mathbf{v}) \quad (2.10.8)$$

One can go back and forth between equations (2.10.7) and (2.10.8) using the fact that \mathbf{Q} is orthogonal, giving

$$\mathbf{t} \equiv \mathbf{v} \quad \text{and either} \quad \mathbf{s} \equiv \mathbf{Q} \cdot \mathbf{u} \quad \text{or} \quad \mathbf{u} \equiv \mathbf{Q}^T \cdot \mathbf{s} \quad (2.10.9)$$

The algorithm [2] has two phases. In the first we apply $N - 1$ Jacobi rotations (§11.1) to reduce $\mathbf{R} + \mathbf{u} \otimes \mathbf{v}$ to upper Hessenberg form. Another $N - 1$ Jacobi rotations transform this upper Hessenberg matrix to the new upper triangular matrix \mathbf{R}' . The matrix \mathbf{Q}' is simply the product of \mathbf{Q} with the $2(N - 1)$ Jacobi rotations. In applications we usually want \mathbf{Q}'^T , and the algorithm can easily be rearranged to work with this matrix instead of with \mathbf{Q} .

```

SUBROUTINE qrupdtr(r,qt,n,np,u,v)
INTEGER n,np
REAL r(np,np),qt(np,np),u(np),v(np)
C USES rotate
      Given the QR decomposition of some  $n \times n$  matrix, calculates the QR decomposition of
      the matrix  $\mathbf{Q} \cdot (\mathbf{R} + \mathbf{u} \otimes \mathbf{v})$ . The matrices  $\mathbf{r}$  and  $\mathbf{qt}$  have physical dimension  $np$ . Note that
       $\mathbf{Q}^T$  is input and returned in  $\mathbf{qt}$ .
      INTEGER i,j,k
      do 11 k=n,1,-1
         if(u(k).ne.0.)goto 1
      enddo 11
      k=1
1     do 12 i=k-1,1,-1
         call rotate(r,qt,n,np,i,u(i),-u(i+1))
         if(u(i).eq.0.)then
            u(i)=abs(u(i+1))
         else if(abs(u(i)).gt.abs(u(i+1)))then
            u(i)=abs(u(i))*sqrt(1.+(u(i+1)/u(i))**2)
         else
            u(i)=abs(u(i+1))*sqrt(1.+(u(i)/u(i+1))**2)
         endif
      enddo 12
      do 13 j=1,n
         r(1,j)=r(1,j)+u(1)*v(j)
      enddo 13
      do 14 i=1,k-1
         call rotate(r,qt,n,np,i,r(i,i),-r(i+1,i))
      enddo 14
      Find largest k such that  $u(k) \neq 0$ .
      Transform  $\mathbf{R} + \mathbf{u} \otimes \mathbf{v}$  to upper Hessenberg.
      Transform upper Hessenberg matrix
      to upper triangular.

```

```

return
END

SUBROUTINE rotate(r,qt,n,np,i,a,b)

2.11 Is Matrix Inversion an N^3 Process?

We close this chapter with a little entertainment, a bit of algorithmic prestidigitation which probes more deeply into the subject of matrix inversion. We start with a seemingly simple question:

How many individual multiplications does it take to perform the matrix multiplication of two 2×2 matrices,

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \cdot \begin{pmatrix} b_{11} & b_{12} \\ b_{21} & b_{22} \end{pmatrix} = \begin{pmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{pmatrix} \quad (2.11.1)$$

Eight, right? Here they are written explicitly:

$$\begin{aligned} c_{11} &= a_{11} \times b_{11} + a_{12} \times b_{21} \\ c_{12} &= a_{11} \times b_{12} + a_{12} \times b_{22} \\ c_{21} &= a_{21} \times b_{11} + a_{22} \times b_{21} \\ c_{22} &= a_{21} \times b_{12} + a_{22} \times b_{22} \end{aligned} \quad (2.11.2)$$

Do you think that one can write formulas for the c 's that involve only *seven* multiplications? (Try it yourself, before reading on.)

Such a set of formulas was, in fact, discovered by Strassen [1]. The formulas are:

$$\begin{aligned} Q_1 &\equiv (a_{11} + a_{22}) \times (b_{11} + b_{22}) \\ Q_2 &\equiv (a_{21} + a_{22}) \times b_{11} \\ Q_3 &\equiv a_{11} \times (b_{12} - b_{22}) \\ Q_4 &\equiv a_{22} \times (-b_{11} + b_{21}) \\ Q_5 &\equiv (a_{11} + a_{12}) \times b_{22} \\ Q_6 &\equiv (-a_{11} + a_{21}) \times (b_{11} + b_{12}) \\ Q_7 &\equiv (a_{12} - a_{22}) \times (b_{21} + b_{22}) \end{aligned} \quad (2.11.3)$$

in terms of which

$$\begin{aligned} c_{11} &= Q_1 + Q_4 - Q_5 + Q_7 \\ c_{21} &= Q_2 + Q_4 \\ c_{12} &= Q_3 + Q_5 \\ c_{22} &= Q_1 + Q_3 - Q_2 + Q_6 \end{aligned} \quad (2.11.4)$$

What's the use of this? There is one fewer multiplication than in equation (2.11.2), but *many more* additions and subtractions. It is not clear that anything has been gained. But notice that in (2.11.3) the a 's and b 's are never commuted. Therefore (2.11.3) and (2.11.4) are valid when the a 's and b 's are themselves matrices. The problem of multiplying two very large matrices (of order $N = 2^m$ for some integer m) can now be broken down recursively by partitioning the matrices into quarters, sixteenths, etc. And note the key point: The savings is not just a factor "7/8"; it is that factor at *each* hierarchical level of the recursion. In total it reduces the process of matrix multiplication to order $N^{\log_2 7}$ instead of N^3 .

What about all the extra additions in (2.11.3)–(2.11.4)? Don’t they outweigh the advantage of the fewer multiplications? For large N , it turns out that there are six times as many additions as multiplications implied by (2.11.3)–(2.11.4). But, if N is very large, this constant factor is no match for the change in the *exponent* from N^3 to $N^{\log_2 7}$.

With this “fast” matrix multiplication, Strassen also obtained a surprising result for matrix inversion [1]. Suppose that the matrices

$$\begin{pmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{pmatrix} \quad \text{and} \quad \begin{pmatrix} c_{11} & c_{12} \\ c_{21} & c_{22} \end{pmatrix} \quad (2.11.5)$$

are inverses of each other. Then the c ’s can be obtained from the a ’s by the following operations (compare equations 2.7.22 and 2.7.25):

$$R_1 = \text{Inverse}(a_{11})$$

$$R_2 = a_{21} \times R_1$$

$$R_3 = R_1 \times a_{12}$$

$$R_4 = a_{21} \times R_3$$

$$R_5 = R_4 - a_{22}$$

$$R_6 = \text{Inverse}(R_5) \quad (2.11.6)$$

$$c_{12} = R_3 \times R_6$$

$$c_{21} = R_6 \times R_2$$

$$R_7 = R_3 \times c_{21}$$

$$c_{11} = R_1 - R_7$$

$$c_{22} = -R_6$$

In (2.11.6) the “inverse” operator occurs just twice. It is to be interpreted as the reciprocal if the a ’s and c ’s are scalars, but as matrix inversion if the a ’s and c ’s are themselves submatrices. Imagine doing the inversion of a very large matrix, of order $N = 2^m$, recursively by partitions in half. At each step, halving the order *doubles* the number of inverse operations. But this means that there are only N divisions in all! So divisions don’t dominate in the recursive use of (2.11.6). Equation (2.11.6) is dominated, in fact, by its 6 multiplications. Since these can be done by an $N^{\log_2 7}$ algorithm, so can the matrix inversion!

This is fun, but let’s look at practicalities: If you estimate how large N has to be before the difference between exponent 3 and exponent $\log_2 7 = 2.807$ is substantial enough to outweigh the bookkeeping overhead, arising from the complicated nature of the recursive Strassen algorithm, you will find that *LU* decomposition is in no immediate danger of becoming obsolete.

If, on the other hand, you like this kind of fun, then try these: (1) Can you multiply the complex numbers $(a+ib)$ and $(c+id)$ in only *three* real multiplications? [Answer: see §5.4.] (2) Can you evaluate a general fourth-degree polynomial in

x for many different values of x with only *three* multiplications per evaluation?
[Answer: see §5.3.]

Chapter 3. Interpolation and Extrapolation

3.0 Introduction

We sometimes know the value of a function $f(x)$ at a set of points x_1, x_2, \dots, x_N (say, with $x_1 < \dots < x_N$), but we don't have an analytic expression for $f(x)$ that lets us calculate its value at an arbitrary point. For example, the $f(x_i)$'s might result from some physical measurement or from long numerical calculation that cannot be cast into a simple functional form. Often the x_i 's are equally spaced, but not necessarily.

The task now is to estimate $f(x)$ for arbitrary x by, in some sense, drawing a smooth curve through (and perhaps beyond) the x_i 's. If the desired x is in between the largest and smallest of the x_i 's, the problem is called *interpolation*; if x is outside that range, it is called *extrapolation*, which is considerably more hazardous (as many former stock-market analysts can attest).

Interpolation and extrapolation schemes must model the function, between or beyond the known points, by some plausible functional form. The form should be sufficiently general so as to be able to approximate large classes of functions which might arise in practice. By far most common among the functional forms used are polynomials (§3.1). Rational functions (quotients of polynomials) also turn out to be extremely useful (§3.2). Trigonometric functions, sines and cosines, give rise to *trigonometric interpolation* and related Fourier methods, which we defer to Chapters 12 and 13.

There is an extensive mathematical literature devoted to theorems about what sort of functions can be well approximated by which interpolating functions. These theorems are, alas, almost completely useless in day-to-day work: If we know enough about our function to apply a theorem of any power, we are usually not in the pitiful state of having to interpolate on a table of its values!

Interpolation is related to, but distinct from, *function approximation*. That task consists of finding an approximate (but easily computable) function to use in place of a more complicated one. In the case of interpolation, you are given the function f at points *not of your own choosing*. For the case of function approximation, you are allowed to compute the function f at *any* desired points for the purpose of developing your approximation. We deal with function approximation in Chapter 5.

One can easily find pathological functions that make a mockery of any interpolation scheme. Consider, for example, the function

$$f(x) = 3x^2 + \frac{1}{\pi^4} \ln [(\pi - x)^2] + 1 \quad (3.0.1)$$

which is well-behaved everywhere except at $x = \pi$, very mildly singular at $x = \pi$, and otherwise takes on all positive and negative values. Any interpolation based on the values $x = 3.13, 3.14, 3.15, 3.16$, will assuredly get a very wrong answer for the value $x = 3.1416$, even though a graph plotting those five points looks really quite smooth! (Try it on your calculator.)

Because pathologies can lurk anywhere, it is highly desirable that an interpolation and extrapolation routine should return an estimate of its own error. Such an error estimate can never be foolproof, of course. We could have a function that, for reasons known only to its maker, takes off wildly and unexpectedly between two tabulated points. Interpolation always presumes some degree of smoothness for the function interpolated, but within this framework of presumption, deviations from smoothness can be detected.

Conceptually, the interpolation process has two stages: (1) Fit an interpolating function to the data points provided. (2) Evaluate that interpolating function at the target point x .

However, this two-stage method is generally not the best way to proceed in practice. Typically it is computationally less efficient, and more susceptible to roundoff error, than methods which construct a functional estimate $f(x)$ directly from the N tabulated values every time one is desired. Most practical schemes start at a nearby point $f(x_i)$, then add a sequence of (hopefully) decreasing corrections, as information from other $f(x_i)$'s is incorporated. The procedure typically takes $O(N^2)$ operations. If everything is well behaved, the last correction will be the smallest, and it can be used as an informal (though not rigorous) bound on the error.

In the case of polynomial interpolation, it sometimes does happen that the coefficients of the interpolating polynomial are of interest, even though their use in *evaluating* the interpolating function should be frowned on. We deal with this eventuality in §3.5.

Local interpolation, using a finite number of “nearest-neighbor” points, gives interpolated values $f(x)$ that do not, in general, have continuous first or higher derivatives. That happens because, as x crosses the tabulated values x_i , the interpolation scheme switches which tabulated points are the “local” ones. (If such a switch is allowed to occur anywhere *else*, then there will be a discontinuity in the interpolated function itself at that point. Bad idea!)

In situations where continuity of derivatives is a concern, one must use the “stiffer” interpolation provided by a so-called *spline* function. A spline is a polynomial between each pair of table points, but one whose coefficients are determined “slightly” nonlocally. The nonlocality is designed to guarantee global smoothness in the interpolated function up to some order of derivative. Cubic splines (§3.3) are the most popular. They produce an interpolated function that is continuous through the second derivative. Splines tend to be stabler than polynomials, with less possibility of wild oscillation between the tabulated points.

The number of points (minus one) used in an interpolation scheme is called the *order* of the interpolation. Increasing the order does not necessarily increase the accuracy, especially in polynomial interpolation. If the added points are distant from the point of interest x , the resulting higher-order polynomial, with its additional constrained points, tends to oscillate wildly between the tabulated values. This oscillation may have no relation at all to the behavior of the “true” function (see Figure 3.0.1). Of course, adding points *close* to the desired point usually does help,

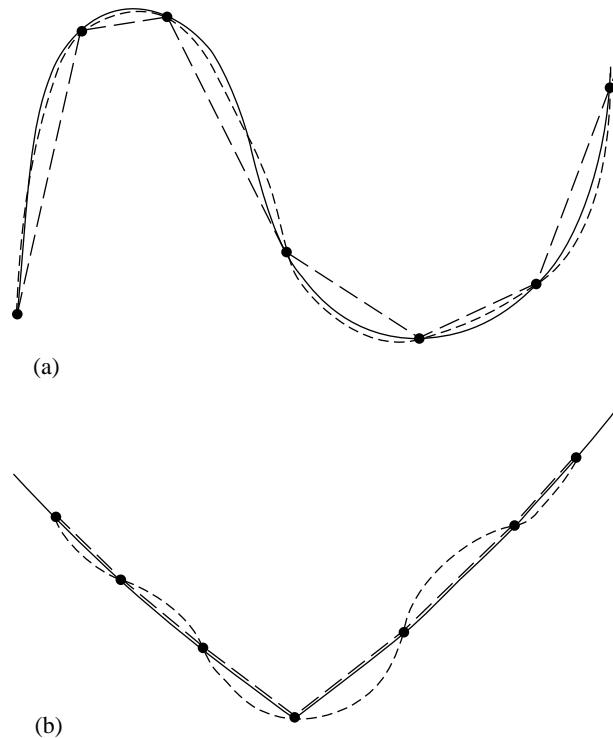

Figure 3.0.1. (a) A smooth function (solid line) is more accurately interpolated by a high-order polynomial (shown schematically as dotted line) than by a low-order polynomial (shown as a piecewise linear dashed line). (b) A function with sharp corners or rapidly changing higher derivatives is *less* accurately approximated by a high-order polynomial (dotted line), which is too “stiff,” than by a low-order polynomial (dashed lines). Even some smooth functions, such as exponentials or rational functions, can be badly approximated by high-order polynomials.

but a finer mesh implies a larger table of values, not always available.

Unless there is solid evidence that the interpolating function is close in form to the true function f , it is a good idea to be cautious about high-order interpolation. We enthusiastically endorse interpolations with 3 or 4 points, we are perhaps tolerant of 5 or 6; but we rarely go higher than that unless there is quite rigorous monitoring of estimated errors.

When your table of values contains many more points than the desirable order of interpolation, you must begin each interpolation with a search for the right “local” place in the table. While not strictly a part of the subject of interpolation, this task is important enough (and often enough botched) that we devote §3.4 to its discussion.

The routines given for interpolation are also routines for extrapolation. An important application, in Chapter 16, is their use in the integration of ordinary differential equations. There, considerable care *is* taken with the monitoring of errors. Otherwise, the dangers of extrapolation cannot be overemphasized: An interpolating function, which is *perforce* an extrapolating function, will typically go berserk when the argument x is outside the range of tabulated values by more than the typical spacing of tabulated points.

Interpolation can be done in more than one dimension, e.g., for a function

$f(x, y, z)$. Multidimensional interpolation is often accomplished by a sequence of one-dimensional interpolations. We discuss this in §3.6.

3.1 Polynomial Interpolation and Extrapolation

Through any two points there is a unique line. Through any three points, a unique quadratic. Et cetera. The interpolating polynomial of degree $N - 1$ through the N points $y_1 = f(x_1), y_2 = f(x_2), \dots, y_N = f(x_N)$ is given explicitly by Lagrange's classical formula,

$$P(x) = \frac{(x - x_2)(x - x_3)\dots(x - x_N)}{(x_1 - x_2)(x_1 - x_3)\dots(x_1 - x_N)}y_1 + \frac{(x - x_1)(x - x_3)\dots(x - x_N)}{(x_2 - x_1)(x_2 - x_3)\dots(x_2 - x_N)}y_2 + \dots + \frac{(x - x_1)(x - x_2)\dots(x - x_{N-1})}{(x_N - x_1)(x_N - x_2)\dots(x_N - x_{N-1})}y_N \quad (3.1.1)$$

There are N terms, each a polynomial of degree $N - 1$ and each constructed to be zero at all of the x_i except one, at which it is constructed to be y_i .

It is not terribly wrong to implement the Lagrange formula straightforwardly, but it is not terribly right either. The resulting algorithm gives no error estimate, and it is also somewhat awkward to program. A much better algorithm (for constructing the same, unique, interpolating polynomial) is *Neville's algorithm*, closely related to and sometimes confused with *Aitken's algorithm*, the latter now considered obsolete.

Let P_1 be the value at x of the unique polynomial of degree zero (i.e., a constant) passing through the point (x_1, y_1) ; so $P_1 = y_1$. Likewise define P_2, P_3, \dots, P_N . Now let P_{12} be the value at x of the unique polynomial of degree one passing through both (x_1, y_1) and (x_2, y_2) . Likewise $P_{23}, P_{34}, \dots, P_{(N-1)N}$. Similarly, for higher-order polynomials, up to $P_{12\dots N}$, which is the value of the unique interpolating polynomial through all N points, i.e., the desired answer.

$f(x, y, z)$. Multidimensional interpolation is often accomplished by a sequence of one-dimensional interpolations. We discuss this in §3.6.

3.1 Polynomial Interpolation and Extrapolation

Through any two points there is a unique line. Through any three points, a unique quadratic. Et cetera. The interpolating polynomial of degree $N - 1$ through the N points $y_1 = f(x_1), y_2 = f(x_2), \dots, y_N = f(x_N)$ is given explicitly by Lagrange's classical formula,

$$P(x) = \frac{(x - x_2)(x - x_3)\dots(x - x_N)}{(x_1 - x_2)(x_1 - x_3)\dots(x_1 - x_N)}y_1 + \frac{(x - x_1)(x - x_3)\dots(x - x_N)}{(x_2 - x_1)(x_2 - x_3)\dots(x_2 - x_N)}y_2 + \dots + \frac{(x - x_1)(x - x_2)\dots(x - x_{N-1})}{(x_N - x_1)(x_N - x_2)\dots(x_N - x_{N-1})}y_N \quad (3.1.1)$$

There are N terms, each a polynomial of degree $N - 1$ and each constructed to be zero at all of the x_i except one, at which it is constructed to be y_i .

It is not terribly wrong to implement the Lagrange formula straightforwardly, but it is not terribly right either. The resulting algorithm gives no error estimate, and it is also somewhat awkward to program. A much better algorithm (for constructing the same, unique, interpolating polynomial) is *Neville's algorithm*, closely related to and sometimes confused with *Aitken's algorithm*, the latter now considered obsolete.

Let P_1 be the value at x of the unique polynomial of degree zero (i.e., a constant) passing through the point (x_1, y_1) ; so $P_1 = y_1$. Likewise define P_2, P_3, \dots, P_N . Now let P_{12} be the value at x of the unique polynomial of degree one passing through both (x_1, y_1) and (x_2, y_2) . Likewise $P_{23}, P_{34}, \dots, P_{(N-1)N}$. Similarly, for higher-order polynomials, up to $P_{12\dots N}$, which is the value of the unique interpolating polynomial through all N points, i.e., the desired answer.

The various P 's form a “tableau” with “ancestors” on the left leading to a single “descendant” at the extreme right. For example, with $N = 4$,

$$\begin{array}{ll} x_1 : & y_1 = P_1 \\ & \quad P_{12} \\ x_2 : & y_2 = P_2 \quad \quad P_{123} \\ & \quad P_{23} \quad \quad P_{1234} \\ x_3 : & y_3 = P_3 \quad \quad P_{234} \\ & \quad P_{34} \\ x_4 : & y_4 = P_4 \end{array} \quad (3.1.2)$$

Neville's algorithm is a recursive way of filling in the numbers in the tableau a column at a time, from left to right. It is based on the relationship between a “daughter” P and its two “parents,”

$$P_{i(i+1)\dots(i+m)} = \frac{(x - x_{i+m})P_{i(i+1)\dots(i+m-1)} + (x_i - x)P_{(i+1)(i+2)\dots(i+m)}}{x_i - x_{i+m}} \quad (3.1.3)$$

This recurrence works because the two parents already agree at points $x_{i+1} \dots x_{i+m-1}$.

An improvement on the recurrence (3.1.3) is to keep track of the small *differences* between parents and daughters, namely to define (for $m = 1, 2, \dots, N - 1$),

$$\begin{aligned} C_{m,i} &\equiv P_{i\dots(i+m)} - P_{i\dots(i+m-1)} \\ D_{m,i} &\equiv P_{i\dots(i+m)} - P_{(i+1)\dots(i+m)}. \end{aligned} \quad (3.1.4)$$

Then one can easily derive from (3.1.3) the relations

$$\begin{aligned} D_{m+1,i} &= \frac{(x_{i+m+1} - x)(C_{m,i+1} - D_{m,i})}{x_i - x_{i+m+1}} \\ C_{m+1,i} &= \frac{(x_i - x)(C_{m,i+1} - D_{m,i})}{x_i - x_{i+m+1}} \end{aligned} \quad (3.1.5)$$

At each level m , the C 's and D 's are the corrections that make the interpolation one order higher. The final answer $P_{1\dots N}$ is equal to the sum of *any* y_i plus a set of C 's and/or D 's that form a path through the family tree to the rightmost daughter.

Here is a routine for polynomial interpolation or extrapolation:

```
SUBROUTINE polint(xa,ya,n,x,y,dy)
INTEGER n,NMAX
REAL dy,x,y,xa(n),ya(n)
PARAMETER (NMAX=10)          Largest anticipated value of n.
Given arrays xa and ya, each of length n, and given a value x, this routine returns a
value y, and an error estimate dy. If P(x) is the polynomial of degree N - 1 such that
P(xai) = yai, i = 1, ..., n, then the returned value y = P(x).
INTEGER i,m,ns
REAL den,dif,dift,ho,hp,w,c(NMAX),d(NMAX)
ns=1
dif=abs(x-xa(1))
```

```

do 11 i=1,n           Here we find the index ns of the closest table entry,
  dift=abs(x-xa(i))
  if (dift.lt.dif) then
    ns=i
    dif=dift
  endif
  c(i)=ya(i)
  d(i)=ya(i)
enddo 11
y=ya(ns)
ns=ns-1
do 13 m=1,n-1         and initialize the tableau of c's and d's.
  do 12 i=1,n-m
    ho=xa(i)-x
    hp=xa(i+m)-x
    w=c(i+1)-d(i)
    den=ho-hp
    if(den.eq.0.)pause 'failure in polint'
      This error can occur only if two input xa's are (to within roundoff) identical.
    den=w/den
    d(i)=hp*den          Here the c's and d's are updated.
    c(i)=ho*den
  enddo 12
  if (2*ns.lt.n-m)then
    dy=c(ns+1)
  else
    dy=d(ns)
    ns=ns-1
  endif
  y=y+dy
enddo 13
return
END

```

For each column of the tableau,
we loop over the current c's and d's and update them.

After each column in the tableau is completed, we decide
which correction, c or d, we want to add to our accumu-
lating value of y, i.e., which path to take through
the tableau—forking up or down. We do this in such a
way as to take the most “straight line” route through the
tableau to its apex, updating ns accordingly to keep track
of where we are. This route keeps the partial approxima-
tions centered (insofar as possible) on the target x. The
last dy added is thus the error indication.

Quite often you will want to call polint with the dummy arguments *xa* and *ya* replaced by actual arrays *with offsets*. For example, the construction call *polint(xx(15),yy(15),4,x,y,dy)* performs 4-point interpolation on the tabulated values *xx(15:18), yy(15:18)*. For more on this, see the end of §3.4.

3.2 Rational Function Interpolation and Extrapolation

Some functions are not well approximated by polynomials, but *are* well approximated by rational functions, that is quotients of polynomials. We denote by $R_{i(i+1)\dots(i+m)}$ a rational function passing through the $m + 1$ points

$(x_i, y_i) \dots (x_{i+m}, y_{i+m})$. More explicitly, suppose

$$R_{i(i+1)\dots(i+m)} = \frac{P_\mu(x)}{Q_\nu(x)} = \frac{p_0 + p_1 x + \dots + p_\mu x^\mu}{q_0 + q_1 x + \dots + q_\nu x^\nu} \quad (3.2.1)$$

Since there are $\mu + \nu + 1$ unknown p 's and q 's (q_0 being arbitrary), we must have

$$m + 1 = \mu + \nu + 1 \quad (3.2.2)$$

In specifying a rational function interpolating function, you must give the desired order of both the numerator and the denominator.

Rational functions are sometimes superior to polynomials, roughly speaking, because of their ability to model functions with poles, that is, zeros of the denominator of equation (3.2.1). These poles might occur for real values of x , if the function to be interpolated itself has poles. More often, the function $f(x)$ is finite for all finite *real* x , but has an analytic continuation with poles in the complex x -plane. Such poles can themselves ruin a polynomial approximation, even one restricted to real values of x , just as they can ruin the convergence of an infinite power series in x . If you draw a circle in the complex plane around your m tabulated points, then you should not expect polynomial interpolation to be good unless the nearest pole is rather far outside the circle. A rational function approximation, by contrast, will stay “good” as long as it has enough powers of x in its denominator to account for (cancel) any nearby poles.

For the interpolation problem, a rational function is constructed so as to go through a chosen set of tabulated functional values. However, we should also mention in passing that rational function approximations can be used in analytic work. One sometimes constructs a rational function approximation by the criterion that the rational function of equation (3.2.1) itself have a power series expansion that agrees with the first $m + 1$ terms of the power series expansion of the desired function $f(x)$. This is called *Padé approximation*, and is discussed in §5.12.

Bulirsch and Stoer found an algorithm of the Neville type which performs rational function extrapolation on tabulated data. A tableau like that of equation (3.1.2) is constructed column by column, leading to a result and an error estimate. The Bulirsch-Stoer algorithm produces the so-called *diagonal* rational function, with the degrees of numerator and denominator equal (if m is even) or with the degree of the denominator larger by one (if m is odd, cf. equation 3.2.2 above). For the derivation of the algorithm, refer to [1]. The algorithm is summarized by a recurrence relation exactly analogous to equation (3.1.3) for polynomial approximation:

$$\begin{aligned} R_{i(i+1)\dots(i+m)} &= R_{(i+1)\dots(i+m)} \\ &+ \frac{R_{(i+1)\dots(i+m)} - R_{i\dots(i+m-1)}}{\left(\frac{x-x_i}{x-x_{i+m}}\right) \left(1 - \frac{R_{(i+1)\dots(i+m)} - R_{i\dots(i+m-1)}}{R_{(i+1)\dots(i+m)} - R_{(i+1)\dots(i+m-1)}}\right) - 1} \end{aligned} \quad (3.2.3)$$

This recurrence generates the rational functions through $m + 1$ points from the ones through m and (the term $R_{(i+1)\dots(i+m-1)}$ in equation 3.2.3) $m - 1$ points. It is started with

$$R_i = y_i \quad (3.2.4)$$

and with

$$R \equiv [R_{i(i+1)\dots(i+m)} \quad \text{with} \quad m = -1] = 0 \quad (3.2.5)$$

Now, exactly as in equations (3.1.4) and (3.1.5) above, we can convert the recurrence (3.2.3) to one involving only the small differences

$$\begin{aligned} C_{m,i} &\equiv R_{i\dots(i+m)} - R_{i\dots(i+m-1)} \\ D_{m,i} &\equiv R_{i\dots(i+m)} - R_{(i+1)\dots(i+m)} \end{aligned} \quad (3.2.6)$$

Note that these satisfy the relation

$$C_{m+1,i} - D_{m+1,i} = C_{m,i+1} - D_{m,i} \quad (3.2.7)$$

which is useful in proving the recurrences

$$\begin{aligned} D_{m+1,i} &= \frac{C_{m,i+1}(C_{m,i+1} - D_{m,i})}{\left(\frac{x-x_i}{x-x_{i+m+1}}\right)D_{m,i} - C_{m,i+1}} \\ C_{m+1,i} &= \frac{\left(\frac{x-x_i}{x-x_{i+m+1}}\right)D_{m,i}(C_{m,i+1} - D_{m,i})}{\left(\frac{x-x_i}{x-x_{i+m+1}}\right)D_{m,i} - C_{m,i+1}} \end{aligned} \quad (3.2.8)$$

This recurrence is implemented in the following subroutine, whose use is analogous in every way to `polint` in §3.1.

```
SUBROUTINE ratint(xa,ya,n,x,y,dy)
INTEGER n,NMAX
REAL dy,x,y,xa(n),ya(n),TINY
PARAMETER (NMAX=10,TINY=1.e-25)      Largest expected value of n, and a small number.
                                         Given arrays xa and ya, each of length n, and given a value of x, this routine returns a
                                         value of y and an accuracy estimate dy. The value returned is that of the diagonal rational
                                         function, evaluated at x, which passes through the n points (xai, yai), i = 1...n.
INTEGER i,m,ns
REAL dd,h,hh,t,w,c(NMAX),d(NMAX)
ns=1
hh=abs(x-xa(1))
do 11 i=1,n
    h=abs(x-xa(i))
    if (h.eq.0.)then
        y=ya(i)
        dy=0.0
        return
    else if (h.lt.hh) then
        ns=i
        hh=h
    endif
    c(i)=ya(i)
    d(i)=ya(i)+TINY
11  enddo 11
y=ya(ns)
ns=ns-1
do 13 m=1,n-1
    do 12 i=1,n-m
        dd=(xa(i)-x)*(xa(i+m)-x)
        t=(xa(i+m)-xa(i))
        w=(ya(i+m)-ya(i))/t
        c(i)=c(i)+w*dd
        d(i)=d(i)+dd
12  continue
13  continue
dy=d(n)/d(n-1)
```

The TINY part is needed to prevent a rare zero-over-zero condition.

```

w=c(i+1)-d(i)
h=xa(i+m)-x
t=(xa(i)-x)*d(i)/h
dd=t-c(i+1)
if(dd.eq.0.)pause 'failure in ratint'
   This error condition indicates that the interpolating function has a pole at the re-
   quested value of x.
dd=w/dd
d(i)=c(i+1)*dd
c(i)=t*dd
enddo i2
if (2*ns.lt.n-m)then
   dy=c(ns+1)
else
   dy=d(ns)
   ns=ns-1
endif
y=y+dy
endo i3
return
END

```

3.3 Cubic Spline Interpolation

Given a tabulated function $y_i = y(x_i)$, $i = 1\dots N$, focus attention on one particular interval, between x_j and x_{j+1} . Linear interpolation in that interval gives the interpolation formula

$$y = Ay_j + By_{j+1} \quad (3.3.1)$$

where

$$A \equiv \frac{x_{j+1} - x}{x_{j+1} - x_j} \quad B \equiv 1 - A = \frac{x - x_j}{x_{j+1} - x_j} \quad (3.3.2)$$

Equations (3.3.1) and (3.3.2) are a special case of the general Lagrange interpolation formula (3.1.1).

Since it is (piecewise) linear, equation (3.3.1) has zero second derivative in the interior of each interval, and an undefined, or infinite, second derivative at the abscissas x_j . The goal of cubic spline interpolation is to get an interpolation formula that is smooth in the first derivative, and continuous in the second derivative, both within an interval and at its boundaries.

Suppose, contrary to fact, that in addition to the tabulated values of y_i , we also have tabulated values for the function's second derivatives, y'' , that is, a set

```

3.3 Cubic Spline Interpolation

Given a tabulated function $y_i = y(x_i)$, $i = 1\dots N$, focus attention on one particular interval, between x_j and x_{j+1} . Linear interpolation in that interval gives the interpolation formula

$$y = Ay_j + By_{j+1} \quad (3.3.1)$$

where

$$A \equiv \frac{x_{j+1} - x}{x_{j+1} - x_j} \quad B \equiv 1 - A = \frac{x - x_j}{x_{j+1} - x_j} \quad (3.3.2)$$

Equations (3.3.1) and (3.3.2) are a special case of the general Lagrange interpolation formula (3.1.1).

Since it is (piecewise) linear, equation (3.3.1) has zero second derivative in the interior of each interval, and an undefined, or infinite, second derivative at the abscissas x_j . The goal of cubic spline interpolation is to get an interpolation formula that is smooth in the first derivative, and continuous in the second derivative, both within an interval and at its boundaries.

Suppose, contrary to fact, that in addition to the tabulated values of y_i , we also have tabulated values for the function's second derivatives, y'' , that is, a set

of numbers y''_i . Then, within each interval, we can add to the right-hand side of equation (3.3.1) a cubic polynomial whose second derivative varies linearly from a value y''_j on the left to a value y''_{j+1} on the right. Doing so, we will have the desired continuous second derivative. If we also construct the cubic polynomial to have zero values at x_j and x_{j+1} , then adding it in will not spoil the agreement with the tabulated functional values y_j and y_{j+1} at the endpoints x_j and x_{j+1} .

A little side calculation shows that there is only one way to arrange this construction, namely replacing (3.3.1) by

$$y = Ay_j + By_{j+1} + Cy''_j + Dy''_{j+1} \quad (3.3.3)$$

where A and B are defined in (3.3.2) and

$$C \equiv \frac{1}{6}(A^3 - A)(x_{j+1} - x_j)^2 \quad D \equiv \frac{1}{6}(B^3 - B)(x_{j+1} - x_j)^2 \quad (3.3.4)$$

Notice that the dependence on the independent variable x in equations (3.3.3) and (3.3.4) is entirely through the linear x -dependence of A and B , and (through A and B) the cubic x -dependence of C and D .

We can readily check that y'' is in fact the second derivative of the new interpolating polynomial. We take derivatives of equation (3.3.3) with respect to x , using the definitions of A, B, C, D to compute $dA/dx, dB/dx, dC/dx$, and dD/dx . The result is

$$\frac{dy}{dx} = \frac{y_{j+1} - y_j}{x_{j+1} - x_j} - \frac{3A^2 - 1}{6}(x_{j+1} - x_j)y''_j + \frac{3B^2 - 1}{6}(x_{j+1} - x_j)y''_{j+1} \quad (3.3.5)$$

for the first derivative, and

$$\frac{d^2y}{dx^2} = Ay''_j + By''_{j+1} \quad (3.3.6)$$

for the second derivative. Since $A = 1$ at x_j , $A = 0$ at x_{j+1} , while B is just the other way around, (3.3.6) shows that y'' is just the tabulated second derivative, and also that the second derivative will be continuous across (e.g.) the boundary between the two intervals (x_{j-1}, x_j) and (x_j, x_{j+1}) .

The only problem now is that we supposed the y''_i 's to be known, when, actually, they are not. However, we have not yet required that the *first* derivative, computed from equation (3.3.5), be continuous across the boundary between two intervals. The key idea of a cubic spline is to require this continuity and to use it to get equations for the second derivatives y''_i .

The required equations are obtained by setting equation (3.3.5) evaluated for $x = x_j$ in the interval (x_{j-1}, x_j) equal to the same equation evaluated for $x = x_j$ but in the interval (x_j, x_{j+1}) . With some rearrangement, this gives (for $j = 2, \dots, N-1$)

$$\frac{x_j - x_{j-1}}{6}y''_{j-1} + \frac{x_{j+1} - x_{j-1}}{3}y''_j + \frac{x_{j+1} - x_j}{6}y''_{j+1} = \frac{y_{j+1} - y_j}{x_{j+1} - x_j} - \frac{y_j - y_{j-1}}{x_j - x_{j-1}} \quad (3.3.7)$$

These are $N - 2$ linear equations in the N unknowns $y''_i, i = 1, \dots, N$. Therefore there is a two-parameter family of possible solutions.

For a unique solution, we need to specify two further conditions, typically taken as boundary conditions at x_1 and x_N . The most common ways of doing this are either

- set one or both of y_1'' and y_N'' equal to zero, giving the so-called *natural cubic spline*, which has zero second derivative on one or both of its boundaries, or
- set either of y_1'' and y_N'' to values calculated from equation (3.3.5) so as to make the first derivative of the interpolating function have a specified value on either or both boundaries.

One reason that cubic splines are especially practical is that the set of equations (3.3.7), along with the two additional boundary conditions, are not only linear, but also *tridiagonal*. Each y_j'' is coupled only to its nearest neighbors at $j \pm 1$. Therefore, the equations can be solved in $O(N)$ operations by the tridiagonal algorithm (§2.4). That algorithm is concise enough to build right into the spline calculational routine. This makes the routine not completely transparent as an implementation of (3.3.7), so we encourage you to study it carefully, comparing with `tridag` (§2.4).

```
SUBROUTINE spline(x,y,n,yp1,ypn,y2)
INTEGER n,NMAX
REAL yp1,ypn,x(n),y(n),y2(n)
PARAMETER (NMAX=500)
  Given arrays x(1:n) and y(1:n) containing a tabulated function, i.e.,  $y_i = f(x_i)$ , with
   $x_1 < x_2 < \dots < x_N$ , and given values yp1 and ypn for the first derivative of the inter-
  polating function at points 1 and n, respectively, this routine returns an array y2(1:n) of
  length n which contains the second derivatives of the interpolating function at the tabulated
  points  $x_i$ . If yp1 and/or ypn are equal to  $1 \times 10^{30}$  or larger, the routine is signaled to set
  the corresponding boundary condition for a natural spline, with zero second derivative on
  that boundary.
  Parameter: NMAX is the largest anticipated value of n.
INTEGER i,k
REAL p,qn,sig,un,u(NMAX)
if (yp1.gt..99e30) then
  y2(1)=0.                                The lower boundary condition is set either to be

else                                         or else to have a specified first derivative.
  qn=0.5
  un=(3./(x(n)-x(n-1)))*(ypn-(y(n)-y(n-1))/(x(n)-x(n-1)))
endif
y2(n)=(un-qn*u(n-1))/(qn*y2(n-1)+1.)      This is the backsubstitution loop of the tridiago-
do 12 k=n-1,1,-1
  y2(k)=y2(k)*y2(k+1)+u(k)                 nal algorithm.
  enddo 12
return
END
```

It is important to understand that the program `spline` is called only *once* to process an entire tabulated function in arrays x_i and y_i . Once this has been done,

values of the interpolated function for any value of x are obtained by calls (as many as desired) to a separate routine `splint` (for “spline interpolation”):

```
SUBROUTINE splint(xa,ya,y2a,n,x,y)
INTEGER n
REAL x,y,xa(n),y2a(n),ya(n)
Given the arrays xa(1:n) and ya(1:n) of length n, which tabulate a function (with the
xai's in order), and given the array y2a(1:n), which is the output from spline above,
and given a value of x, this routine returns a cubic-spline interpolated value y.
INTEGER k,khi,klo
REAL a,b,h
klo=1
khi=n
1 if (khi-klo.gt.1) then
    k=(khi+klo)/2
    if(xa(k).gt.x)then
        khi=k
    else
        klo=k
    endif
    goto 1
endif
h=xa(khi)-xa(klo)
if (h.eq.0.) pause 'bad xa input in splint' The xa's must be distinct.
a=(xa(khi)-x)/h
b=(x-xa(klo))/h
y=a*ya(klo)+b*ya(khi) +
*          ((a**3-a)*y2a(klo)+(b**3-b)*y2a(khi))*(h**2)/6.
return
END
```

We will find the right place in the table by means of bisection. This is optimal if sequential calls to this routine are at random values of x . If sequential calls are in order, and closely spaced, one would do better to store previous values of klo and khi and test if they remain appropriate on the next call.

klo and khi now bracket the input value of x .

Cubic spline polynomial is now evaluated.

3.4 How to Search an Ordered Table

Suppose that you have decided to use some particular interpolation scheme, such as fourth-order polynomial interpolation, to compute a function $f(x)$ from a set of tabulated x_i 's and f_i 's. Then you will need a fast way of finding your place in the table of x_i 's, given some particular value x at which the function evaluation is desired. This problem is not properly one of numerical analysis, but it occurs so often in practice that it would be negligent of us to ignore it.

Formally, the problem is this: Given an array of abscissas $xx(j)$, $j=1, 2, \dots, n$, with the elements either monotonically increasing or monotonically decreasing, and given a number x , find an integer j such that x lies between $xx(j)$ and $xx(j+1)$. For

this task, let us define fictitious array elements $xx(0)$ and $xx(n+1)$ equal to plus or minus infinity (in whichever order is consistent with the monotonicity of the table). Then j will always be between 0 and n , inclusive; a returned value of 0 indicates “off-scale” at one end of the table, n indicates off-scale at the other end.

In most cases, when all is said and done, it is hard to do better than *bisection*, which will find the right place in the table in about $\log_2 n$ tries. We already did use bisection in the spline evaluation routine `splint` of the preceding section, so you might glance back at that. Standing by itself, a bisection routine looks like this:

```
SUBROUTINE locate(xx,n,x,j)
INTEGER j,n
REAL x,xx(n)
      Given an array xx(1:n), and given a value x, returns a value j such that x is between
      xx(j) and xx(j+1). xx(1:n) must be monotonic, either increasing or decreasing. j=0
      or j=n is returned to indicate that x is out of range.
INTEGER jl,jm,ju
jl=0                      Initialize lower
ju=n+1                     and upper limits.
10 if(ju-jl.gt.1)then       If we are not yet done,
      jm=(ju+jl)/2           compute a midpoint,
      if((xx(n).ge.xx(1)).eqv.(x.ge.xx(jm)))then
          jl=jm               and replace either the lower limit
      else
          ju=jm               or the upper limit, as appropriate.
      endif
      goto 10                 Repeat until
      endif                   the test condition 10 is satisfied.
      if(x.eq.xx(1))then     Then set the output
          j=1
      else if(x.eq.xx(n))then
          j=n-1
      else
          j=jl
      endif
      return                  and return.
END
```

Note the use of the logical equality relation `.eqv.`, which is true when its two logical operands are either both true or both false. This relation allows the routine to work for both monotonically increasing and monotonically decreasing orders of $xx(1:n)$.

Search with Correlated Values

Sometimes you will be in the situation of searching a large table many times, and with nearly identical abscissas on consecutive searches. For example, you may be generating a function that is used on the right-hand side of a differential equation: Most differential-equation integrators, as we shall see in Chapter 16, call for right-hand side evaluations at points that hop back and forth a bit, but whose trend moves slowly in the direction of the integration.

In such cases it is wasteful to do a full bisection, *ab initio*, on each call. The following routine instead starts with a guessed position in the table. It first “hunts,” either up or down, in increments of 1, then 2, then 4, etc., until the desired value is bracketed. Second, it then bisects in the bracketed interval. At worst, this routine is about a factor of 2 slower than `locate` above (if the hunt phase expands to include the whole table). At best, it can be a factor of $\log_2 n$ faster than `locate`, if the desired point is usually quite close to the input guess. Figure 3.4.1 compares the two routines.

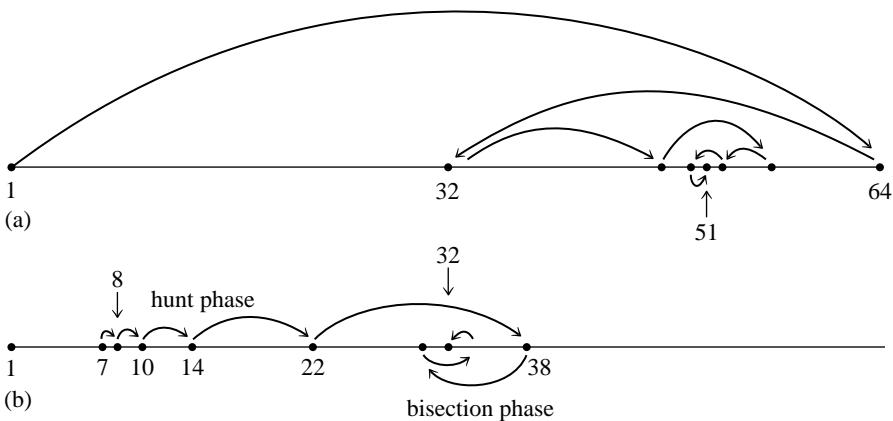

Figure 3.4.1. (a) The routine `locate` finds a table entry by bisection. Shown here is the sequence of steps that converge to element 51 in a table of length 64. (b) The routine `hunt` searches from a previous known position in the table by increasing steps, then converges by bisection. Shown here is a particularly unfavorable example, converging to element 32 from element 7. A favorable example would be convergence to an element near 7, such as 9, which would require just three “hops.”

```

SUBROUTINE hunt(xx,n,x,jlo)
INTEGER jlo,n
REAL x,xx(n)

Given an array xx(1:n), and given a value x, returns a value jlo such that x is between
xx(jlo) and xx(jlo+1). xx(1:n) must be monotonic, either increasing or decreasing.
jlo=0 or jlo=n is returned to indicate that x is out of range. jlo on input is taken as
the initial guess for jlo on output.

INTEGER inc,jhi,jm
LOGICAL ascnd
ascnd=xx(n).ge.xx(1)
if(jlo.le.0.or.jlo.gt.n)then
    jlo=0
    jhi=n+1
    goto 3
endif
inc=1
if(x.ge.xx(jlo).eqv.ascnd)then
    jhi=jlo+inc
    if(jhi.gt.n)then
        jhi=n+1
    else if(x.ge.xx(jhi).eqv.ascnd)then
        jlo=jhi
        inc=inc+inc
        goto 1
    endif
else
    jhi=jlo
    jlo=jhi-inc
    if(jlo.lt.1)then
        jlo=0
    else if(x.lt.xx(jlo).eqv.ascnd)then
        jhi=jlo
        inc=inc+inc
        goto 2
    endif
endif
if(jhi-jlo.eq.1)then
    if(x.eq.xx(n))jlo=n-1
    if(x.eq.xx(1))jlo=1
endif

True if ascending order of table, false otherwise.
Input guess not useful. Go immediately to bisection.

Set the hunting increment.
Hunt up:

Done hunting, since off end of table.

Not done hunting,
so double the increment
and try again.
Done hunting, value bracketed.
Hunt down:

Done hunting, since off end of table.

Not done hunting,
so double the increment
and try again.
Done hunting, value bracketed.
Hunt is done, so begin the final bisection phase:

```

```

        return
    endif
    jm=(jhi+jlo)/2
    if(x.ge.xx(jm).eqv.ascnd)then
        jlo=jm
    else
        jhi=jm
    endif
    goto 3
END

```

After the Hunt

The problem: Routines `locate` and `hunt` return an index j such that your desired value lies between table entries $xx(j)$ and $xx(j+1)$, where $xx(1:n)$ is the full length of the table. But, to obtain an m -point interpolated value using a routine like `polint` (§3.1) or `ratint` (§3.2), you need to supply much shorter `xx` and `yy` arrays, of length m . How do you make the connection?

The solution: Calculate

$$k = \min(\max(j - (m-1)/2, 1), n+1-m)$$

This expression produces the index of the leftmost member of an m -point set of points centered (insofar as possible) between j and $j+1$, but bounded by 1 at the left and n at the right. FORTRAN then lets you call the interpolation routine with array addresses offset by k , e.g.,

```
call polint(xx(k), yy(k), m, ...)
```

3.5 Coefficients of the Interpolating Polynomial

Occasionally you may wish to know not the value of the interpolating polynomial that passes through a (small!) number of points, but the coefficients of that polynomial. A valid use of the coefficients might be, for example, to compute simultaneous interpolated values of the function and of several of its derivatives (see §5.3), or to convolve a segment of the tabulated function with some other function, where the moments of that other function (i.e., its convolution with powers of x) are known analytically.

However, please be certain that the coefficients are what you need. Generally the coefficients of the interpolating polynomial can be determined much less accurately than its value at a desired abscissa. Therefore it is not a good idea to determine the coefficients only for use in calculating interpolating values. Values thus calculated will not pass exactly through the tabulated points, for example, while values computed by the routines in §3.1–§3.3 will pass exactly through such points.

```

        return
    endif
    jm=(jhi+jlo)/2
    if(x.ge.xx(jm).eqv.ascnd)then
        jlo=jm
    else
        jhi=jm
    endif
    goto 3
END

```

After the Hunt

3.5 Coefficients of the Interpolating Polynomial

Occasionally you may wish to know not the value of the interpolating polynomial that passes through a (small!) number of points, but the coefficients of that polynomial. A valid use of the coefficients might be, for example, to compute simultaneous interpolated values of the function and of several of its derivatives (see §5.3), or to convolve a segment of the tabulated function with some other function, where the moments of that other function (i.e., its convolution with powers of x) are known analytically.

However, please be certain that the coefficients are what you need. Generally the coefficients of the interpolating polynomial can be determined much less accurately than its value at a desired abscissa. Therefore it is not a good idea to determine the coefficients only for use in calculating interpolating values. Values thus calculated will not pass exactly through the tabulated points, for example, while values computed by the routines in §3.1–§3.3 will pass exactly through such points.

Also, you should not mistake the interpolating polynomial (and its coefficients) for its cousin, the *best fit* polynomial through a data set. Fitting is a *smoothing* process, since the number of fitted coefficients is typically much less than the number of data points. Therefore, fitted coefficients can be accurately and stably determined even in the presence of statistical errors in the tabulated values. (See §14.8.) Interpolation, where the number of coefficients and number of tabulated points are equal, takes the tabulated values as perfect. If they in fact contain statistical errors, these can be magnified into oscillations of the interpolating polynomial in between the tabulated points.

As before, we take the tabulated points to be $y_i \equiv y(x_i)$. If the interpolating polynomial is written as

$$y = c_1 + c_2x + c_3x^2 + \cdots + c_Nx^{N-1} \quad (3.5.1)$$

then the c_i 's are required to satisfy the linear equation

$$\begin{bmatrix} 1 & x_1 & x_1^2 & \cdots & x_1^{N-1} \\ 1 & x_2 & x_2^2 & \cdots & x_2^{N-1} \\ \vdots & \vdots & \vdots & & \vdots \\ 1 & x_N & x_N^2 & \cdots & x_N^{N-1} \end{bmatrix} \cdot \begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ c_N \end{bmatrix} = \begin{bmatrix} y_1 \\ y_2 \\ \vdots \\ y_N \end{bmatrix} \quad (3.5.2)$$

This is a *Vandermonde matrix*, as described in §2.8. One could in principle solve equation (3.5.2) by standard techniques for linear equations generally (§2.3); however the special method that was derived in §2.8 is more efficient by a large factor, of order N , so it is much better.

Remember that Vandermonde systems can be quite ill-conditioned. In such a case, *no* numerical method is going to give a very accurate answer. Such cases do not, please note, imply any difficulty in finding interpolated *values* by the methods of §3.1, but only difficulty in finding *coefficients*.

Like the routine in §2.8, the following is due to G.B. Rybicki.

```
SUBROUTINE polcoe(x,y,n,cof)
INTEGER n,NMAX
REAL cof(n),x(n),y(n)
PARAMETER (NMAX=15)           Largest anticipated value of n.
                                Given arrays x(1:n) and y(1:n) containing a tabulated function y_i = f(x_i), this routine
                                returns an array of coefficients cof(1:n), such that y_i = sum_j cof_j x_i^{j-1}.
INTEGER i,j,k
REAL b,ff,phi,s(NMAX)
do 11 i=1,n
    s(i)=0.
    cof(i)=0.
  enddo 11
s(n)=-x(1)
do 13 i=2,n
    do 12 j=n+1-i,n-1
        s(j)=s(j)-x(i)*s(j+1)
    enddo 12
    s(n)=s(n)-x(i)
  enddo 13
do 16 j=1,n
    phi=n
    do 14 k=n-1,1,-1
        phi=phi*(j-k)
    enddo 14
    cof(j)=phi*y(j)
  enddo 16
```

Coefficients s_i of the master polynomial $P(x)$ are found by recurrence.

The quantity $\phi = \prod_{j \neq k} (x_j - x_k)$ is found as a derivative of $P(x_j)$.

```

phi=k*s(k+1)+x(j)*phi
enddo 14
ff=y(j)/phi
b=1.
do 15 k=n,1,-1
  cof(k)=cof(k)+b*ff
  b=s(k)+x(j)*b
enddo 15
enddo 16
return
END

```

Coefficients of polynomials in each term of the Lagrange formula are found by synthetic division of $P(x)$ by $(x - x_j)$. The solution c_k is accumulated.

Another Method

Another technique is to make use of the function value interpolation routine already given (polint §3.1). If we interpolate (or extrapolate) to find the value of the interpolating polynomial at $x = 0$, then this value will evidently be c_1 . Now we can subtract c_1 from the y_i 's and divide each by its corresponding x_i . Throwing out one point (the one with smallest x_i is a good candidate), we can repeat the procedure to find c_2 , and so on.

It is not instantly obvious that this procedure is stable, but we have generally found it to be somewhat *more* stable than the routine immediately preceding. This method is of order N^3 , while the preceding one was of order N^2 . You will find, however, that neither works very well for large N , because of the intrinsic ill-condition of the Vandermonde problem. In single precision, N up to 8 or 10 is satisfactory; about double this in double precision.

```

SUBROUTINE polcof(xa,ya,n,cof)
INTEGER n,NMAX
REAL cof(n),xa(n),ya(n)
PARAMETER (NMAX=15)                                Largest anticipated value of n.
C USES polint
      Given arrays xa(1:n) and ya(1:n) of length n containing a tabulated function yai =
      f(xai), this routine returns an array of coefficients cof(1:n), also of length n, such that
      yai =  $\sum_j cof_j xa_i^{j-1}$ .
      INTEGER i,j,k
      REAL dy,xmin,x(NMAX),y(NMAX)
      do 11 j=1,n

        xmin=1.e38                                     tine of §3.1. We extrapolate to x =
        k=0                                              0.
        do 12 i=1,n+1-j
          if (abs(x(i)).lt.xmin)then
            xmin=abs(x(i))
            k=i
          endif
          if(x(i).ne.0.)y(i)=(y(i)-cof(j))/x(i)    Find the remaining xi of smallest abso-
                                                       (meanwhile reducing all the terms)
        enddo 12
        do 13 i=k+1,n+1-j
          y(i-1)=y(i)
          x(i-1)=x(i)
        enddo 13
      enddo 14
      return
END

```

and eliminate it.

If the point $x = 0$ is not in (or at least close to) the range of the tabulated x_i 's, then the coefficients of the interpolating polynomial will in general become very large. However, the real “information content” of the coefficients is in small differences from the “translation-induced” large values. This is one cause of ill-conditioning, resulting in loss of significance and poorly determined coefficients. You should consider redefining the origin of the problem, to put $x = 0$ in a sensible place.

Another pathology is that, if too high a degree of interpolation is attempted on a smooth function, the interpolating polynomial will attempt to use its high-degree coefficients, in combinations with large and almost precisely canceling combinations, to match the tabulated values down to the last possible epsilon of accuracy. This effect is the same as the intrinsic tendency of the interpolating polynomial values to oscillate (wildly) between its constrained points, and would be present even if the machine's floating precision were infinitely good. The above routines polcoe and polcof have slightly different sensitivities to the pathologies that can occur.

Are you still quite certain that using the *coefficients* is a good idea?

3.6 Interpolation in Two or More Dimensions

In multidimensional interpolation, we seek an estimate of $y(x_1, x_2, \dots, x_n)$ from an n -dimensional grid of tabulated values y and n one-dimensional vectors giving the tabulated values of each of the independent variables x_1, x_2, \dots, x_n . We will not here consider the problem of interpolating on a mesh that is not Cartesian, i.e., has tabulated function values at “random” points in n -dimensional space rather than at the vertices of a rectangular array. For clarity, we will consider explicitly only the case of two dimensions, the cases of three or more dimensions being analogous in every way.

In two dimensions, we imagine that we are given a matrix of functional values $y_a(j, k)$, where j varies from 1 to m , and k varies from 1 to n . We are also given an array $x1a$ of length m , and an array $x2a$ of length n . The relation of these input quantities to an underlying function $y(x_1, x_2)$ is

$$y_a(j, k) = y(x1a(j), x2a(k)) \quad (3.6.1)$$

We want to estimate, by interpolation, the function y at some untabulated point (x_1, x_2) .

An important concept is that of the *grid square* in which the point (x_1, x_2) falls, that is, the four tabulated points that surround the desired interior point. For convenience, we will number these points from 1 to 4, counterclockwise starting from the lower left (see Figure 3.6.1). More precisely, if

$$\begin{aligned} x1a(j) &\leq x_1 \leq x1a(j+1) \\ x2a(k) &\leq x_2 \leq x2a(k+1) \end{aligned} \quad (3.6.2)$$

If the point $x = 0$ is not in (or at least close to) the range of the tabulated x_i 's, then the coefficients of the interpolating polynomial will in general become very large. However, the real “information content” of the coefficients is in small differences from the “translation-induced” large values. This is one cause of ill-conditioning, resulting in loss of significance and poorly determined coefficients. You should consider redefining the origin of the problem, to put $x = 0$ in a sensible place.

Another pathology is that, if too high a degree of interpolation is attempted on a smooth function, the interpolating polynomial will attempt to use its high-degree coefficients, in combinations with large and almost precisely canceling combinations, to match the tabulated values down to the last possible epsilon of accuracy. This effect is the same as the intrinsic tendency of the interpolating polynomial values to oscillate (wildly) between its constrained points, and would be present even if the machine's floating precision were infinitely good. The above routines `polcoe` and `polcof` have slightly different sensitivities to the pathologies that can occur.

Are you still quite certain that using the *coefficients* is a good idea?

3.6 Interpolation in Two or More Dimensions

In multidimensional interpolation, we seek an estimate of $y(x_1, x_2, \dots, x_n)$ from an n -dimensional grid of tabulated values y and n one-dimensional vectors giving the tabulated values of each of the independent variables x_1, x_2, \dots, x_n . We will not here consider the problem of interpolating on a mesh that is not Cartesian, i.e., has tabulated function values at “random” points in n -dimensional space rather than at the vertices of a rectangular array. For clarity, we will consider explicitly only the case of two dimensions, the cases of three or more dimensions being analogous in every way.

In two dimensions, we imagine that we are given a matrix of functional values $y_a(j, k)$, where j varies from 1 to m , and k varies from 1 to n . We are also given an array $x1a$ of length m , and an array $x2a$ of length n . The relation of these input quantities to an underlying function $y(x_1, x_2)$ is

$$y_a(j, k) = y(x1a(j), x2a(k)) \quad (3.6.1)$$

We want to estimate, by interpolation, the function y at some untabulated point (x_1, x_2) .

An important concept is that of the *grid square* in which the point (x_1, x_2) falls, that is, the four tabulated points that surround the desired interior point. For convenience, we will number these points from 1 to 4, counterclockwise starting from the lower left (see Figure 3.6.1). More precisely, if

$$\begin{aligned} x1a(j) &\leq x_1 \leq x1a(j+1) \\ x2a(k) &\leq x_2 \leq x2a(k+1) \end{aligned} \quad (3.6.2)$$

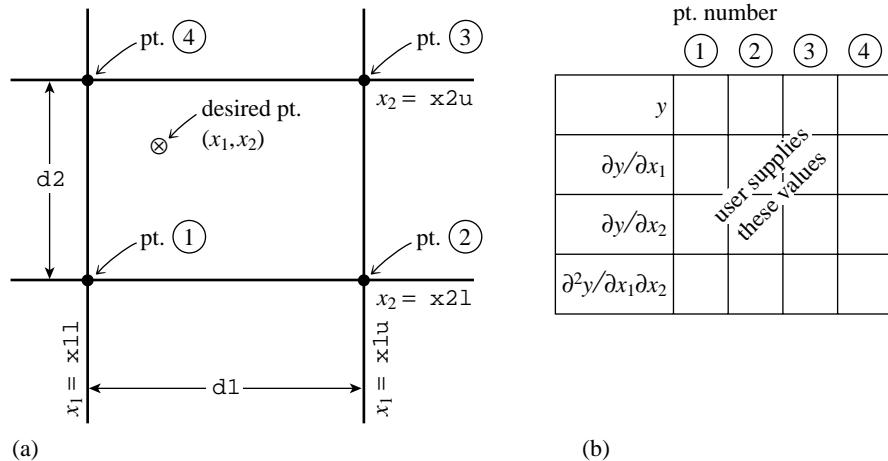

Figure 3.6.1. (a) Labeling of points used in the two-dimensional interpolation routines `bciint` and `bcucof`. (b) For each of the four points in (a), the user supplies one function value, two first derivatives, and one cross-derivative, a total of 16 numbers.

defines j and k , then

$$\begin{aligned}
 y_1 &\equiv ya(j, k) \\
 y_2 &\equiv ya(j+1, k) \\
 y_3 &\equiv ya(j+1, k+1) \\
 y_4 &\equiv ya(j, k+1)
 \end{aligned} \tag{3.6.3}$$

The simplest interpolation in two dimensions is *bilinear interpolation* on the grid square. Its formulas are:

$$\begin{aligned}
 t &\equiv (x_1 - x1a(j)) / (x1a(j+1) - x1a(j)) \\
 u &\equiv (x_2 - x2a(k)) / (x2a(k+1) - x2a(k))
 \end{aligned} \tag{3.6.4}$$

(so that t and u each lie between 0 and 1), and

$$y(x_1, x_2) = (1 - t)(1 - u)y_1 + t(1 - u)y_2 + tuy_3 + (1 - t)uy_4 \tag{3.6.5}$$

Bilinear interpolation is frequently “close enough for government work.” As the interpolating point wanders from grid square to grid square, the interpolated function value changes continuously. However, the gradient of the interpolated function changes discontinuously at the boundaries of each grid square.

There are two distinctly different directions that one can take in going beyond bilinear interpolation to higher-order methods: One can use higher order to obtain increased accuracy for the interpolated function (for sufficiently smooth functions!), without necessarily trying to fix up the continuity of the gradient and higher derivatives. Or, one can make use of higher order to enforce smoothness of some of these derivatives as the interpolating point crosses grid-square boundaries. We will now consider each of these two directions in turn.

Higher Order for Accuracy

The basic idea is to break up the problem into a succession of one-dimensional interpolations. If we want to do $m-1$ order interpolation in the x_1 direction, and $n-1$ order in the x_2 direction, we first locate an $m \times n$ sub-block of the tabulated function matrix that contains our desired point (x_1, x_2) . We then do m one-dimensional interpolations in the x_2 direction, i.e., on the rows of the sub-block, to get function values at the points $(x_{1a}(j), x_2)$, $j = 1, \dots, m$. Finally, we do a last interpolation in the x_1 direction to get the answer. If we use the polynomial interpolation routine `polint` of §3.1, and a sub-block which is presumed to be already located (and copied into an m by n array `ya`), the procedure looks like this:

```

SUBROUTINE polin2(x1a,x2a,ya,m,n,x1,x2,y,dy)
INTEGER m,n,NMAX,MMAX
REAL dy,x1,x2,y,x1a(m),x2a(n),ya(m,n)
PARAMETER (NMAX=20,MMAX=20)                                Maximum expected values of n and m.
C USES polint
Given arrays x1a(1:m) and x2a(1:n) of independent variables, and an m by n array of
function values ya(1:m,1:n), tabulated at the grid points defined by x1a and x2a; and
given values x1 and x2 of the independent variables; this routine returns an interpolated
function value y, and an accuracy indication dy (based only on the interpolation in the x1
direction, however).
INTEGER j,k
REAL ymtmp(MMAX),yntmp(NMAX)
do 12 j=1,m                                              Loop over rows.
    do 11 k=1,n                                          Copy the row into temporary storage.
        yntmp(k)=ya(j,k)
    enddo 11
    call polint(x2a,yntmp,n,x2,ymtmp(j),dy)           Interpolate answer into temporary stor-
    age.
12   enddo 12
call polint(x1a,yntmp,m,x1,y,dy)                         Do the final interpolation.
return
END

```

Higher Order for Smoothness: Bicubic Interpolation

We will give two methods that are in common use, and which are themselves not unrelated. The first is usually called *bicubic interpolation*.

Bicubic interpolation requires the user to specify at each grid point not just the function $y(x_1, x_2)$, but also the gradients $\partial y / \partial x_1 \equiv y_{,1}$, $\partial y / \partial x_2 \equiv y_{,2}$ and the cross derivative $\partial^2 y / \partial x_1 \partial x_2 \equiv y_{,12}$. Then an interpolating function that is *cubic* in the scaled coordinates t and u (equation 3.6.4) can be found, with the following properties: (i) The values of the function and the specified derivatives are reproduced exactly on the grid points, and (ii) the values of the function and the specified derivatives change continuously as the interpolating point crosses from one grid square to another.

It is important to understand that nothing in the equations of bicubic interpolation requires you to specify the extra derivatives *correctly!* The smoothness properties are tautologically “forced,” and have nothing to do with the “accuracy” of the specified derivatives. It is a separate problem for you to decide how to obtain the values that are specified. The better you do, the more *accurate* the interpolation will be. But it will be *smooth* no matter what you do.

Best of all is to know the derivatives analytically, or to be able to compute them accurately by numerical means, at the grid points. Next best is to determine them by numerical differencing from the functional values already tabulated on the grid. The relevant code would be something like this (using centered differencing):

$$\begin{aligned}
 y_{1A}(j,k) &= (y_A(j+1,k) - y_A(j-1,k)) / (x_{1A}(j+1) - x_{1A}(j-1)) \\
 y_{2A}(j,k) &= (y_A(j,k+1) - y_A(j,k-1)) / (x_{2A}(k+1) - x_{2A}(k-1)) \\
 y_{12A}(j,k) &= (y_A(j+1,k+1) - y_A(j+1,k-1) - y_A(j-1,k+1) + y_A(j-1,k-1)) \\
 &\quad / ((x_{1A}(j+1) - x_{1A}(j-1)) * (x_{2A}(k+1) - x_{2A}(k-1)))
 \end{aligned}$$

To do a bicubic interpolation within a grid square, given the function y and the derivatives y_1, y_2, y_{12} at each of the four corners of the square, there are two steps: First obtain the sixteen quantities c_{ij} , $i, j = 1, \dots, 4$ using the routine `bcucof` below. (The formulas that obtain the c 's from the function and derivative values are just a complicated linear transformation, with coefficients which, having been determined once in the mists of numerical history, can be tabulated and forgotten.) Next, substitute the c 's into any or all of the following bicubic formulas for function and derivatives, as desired:

$$\begin{aligned}
 y(x_1, x_2) &= \sum_{i=1}^4 \sum_{j=1}^4 c_{ij} t^{i-1} u^{j-1} \\
 y_{,1}(x_1, x_2) &= \sum_{i=1}^4 \sum_{j=1}^4 (i-1) c_{ij} t^{i-2} u^{j-1} (dt/dx_1) \\
 y_{,2}(x_1, x_2) &= \sum_{i=1}^4 \sum_{j=1}^4 (j-1) c_{ij} t^{i-1} u^{j-2} (du/dx_2) \\
 y_{,12}(x_1, x_2) &= \sum_{i=1}^4 \sum_{j=1}^4 (i-1)(j-1) c_{ij} t^{i-2} u^{j-2} (dt/dx_1)(du/dx_2)
 \end{aligned} \tag{3.6.6}$$

where t and u are again given by equation (3.6.4)

```
SUBROUTINE bcucof(y,y1,y2,y12,d1,d2,c)
REAL d1,d2,c(4,4),y(4),y1(4),y12(4),y2(4)
```

Given arrays y , y_1 , y_2 , and y_{12} , each of length 4, containing the function, gradients, and cross derivative at the four grid points of a rectangular grid cell (numbered counterclockwise from the lower left), and given d_1 and d_2 , the length of the grid cell in the 1- and 2-directions, this routine returns the table $c(1:4,1:4)$ that is used by routine `bcout` for bicubic interpolation.

```

INTEGER i,j,k,l
REAL d1d2,xx,cl(16),wt(16,16),x(16)

d1d2=d1*d2
do ii i=1,4                                Pack a temporary vector x.
    x(i)=y(i)

```

```

x(i+4)=y1(i)*d1
x(i+8)=y2(i)*d2
x(i+12)=y12(i)*d1d2
enddo 11
do 13 i=1,16           Matrix multiply by the stored table.
    xx=0.
    do 12 k=1,16
        xx=xx+wt(i,k)*x(k)
    enddo 12
    c1(i)=xx
enddo 13
l=0
do 15 i=1,4           Unpack the result into the output table.
    do 14 j=1,4
        l=l+1
        c(i,j)=c1(l)
    enddo 14
enddo 15
return
END

```

The implementation of equation (3.6.6), which performs a bicubic interpolation, returns the interpolated function value and the two gradient values, and uses the above routine `bcucof`, is simply:

```

* SUBROUTINE bcout(y,y1,y2,y12,x11,x1u,x21,x2u,x1,x2,ansy,
*   ansy1,ansy2)
REAL ansy,ansy1,ansy2,x1,x11,x1u,x2,x21,x2u,y(4),y1(4),
*   y12(4),y2(4)
C USES bcucof
      Bicubic interpolation within a grid square. Input quantities are y,y1,y2,y12 (as described
      in bcucof); x11 and x1u, the lower and upper coordinates of the grid square in the 1-
      direction; x21 and x2u likewise for the 2-direction; and x1,x2, the coordinates of the
      desired point for the interpolation. The interpolated function value is returned as ansy,
      and the interpolated gradient values as ansy1 and ansy2. This routine calls bcucof.
INTEGER i
REAL t,u,c(4,4)
call bcucof(y,y1,y2,y12,x1u-x11,x2u-x21,c)      Get the c's.
if(x1u.eq.x11.or.x2u.eq.x21)pause 'bad input in bcout'
t=(x1-x11)/(x1u-x11)                                Equation (3.6.4).
u=(x2-x21)/(x2u-x21)
ansy=0.
ansy2=0.
ansy1=0.
do 11 i=4,1,-1                                     Equation (3.6.6).
    ansy=t*ansy+((c(i,4)*u+c(i,3))*u+c(i,2))*u+c(i,1)
    ansy2=t*ansy2+(3.*c(i,4)*u+2.*c(i,3))*u+c(i,2)
    ansy1=u*ansy1+(3.*c(4,i)*t+2.*c(3,i))*t+c(2,i)
enddo 11
ansy1=ansy1/(x1u-x11)
ansy2=ansy2/(x2u-x21)
return
END

```

Higher Order for Smoothness: Bicubic Spline

The other common technique for obtaining smoothness in two-dimensional interpolation is the *bicubic spline*. Actually, this is equivalent to a special case

of bicubic interpolation: The interpolating function is of the same functional form as equation (3.6.6); the values of the derivatives at the grid points are, however, determined “globally” by one-dimensional splines. However, bicubic splines are usually implemented in a form that looks rather different from the above bicubic interpolation routines, instead looking much closer in form to the routine `polin2` above: To interpolate one functional value, one performs m one-dimensional splines across the rows of the table, followed by one additional one-dimensional spline down the newly created column. It is a matter of taste (and trade-off between time and memory) as to how much of this process one wants to precompute and store. Instead of precomputing and storing all the derivative information (as in bicubic interpolation), spline users typically precompute and store only one auxiliary table, of second derivatives in one direction only. Then one need only do spline *evaluations* (not constructions) for the m row splines; one must still do a construction *and* an evaluation for the final column spline. (Recall that a spline construction is a process of order N , while a spline evaluation is only of order $\log N$ — and that is just to find the place in the table!)

Here is a routine to precompute the auxiliary second-derivative table:

```
SUBROUTINE splie2(x1a,x2a,ya,m,n,y2a)
INTEGER m,n,NN
REAL x1a(m),x2a(n),y2a(m,n),ya(m,n)
PARAMETER (NN=100)                                Maximum expected value of n and m.
C USES spline
      Given an m by n tabulated function ya(1:m,1:n), and tabulated independent variables
      x2a(1:n), this routine constructs one-dimensional natural cubic splines of the rows of ya
      and returns the second-derivatives in the array y2a(1:m,1:n). (The array x1a is included
      in the argument list merely for consistency with routine splin2.)
INTEGER j,k
REAL y2tmp(NN),ytmp(NN)
do i3 j=1,m
  do i1 k=1,n
    ytmp(k)=ya(j,k)
  enddo i1
  call spline(x2a,ytmp,n,1.e30,1.e30,y2tmp)      Values 1×1030 signal a natural spline.
  do i2 k=1,n
    y2a(j,k)=y2tmp(k)
  enddo i2
enddo i3
return
END
```

After the above routine has been executed once, any number of bicubic spline interpolations can be performed by successive calls of the following routine:

```
SUBROUTINE splin2(x1a,x2a,ya,y2a,m,n,x1,x2,y)
INTEGER m,n,NN
REAL x1,x2,y,x1a(m),x2a(n),y2a(m,n),ya(m,n)
PARAMETER (NN=100)                                Maximum expected value of n and m.
C USES spline,splint
      Given x1a, x2a, ya, m, n as described in splie2 and y2a as produced by that routine;
      and given a desired interpolating point x1,x2; this routine returns an interpolated function
      value y by bicubic spline interpolation.
INTEGER j,k
REAL y2tmp(NN),ytmp(NN),yytmp(NN)
```

```

do 12 j=1,m
  do 11 k=1,n
    ytmp(k)=ya(j,k)
    y2tmp(k)=y2a(j,k)
  enddo 11
  call splint(x2a,ytmp,y2tmp,n,x2,yytmp(j))
enddo 12
call spline(x1a,yytmp,m,1.e30,1.e30,y2tmp)   Perform m evaluations of the row splines
call spline(x1a,yytmp,y2tmp,m,x1,y)           constructed by spline2, using the one-
                                               dimensional spline evaluator splint.
return
END

```

Chapter 4. Integration of Functions

4.0 Introduction

Numerical integration, which is also called *quadrature*, has a history extending back to the invention of calculus and before. The fact that integrals of elementary functions could not, in general, be computed analytically, while derivatives *could* be, served to give the field a certain panache, and to set it a cut above the arithmetic drudgery of numerical analysis during the whole of the 18th and 19th centuries.

With the invention of automatic computing, quadrature became just one numerical task among many, and not a very interesting one at that. Automatic computing, even the most primitive sort involving desk calculators and rooms full of “computers” (that were, until the 1950s, people rather than machines), opened to feasibility the much richer field of numerical integration of differential equations. Quadrature is merely the simplest special case: The evaluation of the integral

$$I = \int_a^b f(x)dx \quad (4.0.1)$$

is precisely equivalent to solving for the value $I \equiv y(b)$ the differential equation

$$\frac{dy}{dx} = f(x) \quad (4.0.2)$$

with the boundary condition

$$y(a) = 0 \quad (4.0.3)$$

Chapter 16 of this book deals with the numerical integration of differential equations. In that chapter, much emphasis is given to the concept of “variable” or “adaptive” choices of stepsize. We will not, therefore, develop that material here. If the function that you propose to integrate is sharply concentrated in one or more peaks, or if its shape is not readily characterized by a single length-scale, then it is likely that you should cast the problem in the form of (4.0.2)–(4.0.3) and use the methods of Chapter 16.

The quadrature methods in this chapter are based, in one way or another, on the obvious device of adding up the value of the integrand at a sequence of abscissas within the range of integration. The game is to obtain the integral as accurately as possible with the smallest number of function evaluations of the integrand. Just as in the case of interpolation (Chapter 3), one has the freedom to choose methods

of various *orders*, with higher order sometimes, but not always, giving higher accuracy. “Romberg integration,” which is discussed in §4.3, is a general formalism for making use of integration methods of a variety of different orders, and we recommend it highly.

Apart from the methods of this chapter and of Chapter 16, there are yet other methods for obtaining integrals. One important class is based on function approximation. We discuss explicitly the integration of functions by Chebyshev approximation (“Clenshaw-Curtis” quadrature) in §5.9. Although not explicitly discussed here, you ought to be able to figure out how to do *cubic spline quadrature* using the output of the routine `spline` in §3.3. (Hint: Integrate equation 3.3.3 over x analytically. See [1].)

Some integrals related to Fourier transforms can be calculated using the fast Fourier transform (FFT) algorithm. This is discussed in §13.9.

Multidimensional integrals are another whole multidimensional bag of worms. Section 4.6 is an introductory discussion in this chapter; the important technique of *Monte-Carlo integration* is treated in Chapter 7.

4.1 Classical Formulas for Equally Spaced Abscissas

Where would any book on numerical analysis be without Mr. Simpson and his “rule”? The classical formulas for integrating a function whose value is known at equally spaced steps have a certain elegance about them, and they are redolent with historical association. Through them, the modern numerical analyst communes with the spirits of his or her predecessors back across the centuries, as far as the time of Newton, if not farther. Alas, times *do* change; with the exception of two of the most modest formulas (“extended trapezoidal rule,” equation 4.1.11, and “extended

of various *orders*, with higher order sometimes, but not always, giving higher accuracy. “Romberg integration,” which is discussed in §4.3, is a general formalism for making use of integration methods of a variety of different orders, and we recommend it highly.

Apart from the methods of this chapter and of Chapter 16, there are yet other methods for obtaining integrals. One important class is based on function approximation. We discuss explicitly the integration of functions by Chebyshev approximation (“Clenshaw-Curtis” quadrature) in §5.9. Although not explicitly discussed here, you ought to be able to figure out how to do *cubic spline quadrature* using the output of the routine `spline` in §3.3. (Hint: Integrate equation 3.3.3 over x analytically. See [1].)

Some integrals related to Fourier transforms can be calculated using the fast Fourier transform (FFT) algorithm. This is discussed in §13.9.

Multidimensional integrals are another whole multidimensional bag of worms. Section 4.6 is an introductory discussion in this chapter; the important technique of *Monte-Carlo integration* is treated in Chapter 7.

4.1 Classical Formulas for Equally Spaced Abscissas

Where would any book on numerical analysis be without Mr. Simpson and his “rule”? The classical formulas for integrating a function whose value is known at equally spaced steps have a certain elegance about them, and they are redolent with historical association. Through them, the modern numerical analyst communes with the spirits of his or her predecessors back across the centuries, as far as the time of Newton, if not farther. Alas, times *do* change; with the exception of two of the most modest formulas (“extended trapezoidal rule,” equation 4.1.11, and “extended

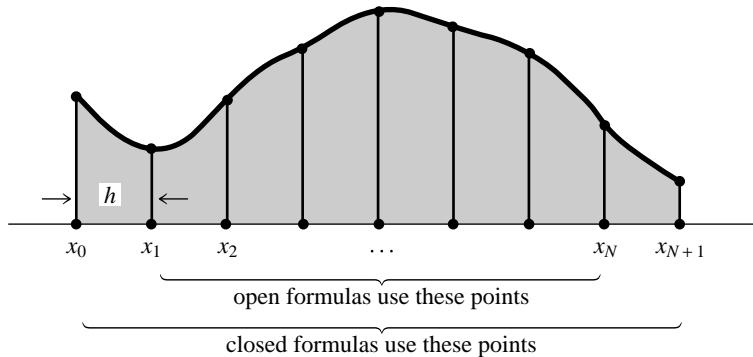

Figure 4.1.1. Quadrature formulas with equally spaced abscissas compute the integral of a function between x_0 and x_{N+1} . Closed formulas evaluate the function on the boundary points, while open formulas refrain from doing so (useful if the evaluation algorithm breaks down on the boundary points).

midpoint rule,” equation 4.1.19, see §4.2), the classical formulas are almost entirely useless. They are museum pieces, but beautiful ones.

Some notation: We have a sequence of abscissas, denoted $x_0, x_1, \dots, x_N, x_{N+1}$ which are spaced apart by a constant step h ,

$$x_i = x_0 + ih \quad i = 0, 1, \dots, N + 1 \quad (4.1.1)$$

A function $f(x)$ has known values at the x_i 's,

$$f(x_i) \equiv f_i \quad (4.1.2)$$

We want to integrate the function $f(x)$ between a lower limit a and an upper limit b , where a and b are each equal to one or the other of the x_i 's. An integration formula that uses the value of the function at the endpoints, $f(a)$ or $f(b)$, is called a *closed* formula. Occasionally, we want to integrate a function whose value at one or both endpoints is difficult to compute (e.g., the computation of f goes to a limit of zero over zero there, or worse yet has an integrable singularity there). In this case we want an *open* formula, which estimates the integral using only x_i 's strictly *between* a and b (see Figure 4.1.1).

The basic building blocks of the classical formulas are rules for integrating a function over a small number of intervals. As that number increases, we can find rules that are exact for polynomials of increasingly high order. (Keep in mind that higher order does not always imply higher accuracy in real cases.) A sequence of such closed formulas is now given.

Closed Newton-Cotes Formulas

Trapezoidal rule:

$$\int_{x_1}^{x_2} f(x) dx = h \left[\frac{1}{2} f_1 + \frac{1}{2} f_2 \right] + O(h^3 f'') \quad (4.1.3)$$

Here the error term $O()$ signifies that the true answer differs from the estimate by an amount that is the product of some numerical coefficient times h^3 times the value

of the function's second derivative somewhere in the interval of integration. The coefficient is knowable, and it can be found in all the standard references on this subject. The point at which the second derivative is to be evaluated is, however, unknowable. If we knew it, we could evaluate the function there and have a higher-order method! Since the product of a knowable and an unknowable is unknowable, we will streamline our formulas and write only $O(\cdot)$, instead of the coefficient.

Equation (4.1.3) is a two-point formula (x_1 and x_2). It is exact for polynomials up to and including degree 1, i.e., $f(x) = x$. One anticipates that there is a three-point formula exact up to polynomials of degree 2. This is true; moreover, by a cancellation of coefficients due to left-right symmetry of the formula, the three-point formula is exact for polynomials up to and including degree 3, i.e., $f(x) = x^3$:

Simpson's rule:

$$\int_{x_1}^{x_3} f(x)dx = h \left[\frac{1}{3}f_1 + \frac{4}{3}f_2 + \frac{1}{3}f_3 \right] + O(h^5 f^{(4)}) \quad (4.1.4)$$

Here $f^{(4)}$ means the fourth derivative of the function f evaluated at an unknown place in the interval. Note also that the formula gives the integral over an interval of size $2h$, so the coefficients add up to 2.

There is no lucky cancellation in the four-point formula, so it is also exact for polynomials up to and including degree 3.

Simpson's $\frac{3}{8}$ rule:

$$\int_{x_1}^{x_4} f(x)dx = h \left[\frac{3}{8}f_1 + \frac{9}{8}f_2 + \frac{9}{8}f_3 + \frac{3}{8}f_4 \right] + O(h^5 f^{(4)}) \quad (4.1.5)$$

The five-point formula again benefits from a cancellation:

Bode's rule:

$$\int_{x_1}^{x_5} f(x)dx = h \left[\frac{14}{45}f_1 + \frac{64}{45}f_2 + \frac{24}{45}f_3 + \frac{64}{45}f_4 + \frac{14}{45}f_5 \right] + O(h^7 f^{(6)}) \quad (4.1.6)$$

This is exact for polynomials up to and including degree 5.

At this point the formulas stop being named after famous personages, so we will not go any further. Consult [1] for additional formulas in the sequence.

Extrapolative Formulas for a Single Interval

We are going to depart from historical practice for a moment. Many texts would give, at this point, a sequence of "Newton-Cotes Formulas of Open Type." Here is an example:

$$\int_{x_0}^{x_5} f(x)dx = h \left[\frac{55}{24}f_1 + \frac{5}{24}f_2 + \frac{5}{24}f_3 + \frac{55}{24}f_4 \right] + O(h^5 f^{(4)})$$

Notice that the integral from $a = x_0$ to $b = x_5$ is estimated, using only the interior points x_1, x_2, x_3, x_4 . In our opinion, formulas of this type are not useful for the reasons that (i) they cannot usefully be strung together to get “extended” rules, as we are about to do with the closed formulas, and (ii) for all other possible uses they are dominated by the Gaussian integration formulas which we will introduce in §4.5.

Instead of the Newton-Cotes open formulas, let us set out the formulas for estimating the integral in the single interval from x_0 to x_1 , using values of the function f at x_1, x_2, \dots . These will be useful building blocks for the “extended” open formulas.

$$\int_{x_0}^{x_1} f(x)dx = h[f_1] + O(h^2 f') \quad (4.1.7)$$

$$\int_{x_0}^{x_1} f(x)dx = h\left[\frac{3}{2}f_1 - \frac{1}{2}f_2\right] + O(h^3 f'') \quad (4.1.8)$$

$$\int_{x_0}^{x_1} f(x)dx = h\left[\frac{23}{12}f_1 - \frac{16}{12}f_2 + \frac{5}{12}f_3\right] + O(h^4 f^{(3)}) \quad (4.1.9)$$

$$\int_{x_0}^{x_1} f(x)dx = h\left[\frac{55}{24}f_1 - \frac{59}{24}f_2 + \frac{37}{24}f_3 - \frac{9}{24}f_4\right] + O(h^5 f^{(4)}) \quad (4.1.10)$$

Perhaps a word here would be in order about how formulas like the above can be derived. There are elegant ways, but the most straightforward is to write down the basic form of the formula, replacing the numerical coefficients with unknowns, say p, q, r, s . Without loss of generality take $x_0 = 0$ and $x_1 = 1$, so $h = 1$. Substitute in turn for $f(x)$ (and for f_1, f_2, f_3, f_4) the functions $f(x) = 1$, $f(x) = x$, $f(x) = x^2$, and $f(x) = x^3$. Doing the integral in each case reduces the left-hand side to a number, and the right-hand side to a linear equation for the unknowns p, q, r, s . Solving the four equations produced in this way gives the coefficients.

Extended Formulas (Closed)

If we use equation (4.1.3) $N - 1$ times, to do the integration in the intervals $(x_1, x_2), (x_2, x_3), \dots, (x_{N-1}, x_N)$, and then add the results, we obtain an “extended” or “composite” formula for the integral from x_1 to x_N .

Extended trapezoidal rule:

$$\begin{aligned} \int_{x_1}^{x_N} f(x)dx &= h\left[\frac{1}{2}f_1 + f_2 + f_3 + \right. \\ &\quad \left. \dots + f_{N-1} + \frac{1}{2}f_N\right] + O\left(\frac{(b-a)^3 f''}{N^2}\right) \end{aligned} \quad (4.1.11)$$

Here we have written the error estimate in terms of the interval $b - a$ and the number of points N instead of in terms of h . This is clearer, since one is usually holding a and b fixed and wanting to know (e.g.) how much the error will be decreased

by taking twice as many steps (in this case, it is by a factor of 4). In subsequent equations we will show *only* the scaling of the error term with the number of steps.

For reasons that will not become clear until §4.2, equation (4.1.11) is in fact the most important equation in this section, the basis for most practical quadrature schemes.

The *extended formula of order $1/N^3$* is:

$$\int_{x_1}^{x_N} f(x)dx = h \left[\frac{5}{12}f_1 + \frac{13}{12}f_2 + f_3 + f_4 + \cdots + f_{N-2} + \frac{13}{12}f_{N-1} + \frac{5}{12}f_N \right] + O\left(\frac{1}{N^3}\right) \quad (4.1.12)$$

(We will see in a moment where this comes from.)

If we apply equation (4.1.4) to successive, nonoverlapping *pairs* of intervals, we get the *extended Simpson's rule*:

$$\int_{x_1}^{x_N} f(x)dx = h \left[\frac{1}{3}f_1 + \frac{4}{3}f_2 + \frac{2}{3}f_3 + \frac{4}{3}f_4 + \cdots + \frac{2}{3}f_{N-2} + \frac{4}{3}f_{N-1} + \frac{1}{3}f_N \right] + O\left(\frac{1}{N^4}\right) \quad (4.1.13)$$

Notice that the $2/3$, $4/3$ alternation continues throughout the interior of the evaluation. Many people believe that the wobbling alternation somehow contains deep information about the integral of their function that is not apparent to mortal eyes. In fact, the alternation is an artifact of using the building block (4.1.4). Another extended formula with the same order as Simpson's rule is

$$\begin{aligned} \int_{x_1}^{x_N} f(x)dx = h & \left[\frac{3}{8}f_1 + \frac{7}{6}f_2 + \frac{23}{24}f_3 + f_4 + f_5 + \cdots + f_{N-4} + f_{N-3} + \frac{23}{24}f_{N-2} + \frac{7}{6}f_{N-1} + \frac{3}{8}f_N \right] \\ & + O\left(\frac{1}{N^4}\right) \end{aligned} \quad (4.1.14)$$

This equation is constructed by fitting cubic polynomials through successive groups of four points; we defer details to §18.3, where a similar technique is used in the solution of integral equations. We can, however, tell you where equation (4.1.12) came from. It is Simpson's extended rule, averaged with a modified version of itself in which the first and last step are done with the trapezoidal rule (4.1.3). The trapezoidal step is *two* orders lower than Simpson's rule; however, its contribution to the integral goes down as an additional power of N (since it is used only twice, not N times). This makes the resulting formula of degree *one* less than Simpson.

Extended Formulas (Open and Semi-open)

We can construct open and semi-open extended formulas by adding the closed formulas (4.1.11)–(4.1.14), evaluated for the second and subsequent steps, to the extrapolative open formulas for the first step, (4.1.7)–(4.1.10). As discussed immediately above, it is consistent to use an end step that is of one order lower than the (repeated) interior step. The resulting formulas for an interval open at both ends are as follows:

Equations (4.1.7) and (4.1.11) give

$$\int_{x_1}^{x_N} f(x)dx = h \left[\frac{3}{2}f_2 + f_3 + f_4 + \cdots + f_{N-2} + \frac{3}{2}f_{N-1} \right] + O\left(\frac{1}{N^2}\right) \quad (4.1.15)$$

Equations (4.1.8) and (4.1.12) give

$$\begin{aligned} \int_{x_1}^{x_N} f(x)dx &= h \left[\frac{23}{12}f_2 + \frac{7}{12}f_3 + f_4 + f_5 + \right. \\ &\quad \cdots + f_{N-3} + \frac{7}{12}f_{N-2} + \frac{23}{12}f_{N-1} \left. \right] \\ &\quad + O\left(\frac{1}{N^3}\right) \end{aligned} \quad (4.1.16)$$

Equations (4.1.9) and (4.1.13) give

$$\begin{aligned} \int_{x_1}^{x_N} f(x)dx &= h \left[\frac{27}{12}f_2 + 0 + \frac{13}{12}f_4 + \frac{4}{3}f_5 + \right. \\ &\quad \cdots + \frac{4}{3}f_{N-4} + \frac{13}{12}f_{N-3} + 0 + \frac{27}{12}f_{N-1} \left. \right] \\ &\quad + O\left(\frac{1}{N^4}\right) \end{aligned} \quad (4.1.17)$$

The interior points alternate $4/3$ and $2/3$. If we want to avoid this alternation, we can combine equations (4.1.9) and (4.1.14), giving

$$\begin{aligned} \int_{x_1}^{x_N} f(x)dx &= h \left[\frac{55}{24}f_2 - \frac{1}{6}f_3 + \frac{11}{8}f_4 + f_5 + f_6 + f_7 + \right. \\ &\quad \cdots + f_{N-5} + f_{N-4} + \frac{11}{8}f_{N-3} - \frac{1}{6}f_{N-2} + \frac{55}{24}f_{N-1} \left. \right] \\ &\quad + O\left(\frac{1}{N^4}\right) \end{aligned} \quad (4.1.18)$$

We should mention in passing another extended open formula, for use where the limits of integration are located halfway between tabulated abscissas. This one is known as the *extended midpoint rule*, and is accurate to the same order as (4.1.15):

$$\begin{aligned} \int_{x_1}^{x_N} f(x)dx &= h[f_{3/2} + f_{5/2} + f_{7/2} + \\ &\quad \cdots + f_{N-3/2} + f_{N-1/2}] + O\left(\frac{1}{N^2}\right) \end{aligned} \quad (4.1.19)$$

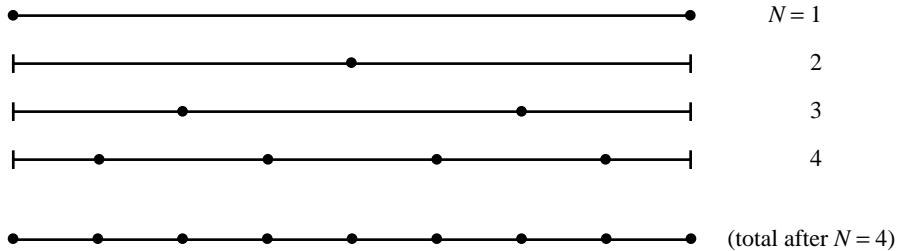

Figure 4.2.1. Sequential calls to the routine `trapzd` incorporate the information from previous calls and evaluate the integrand only at those new points necessary to refine the grid. The bottom line shows the totality of function evaluations after the fourth call. The routine `qsimp`, by weighting the intermediate results, transforms the trapezoid rule into Simpson's rule with essentially no additional overhead.

There are also formulas of higher order for this situation, but we will refrain from giving them.

The *semi-open formulas* are just the obvious combinations of equations (4.1.11)–(4.1.14) with (4.1.15)–(4.1.18), respectively. At the closed end of the integration, use the weights from the former equations; at the open end use the weights from the latter equations. One example should give the idea, the formula with error term decreasing as $1/N^3$ which is closed on the right and open on the left:

$$\int_{x_1}^{x_N} f(x)dx = h \left[\frac{23}{12}f_2 + \frac{7}{12}f_3 + f_4 + f_5 + \dots + f_{N-2} + \frac{13}{12}f_{N-1} + \frac{5}{12}f_N \right] + O\left(\frac{1}{N^3}\right) \quad (4.1.20)$$

4.2 Elementary Algorithms

Our starting point is equation (4.1.11), the extended trapezoidal rule. There are two facts about the trapezoidal rule which make it the starting point for a variety of algorithms. One fact is rather obvious, while the second is rather “deep.”

The obvious fact is that, for a fixed function $f(x)$ to be integrated between fixed limits a and b , one can double the number of intervals in the extended trapezoidal rule without losing the benefit of previous work. The coarsest implementation of the trapezoidal rule is to average the function at its endpoints a and b . The first stage of refinement is to add to this average the value of the function at the halfway point. The second stage of refinement is to add the values at the $1/4$ and $3/4$ points. And so on (see Figure 4.2.1).

Without further ado we can write a routine with this kind of logic to it:

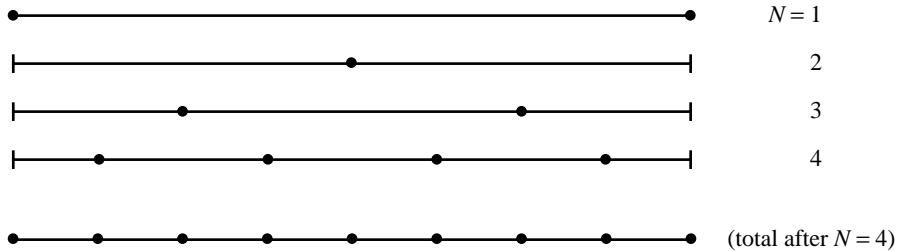

Figure 4.2.1. Sequential calls to the routine `trapzd` incorporate the information from previous calls and evaluate the integrand only at those new points necessary to refine the grid. 4.2 Elementary Algorithms

Our starting point is equation (4.1.11), the extended trapezoidal rule. There are two facts about the trapezoidal rule which make it the starting point for a variety of algorithms. One fact is rather obvious, while the second is rather “deep.”

The obvious fact is that, for a fixed function $f(x)$ to be integrated between fixed limits a and b , one can double the number of intervals in the extended trapezoidal rule without losing the benefit of previous work. The coarsest implementation of the trapezoidal rule is to average the function at its endpoints a and b . The first stage of refinement is to add to this average the value of the function at the halfway point. The second stage of refinement is to add the values at the $1/4$ and $3/4$ points. And so on (see Figure 4.2.1).

Without further ado we can write a routine with this kind of logic to it:

```
SUBROUTINE trapzd(func,a,b,s,n)
INTEGER n
REAL a,b,s,func
EXTERNAL func
```

This routine computes the nth stage of refinement of an extended trapezoidal rule. func is input as the name of the function to be integrated between limits a and b, also input. When called with n=1, the routine returns as s the crudest estimate of $\int_a^b f(x)dx$. Subsequent calls with n=2,3,... (in that sequential order) will improve the accuracy of s by adding 2^{n-2} additional interior points. s should not be modified between sequential calls.

```
INTEGER it,j
REAL del,sum,tnm,x
if (n.eq.1) then
  s=0.5*(b-a)*(func(a)+func(b))
else
  it=2**n-2
  tnm=it
  del=(b-a)/tnm           This is the spacing of the points to be added.
  x=a+0.5*del
  sum=0.
  do 11 j=1,it
    sum=sum+func(x)
    x=x+del
  enddo 11
  s=0.5*(s+(b-a)*sum/tnm)   This replaces s by its refined value.
endif
return
END
```

The above routine (trapzd) is a workhorse that can be harnessed in several ways. The simplest and crudest is to integrate a function by the extended trapezoidal rule where you know in advance (we can't imagine how!) the number of steps you want. If you want $2^M + 1$, you can accomplish this by the fragment

```
do 11 j=1,m+1
  call trapzd(func,a,b,s,j)
enddo 11
```

with the answer returned as s.

Much better, of course, is to refine the trapezoidal rule until some specified degree of accuracy has been achieved:

```
SUBROUTINE qtrap(func,a,b,s)
INTEGER JMAX
REAL a,b,func,s,EPS
EXTERNAL func
PARAMETER (EPS=1.e-6, JMAX=20)
C USES trapzd
  Returns as s the integral of the function func from a to b. The parameters EPS can be set
  to the desired fractional accuracy and JMAX so that  $2^{JMAX-1}$  is the maximum
  allowed number of steps. Integration is performed by the trapezoidal rule.
INTEGER j
REAL olds
olds=-1.e30          Any number that is unlikely to be the average of the function
do 11 j=1,JMAX        at its endpoints will do here.
  call trapzd(func,a,b,s,j)
  if (j.gt.5) then      Avoid spurious early convergence.
    if (abs(s-olds).lt.EPS*abs(olds).or.
*      (s.eq.0..and.old.s.eq.0.)) return
    endif
    olds=s
  enddo 11
  pause 'too many steps in qtrap'
END
```

Unsophisticated as it is, routine `qtrap` is in fact a fairly robust way of doing integrals of functions that are not very smooth. Increased sophistication will usually translate into a higher-order method whose efficiency will be greater only for sufficiently smooth integrands. `qtrap` is the method of choice, e.g., for an integrand which is a function of a variable that is linearly interpolated between measured data points. Be sure that you do not require too stringent an EPS, however: If `qtrap` takes too many steps in trying to achieve your required accuracy, accumulated roundoff errors may start increasing, and the routine may never converge. A value 10^{-6} is just on the edge of trouble for most 32-bit machines; it is achievable when the convergence is moderately rapid, but not otherwise.

We come now to the “deep” fact about the extended trapezoidal rule, equation (4.1.11). It is this: The error of the approximation, which begins with a term of order $1/N^2$, is in fact *entirely even* when expressed in powers of $1/N$. This follows directly from the *Euler-Maclaurin Summation Formula*,

$$\int_{x_1}^{x_N} f(x)dx = h \left[\frac{1}{2}f_1 + f_2 + f_3 + \cdots + f_{N-1} + \frac{1}{2}f_N \right] - \frac{B_2 h^2}{2!}(f'_N - f'_1) - \cdots - \frac{B_{2k} h^{2k}}{(2k)!}(f_N^{(2k-1)} - f_1^{(2k-1)}) - \cdots \quad (4.2.1)$$

Here B_{2k} is a *Bernoulli number*, defined by the generating function

$$\frac{t}{e^t - 1} = \sum_{n=0}^{\infty} B_n \frac{t^n}{n!} \quad (4.2.2)$$

with the first few even values (odd values vanish except for $B_1 = -1/2$)

$$\begin{aligned} B_0 &= 1 & B_2 &= \frac{1}{6} & B_4 &= -\frac{1}{30} & B_6 &= \frac{1}{42} \\ B_8 &= -\frac{1}{30} & B_{10} &= \frac{5}{66} & B_{12} &= -\frac{691}{2730} \end{aligned} \quad (4.2.3)$$

Equation (4.2.1) is not a convergent expansion, but rather only an asymptotic expansion whose error when truncated at any point is always less than twice the magnitude of the first neglected term. The reason that it is not convergent is that the Bernoulli numbers become very large, e.g.,

$$B_{50} = \frac{495057205241079648212477525}{66}$$

The key point is that only even powers of h occur in the error series of (4.2.1). This fact is not, in general, shared by the higher-order quadrature rules in §4.1. For example, equation (4.1.12) has an error series beginning with $O(1/N^3)$, but continuing with all subsequent powers of N : $1/N^4, 1/N^5$, etc.

Suppose we evaluate (4.1.11) with N steps, getting a result S_N , and then again with $2N$ steps, getting a result S_{2N} . (This is done by any two consecutive calls of

`trapzd.`) The leading error term in the second evaluation will be $1/4$ the size of the error in the first evaluation. Therefore the combination

$$S = \frac{4}{3}S_{2N} - \frac{1}{3}S_N \quad (4.2.4)$$

will cancel out the leading order error term. But there *is* no error term of order $1/N^3$, by (4.2.1). The surviving error is of order $1/N^4$, the same as Simpson's rule. In fact, it should not take long for you to see that (4.2.4) is *exactly* Simpson's rule (4.1.13), alternating $2/3$'s, $4/3$'s, and all. This is the preferred method for evaluating that rule, and we can write it as a routine exactly analogous to `qtrap` above:

```
SUBROUTINE qsimp(func,a,b,s)
INTEGER JMAX
REAL a,b,func,s,EPS
EXTERNAL func
PARAMETER (EPS=1.e-6, JMAX=20)
C USES trapzd
      Returns as s the integral of the function func from a to b. The parameters EPS can be set
      to the desired fractional accuracy and JMAX so that  $2^{JMAX-1}$  is the maximum
      allowed number of steps. Integration is performed by Simpson's rule.
INTEGER j
REAL os,ost,st
ost=-1.e30
os= -1.e30
do ii j=1,JMAX
  call trapzd(func,a,b,st,j)
  s=(4.*st-ost)/3.          Compare equation (4.2.4), above.
  if (j.gt.5) then          Avoid spurious early convergence.
    if (abs(s-os).lt.EPS*abs(os).or.
       (s.eq.0..and.os.eq.0.)) return
  endif
  os=s
  ost=st
enddo ii
pause 'too many steps in qsimp'
END
```

The routine `qsimp` will in general be more efficient than `qtrap` (i.e., require fewer function evaluations) when the function to be integrated has a finite 4th derivative (i.e., a continuous 3rd derivative). The combination of `qsimp` and its necessary workhorse `trapzd` is a good one for light-duty work.

4.3 Romberg Integration

We can view Romberg's method as the natural generalization of the routine `qsimp` in the last section to integration schemes that are of higher order than Simpson's rule. The basic idea is to use the results from k successive refinements of the extended trapezoidal rule (implemented in `trapzd`) to remove all terms in the error series up to but not including $O(1/N^{2k})$. The routine `qsimp` is the case of $k = 2$. This is one example of a very general idea that goes by the name of *Richardson's deferred approach to the limit*: Perform some numerical algorithm for various values of a parameter h , and then extrapolate the result to the continuum limit $h = 0$.

Equation (4.2.4), which subtracts off the leading error term, is a special case of polynomial extrapolation. In the more general Romberg case, we can use Neville's algorithm (see §3.1) to extrapolate the successive refinements to zero stepsize. Neville's algorithm can in fact be coded very concisely within a Romberg integration routine. For clarity of the program, however, it seems better to do the extrapolation by subroutine call to `polint`, already given in §3.1.

```
SUBROUTINE qromb(func,a,b,ss)
INTEGER JMAX,JMAXP,K,KM
REAL a,b,func,ss,EPS
EXTERNAL func
PARAMETER (EPS=1.e-6, JMAX=20, JMAXP=JMAX+1, K=5, KM=K-1)
C USES polint,trapzd
    Returns as ss the integral of the function func from a to b. Integration is performed by
    Romberg's method of order 2K, where, e.g., K=2 is Simpson's rule.
    Parameters: EPS is the fractional accuracy desired, as determined by the extrapolation
    error estimate; JMAX limits the total number of steps; K is the number of points used in
    the extrapolation.
    INTEGER j
    REAL dss,h(JMAXP),s(JMAXP)           These store the successive trapezoidal approximations
    h(1)=1.                                and their relative stepsizes.
    do ii j=1,JMAX
        call trapzd(func,a,b,s(j),j)
        if (j.ge.K) then
            call polint(h(j-KM),s(j-KM),K,0.,ss,dss)
            if (abs(dss).le.EPS*abs(ss)) return
        endif
        s(j+1)=s(j)
        h(j+1)=0.25*h(j)
    enddo ii
    pause 'too many steps in qromb'
END
```

This is a key step: The factor is 0.25 even though the stepsize is decreased by only 0.5. This makes the extrapolation a polynomial in h^2 as allowed by equation (4.2.1), not just a polynomial in h .

The routine `qromb`, along with its required `trapzd` and `polint`, is quite powerful for sufficiently smooth (e.g., analytic) integrands, integrated over intervals which contain no singularities, and where the endpoints are also nonsingular. `qromb`, in such circumstances, takes many, *many* fewer function evaluations than either of the routines in §4.2. For example, the integral

$$\int_0^2 x^4 \log(x + \sqrt{x^2 + 1}) dx$$

4.3 Romberg Integration

We can view Romberg's method as the natural generalization of the routine `qsimp` in the last section to integration schemes that are of higher order than Simpson's rule. The basic idea is to use the results from k successive refinements of the extended trapezoidal rule (implemented in `trapzd`) to remove all terms in the error series up to but not including $O(1/N^{2k})$. The routine `qsimp` is the case of $k = 2$. This is one example of a very general idea that goes by the name of *Richardson's deferred approach to the limit*: Perform some numerical algorithm for various values of a parameter h , and then extrapolate the result to the continuum limit $h = 0$.

Equation (4.2.4), which subtracts off the leading error term, is a special case of polynomial extrapolation. In the more general Romberg case, we can use Neville's algorithm (see §3.1) to extrapolate the successive refinements to zero stepsize. Neville's algorithm can in fact be coded very concisely within a Romberg integration routine. For clarity of the program, however, it seems better to do the extrapolation by subroutine call to `polint`, already given in §3.1.

```
SUBROUTINE qromb(func,a,b,ss)
INTEGER JMAX,JMAXP,K,KM
REAL a,b,func,ss,EPS
EXTERNAL func
PARAMETER (EPS=1.e-6, JMAX=20, JMAXP=JMAX+1, K=5, KM=K-1)
C USES polint,trapzd
    Returns as ss the integral of the function func from a to b. Integration is performed by
    Romberg's method of order 2K, where, e.g., K=2 is Simpson's rule.
    Parameters: EPS is the fractional accuracy desired, as determined by the extrapolation
    error estimate; JMAX limits the total number of steps; K is the number of points used in
    the extrapolation.
    INTEGER j
    REAL dss,h(JMAXP),s(JMAXP)           These store the successive trapezoidal approximations
    h(1)=1.                                and their relative stepsizes.
    do ii j=1,JMAX
        call trapzd(func,a,b,s(j),j)
        if (j.ge.K) then
            call polint(h(j-KM),s(j-KM),K,0.,ss,dss)
            if (abs(dss).le.EPS*abs(ss)) return
        endif
        s(j+1)=s(j)
        h(j+1)=0.25*h(j)
    enddo ii
    pause 'too many steps in qromb'
END
```

This is a key step: The factor is 0.25 even though the stepsize is decreased by only 0.5. This makes the extrapolation a polynomial in h^2 as allowed by equation (4.2.1), not just a polynomial in h .

The routine `qromb`, along with its required `trapzd` and `polint`, is quite powerful for sufficiently smooth (e.g., analytic) integrands, integrated over intervals which contain no singularities, and where the endpoints are also nonsingular. `qromb`, in such circumstances, takes many, *many* fewer function evaluations than either of the routines in §4.2. For example, the integral

$$\int_0^2 x^4 \log(x + \sqrt{x^2 + 1}) dx$$

converges (with parameters as shown above) on the very first extrapolation, after just 5 calls to `trapzd`, while `qsimp` requires 8 calls (8 times as many evaluations of the integrand) and `qtrap` requires 13 calls (making 256 times as many evaluations of the integrand).

4.4 Improper Integrals

For our present purposes, an integral will be “improper” if it has any of the following problems:

- its integrand goes to a finite limiting value at finite upper and lower limits, but cannot be evaluated *right on* one of those limits (e.g., $\sin x/x$ at $x = 0$)
- its upper limit is ∞ , or its lower limit is $-\infty$
- it has an integrable singularity at either limit (e.g., $x^{-1/2}$ at $x = 0$)
- it has an integrable singularity at a known place between its upper and lower limits
- it has an integrable singularity at an unknown place between its upper and lower limits

If an integral is infinite (e.g., $\int_1^\infty x^{-1} dx$), or does not exist in a limiting sense (e.g., $\int_{-\infty}^\infty \cos x dx$), we do not call it improper; we call it impossible. No amount of clever algorithmics will return a meaningful answer to an ill-posed problem.

In this section we will generalize the techniques of the preceding two sections to cover the first four problems on the above list. A more advanced discussion of quadrature with integrable singularities occurs in Chapter 18, notably §18.3. The fifth problem, singularity at unknown location, can really only be handled by the use of a variable stepsize differential equation integration routine, as will be given in Chapter 16.

We need a workhorse like the extended trapezoidal rule (equation 4.1.11), but one which is an *open* formula in the sense of §4.1, i.e., does not require the integrand to be evaluated at the endpoints. Equation (4.1.19), the extended midpoint rule, is the best choice. The reason is that (4.1.19) shares with (4.1.11) the “deep” property of having an error series that is entirely even in h . Indeed there is a formula, not as well known as it ought to be, called the *Second Euler-Maclaurin summation formula*,

$$\begin{aligned} \int_{x_1}^{x_N} f(x) dx &= h[f_{3/2} + f_{5/2} + f_{7/2} + \cdots + f_{N-3/2} + f_{N-1/2}] \\ &\quad + \frac{B_2 h^2}{4}(f'_N - f'_1) + \cdots \\ &\quad + \frac{B_{2k} h^{2k}}{(2k)!}(1 - 2^{-2k+1})(f_N^{(2k-1)} - f_1^{(2k-1)}) + \cdots \end{aligned} \tag{4.4.1}$$

converges (with parameters as shown above) on the very first extrapolation, after just 5 calls to `trapzd`, while `qsimp` requires 8 calls (8 times as many evaluations of the integrand) and `qtrap` requires 13 calls (making 256 times as many evaluations of the integrand).

4.4 Improper Integrals

For our present purposes, an integral will be “improper” if it has any of the following problems:

- its integrand goes to a finite limiting value at finite upper and lower limits, but cannot be evaluated *right on* one of those limits (e.g., $\sin x/x$ at $x = 0$)
- its upper limit is ∞ , or its lower limit is $-\infty$
- it has an integrable singularity at either limit (e.g., $x^{-1/2}$ at $x = 0$)
- it has an integrable singularity at a known place between its upper and lower limits
- it has an integrable singularity at an unknown place between its upper and lower limits

If an integral is infinite (e.g., $\int_1^\infty x^{-1} dx$), or does not exist in a limiting sense (e.g., $\int_{-\infty}^\infty \cos x dx$), we do not call it improper; we call it impossible. No amount of clever algorithmics will return a meaningful answer to an ill-posed problem.

In this section we will generalize the techniques of the preceding two sections to cover the first four problems on the above list. A more advanced discussion of quadrature with integrable singularities occurs in Chapter 18, notably §18.3. The fifth problem, singularity at unknown location, can really only be handled by the use of a variable stepsize differential equation integration routine, as will be given in Chapter 16.

We need a workhorse like the extended trapezoidal rule (equation 4.1.11), but one which is an *open* formula in the sense of §4.1, i.e., does not require the integrand to be evaluated at the endpoints. Equation (4.1.19), the extended midpoint rule, is the best choice. The reason is that (4.1.19) shares with (4.1.11) the “deep” property of having an error series that is entirely even in h . Indeed there is a formula, not as well known as it ought to be, called the *Second Euler-Maclaurin summation formula*,

$$\begin{aligned} \int_{x_1}^{x_N} f(x) dx &= h[f_{3/2} + f_{5/2} + f_{7/2} + \cdots + f_{N-3/2} + f_{N-1/2}] \\ &\quad + \frac{B_2 h^2}{4}(f'_N - f'_1) + \cdots \\ &\quad + \frac{B_{2k} h^{2k}}{(2k)!}(1 - 2^{-2k+1})(f_N^{(2k-1)} - f_1^{(2k-1)}) + \cdots \end{aligned} \tag{4.4.1}$$

This equation can be derived by writing out (4.2.1) with stepsize h , then writing it out again with stepsize $h/2$, then subtracting the first from twice the second.

It is not possible to double the number of steps in the extended midpoint rule and still have the benefit of previous function evaluations (try it!). However, it is possible to *triple* the number of steps and do so. Shall we do this, or double and accept the loss? On the average, tripling does a factor $\sqrt{3}$ of unnecessary work, since the “right” number of steps for a desired accuracy criterion may in fact fall anywhere in the logarithmic interval implied by tripling. For doubling, the factor is only $\sqrt{2}$, but we lose an extra factor of 2 in being unable to use all the previous evaluations. Since $1.732 < 2 \times 1.414$, it is better to triple.

Here is the resulting routine, which is directly comparable to trapzd.

```
SUBROUTINE midpnt(func,a,b,s,n)
INTEGER n
REAL a,b,s,func
EXTERNAL func
This routine computes the nth stage of refinement of an extended midpoint rule. func is
input as the name of the function to be integrated between limits a and b, also input. When
called with n=1, the routine returns as s the crudest estimate of  $\int_a^b f(x)dx$ . Subsequent
calls with n=2,3,... (in that sequential order) will improve the accuracy of s by adding
(2/3)  $\times 3^{n-1}$  additional interior points. s should not be modified between sequential calls.
INTEGER it,j
REAL ddel,del,sum,tnm,x
if (n.eq.1) then
    s=(b-a)*func(0.5*(a+b))
else
    it=3**n-2
    tnm=it
    del=(b-a)/(3.*tnm)
    ddel=del+del
    x=a+0.5*del
    sum=0.
    do 11 j=1,it
        sum=sum+func(x)
        x=x+ddel
        sum=sum+func(x)
        x=x+del
    enddo 11
    s=(s+(b-a)*sum/tnm)/3.   The new sum is combined with the old integral to give a
endif                                         refined integral.
return
END
```

The routine midpnt can exactly replace trapzd in a driver routine like qtrap (§4.2); one simply changes call trapzd to call midpnt, and perhaps also decreases the parameter JMAX since 3^{JMAX-1} (from step tripling) is a much larger number than 2^{JMAX-1} (step doubling).

The open formula implementation analogous to Simpson’s rule (qsimp in §4.2) substitutes midpnt for trapzd and decreases JMAX as above, but now also changes the extrapolation step to be

$$s=(9.*st-ost)/8.$$

since, when the number of steps is tripled, the error decreases to 1/9th its size, not 1/4th as with step doubling.

Either the modified `qtrap` or the modified `qsimp` will fix the first problem on the list at the beginning of this section. Yet more sophisticated is to generalize Romberg integration in like manner:

```
SUBROUTINE qromo(func,a,b,ss,choose)
INTEGER JMAX,JMAXP,K,KM
REAL a,b,func,ss,EPS
EXTERNAL func,choose
PARAMETER (EPS=1.e-6, JMAX=14, JMAXP=JMAX+1, K=5, KM=K-1)
C USES polint
      Romberg integration on an open interval. Returns as ss the integral of the function func
      from a to b, using any specified integrating subroutine choose and Romberg's method.
      Normally choose will be an open formula, not evaluating the function at the endpoints. It
      is assumed that choose triples the number of steps on each call, and that its error series
      contains only even powers of the number of steps. The routines midpnt, midinf, midsq1,
      midsqu, are possible choices for choose. The parameters have the same meaning as in
      qromb.
      INTEGER j
      REAL dss,h(JMAXP),s(JMAXP)
      h(1)=1.
      do ii j=1,JMAX
         call choose(func,a,b,s(j),j)
         if (j.ge.K) then
            call polint(h(j-KM),s(j-KM),K,0.,ss,dss)
            if (abs(dss).le.EPS*abs(ss)) return
         endif
         s(j+1)=s(j)
         h(j+1)=h(j)/9.           This is where the assumption of step tripling and an even
      enddo ii                           error series is used.
      pause 'too many steps in qromo'
END
```

The differences between `qromo` and `qromb` (§4.3) are so slight that it is perhaps gratuitous to list `qromo` in full. It, however, is an excellent driver routine for solving all the other problems of improper integrals in our first list (except the intractable fifth), as we shall now see.

The basic trick for improper integrals is to make a change of variables to eliminate the singularity, or to map an infinite range of integration to a finite one. For example, the identity

$$\int_a^b f(x)dx = \int_{1/b}^{1/a} \frac{1}{t^2} f\left(\frac{1}{t}\right) dt \quad ab > 0 \quad (4.4.2)$$

can be used with either $b \rightarrow \infty$ and a positive, or with $a \rightarrow -\infty$ and b negative, and works for any function which decreases towards infinity faster than $1/x^2$.

You can make the change of variable implied by (4.4.2) either analytically and then use (e.g.) `qromo` and `midpnt` to do the numerical evaluation, or you can let the numerical algorithm make the change of variable for you. We prefer the latter method as being more transparent to the user. To implement equation (4.4.2) we simply write a modified version of `midpnt`, called `midinf`, which allows b to be infinite (or, more precisely, a very large number on your particular machine, such as 1×10^{30}), or a to be negative and infinite.

```

SUBROUTINE midinf(funk,aa,bb,s,n)
INTEGER n
REAL aa,bb,s,funk
EXTERNAL funk
This routine is an exact replacement for midpnt, i.e., returns as s the nth stage of refinement
of the integral of funk from aa to bb, except that the function is evaluated at evenly spaced
points in 1/x rather than in x. This allows the upper limit bb to be as large and positive
as the computer allows, or the lower limit aa to be as large and negative, but not both.
aa and bb must have the same sign.
INTEGER it,j
REAL a,b,ddel,del,sum,tnm,func,x
func(x)=funk(1./x)/x**2      This statement function effects the change of variable.
b=1./aa                      These two statements change the limits of integration ac-
a=1./bb                      cordingly.
if (n.eq.1) then              From this point on, the routine is exactly identical to midpnt.
    s=(b-a)*func(0.5*(a+b))
else
    it=3**n-2
    tnm=it
    del=(b-a)/(3.*tnm)
    ddel=del+del
    x=a+0.5*del
    sum=0.
    do ii j=1,it
        sum=sum+func(x)
        x=x+ddel
        sum=sum+func(x)
        x=x+del
    enddo ii
    s=(s+(b-a)*sum/tnm)/3.
endif
return
END

```

If you need to integrate from a negative lower limit to positive infinity, you do this by breaking the integral into two pieces at some positive value, for example,

```

call qromo(funk,-5.,2.,s1,midpnt)
call qromo(funk,2.,1.e30,s2,midinf)
answer=s1+s2

```

Where should you choose the breakpoint? At a sufficiently large positive value so that the function funk is at least beginning to approach its asymptotic decrease to zero value at infinity. The polynomial extrapolation implicit in the second call to qromo deals with a polynomial in $1/x$, not in x .

To deal with an integral that has an integrable power-law singularity at its lower limit, one also makes a change of variable. If the integrand diverges as $(x - a)^{-\gamma}$, $0 \leq \gamma < 1$, near $x = a$, use the identity

$$\int_a^b f(x)dx = \frac{1}{1-\gamma} \int_0^{(b-a)^{1-\gamma}} t^{\frac{\gamma}{1-\gamma}} f(t^{\frac{1}{1-\gamma}} + a)dt \quad (b > a) \quad (4.4.3)$$

If the singularity is at the upper limit, use the identity

$$\int_a^b f(x)dx = \frac{1}{1-\gamma} \int_0^{(b-a)^{1-\gamma}} t^{\frac{\gamma}{1-\gamma}} f(b - t^{\frac{1}{1-\gamma}})dt \quad (b > a) \quad (4.4.4)$$

If there is a singularity at both limits, divide the integral at an interior breakpoint as in the example above.

Equations (4.4.3) and (4.4.4) are particularly simple in the case of inverse square-root singularities, a case that occurs frequently in practice:

$$\int_a^b f(x)dx = \int_0^{\sqrt{b-a}} 2tf(a+t^2)dt \quad (b > a) \quad (4.4.5)$$

for a singularity at a , and

$$\int_a^b f(x)dx = \int_0^{\sqrt{b-a}} 2tf(b-t^2)dt \quad (b > a) \quad (4.4.6)$$

for a singularity at b . Once again, we can implement these changes of variable transparently to the user by defining substitute routines for `midpnt` which make the change of variable automatically:

```
SUBROUTINE midsq(funk,aa,bb,s,n)
INTEGER n
REAL aa,bb,s,funk
EXTERNAL funk
      This routine is an exact replacement for midpnt, except that it allows for an inverse square-
      root singularity in the integrand at the lower limit aa.
INTEGER it,j
REAL ddel,del,sum,tnm,x,func,a,b
func(x)=2.*x*funk(aa+x**2)
b=sqrt(bb-aa)
a=0.
if (n.eq.1) then
      The rest of the routine is exactly like midpnt and is omitted.
```

Similarly,

```
SUBROUTINE midsqu(funk,aa,bb,s,n)
INTEGER n
REAL aa,bb,s,funk
EXTERNAL funk
      This routine is an exact replacement for midpnt, except that it allows for an inverse square-
      root singularity in the integrand at the upper limit bb.
INTEGER it,j
REAL ddel,del,sum,tnm,x,func,a,b
func(x)=2.*x*funk(bb-x**2)
b=sqrt(bb-aa)
a=0.
if (n.eq.1) then
      The rest of the routine is exactly like midpnt and is omitted.
```

One last example should suffice to show how these formulas are derived in general. Suppose the upper limit of integration is infinite, and the integrand falls off exponentially. Then we want a change of variable that maps $e^{-x}dx$ into $(\pm)dt$ (with the sign chosen to keep the upper limit of the new variable larger than the lower limit). Doing the integration gives by inspection

$$t = e^{-x} \quad \text{or} \quad x = -\log t \quad (4.4.7)$$

so that

$$\int_{x=a}^{x=\infty} f(x)dx = \int_{t=0}^{t=e^{-a}} f(-\log t) \frac{dt}{t} \quad (4.4.8)$$

The user-transparent implementation would be

```
SUBROUTINE midexp(funk,aa,bb,s,n)
INTEGER n
REAL aa,bb,s,funk
EXTERNAL funk
      This routine is an exact replacement for midpnt, except that bb is assumed to be infinite
      (value passed not actually used). It is assumed that the function funk decreases exponentially rapidly at infinity.
INTEGER it,j
REAL ddel,del,sum,tnm,x,func,a,b
func(x)=funk(-log(x))/x
b=exp(-aa)
a=0.
if (n.eq.1) then
      The rest of the routine is exactly like midpnt and is omitted.
```

4.5 Gaussian Quadratures and Orthogonal Polynomials

In the formulas of §4.1, the integral of a function was approximated by the sum of its functional values at a set of equally spaced points, multiplied by certain aptly chosen weighting coefficients. We saw that as we allowed ourselves more freedom in choosing the coefficients, we could achieve integration formulas of higher and higher order. The idea of *Gaussian quadratures* is to give ourselves the freedom to choose not only the weighting coefficients, but also the location of the abscissas at which the function is to be evaluated: They will no longer be equally spaced. Thus, we will have *twice* the number of degrees of freedom at our disposal; it will turn out that we can achieve Gaussian quadrature formulas whose order is, essentially, twice that of the Newton-Cotes formula with the same number of function evaluations.

Does this sound too good to be true? Well, in a sense it is. The catch is a familiar one, which cannot be overemphasized: High order is not the same as high accuracy. High order translates to high accuracy only when the integrand is very smooth, in the sense of being “well-approximated by a polynomial.”

4.5 Gaussian Quadratures and Orthogonal Polynomials

In the formulas of §4.1, the integral of a function was approximated by the sum of its functional values at a set of equally spaced points, multiplied by certain aptly chosen weighting coefficients. We saw that as we allowed ourselves more freedom in choosing the coefficients, we could achieve integration formulas of higher and higher order. The idea of *Gaussian quadratures* is to give ourselves the freedom to choose not only the weighting coefficients, but also the location of the abscissas at which the function is to be evaluated: They will no longer be equally spaced. Thus, we will have *twice* the number of degrees of freedom at our disposal; it will turn out that we can achieve Gaussian quadrature formulas whose order is, essentially, twice that of the Newton-Cotes formula with the same number of function evaluations.

Does this sound too good to be true? Well, in a sense it is. The catch is a familiar one, which cannot be overemphasized: High order is not the same as high accuracy. High order translates to high accuracy only when the integrand is very smooth, in the sense of being “well-approximated by a polynomial.”

There is, however, one additional feature of Gaussian quadrature formulas that adds to their usefulness: We can arrange the choice of weights and abscissas to make the integral exact for a class of integrands “polynomials times some known function $W(x)$ ” rather than for the usual class of integrands “polynomials.” The function $W(x)$ can then be chosen to remove integrable singularities from the desired integral. Given $W(x)$, in other words, and given an integer N , we can find a set of weights w_j and abscissas x_j such that the approximation

$$\int_a^b W(x)f(x)dx \approx \sum_{j=1}^N w_j f(x_j) \quad (4.5.1)$$

is exact if $f(x)$ is a polynomial. For example, to do the integral

$$\int_{-1}^1 \frac{\exp(-\cos^2 x)}{\sqrt{1-x^2}} dx \quad (4.5.2)$$

(not a very natural looking integral, it must be admitted), we might well be interested in a Gaussian quadrature formula based on the choice

$$W(x) = \frac{1}{\sqrt{1-x^2}} \quad (4.5.3)$$

in the interval $(-1, 1)$. (This particular choice is called *Gauss-Chebyshev integration*, for reasons that will become clear shortly.)

Notice that the integration formula (4.5.1) can also be written with the weight function $W(x)$ not overtly visible: Define $g(x) \equiv W(x)f(x)$ and $v_j \equiv w_j/W(x_j)$. Then (4.5.1) becomes

$$\int_a^b g(x)dx \approx \sum_{j=1}^N v_j g(x_j) \quad (4.5.4)$$

Where did the function $W(x)$ go? It is lurking there, ready to give high-order accuracy to integrands of the form polynomials times $W(x)$, and ready to *deny* high-order accuracy to integrands that are otherwise perfectly smooth and well-behaved. When you find tabulations of the weights and abscissas for a given $W(x)$, you have to determine carefully whether they are to be used with a formula in the form of (4.5.1), or like (4.5.4).

Here is an example of a quadrature routine that contains the tabulated abscissas and weights for the case $W(x) = 1$ and $N = 10$. Since the weights and abscissas are, in this case, symmetric around the midpoint of the range of integration, there are actually only five distinct values of each:

```
SUBROUTINE qgaus(func,a,b,ss)
REAL a,b,ss,func
EXTERNAL func
      Returns as ss the integral of the function func between a and b, by ten-point Gauss-
      Legendre integration: the function is evaluated exactly ten times at interior points in the
      range of integration.
INTEGER j
```

```

REAL dx,xm,xr,w(5),x(5)      The abscissas and weights.

do ii j=1,5                  weights (five numbers above each used twice) sum to 2.
    dx=xr*x(j)
    ss=ss+w(j)*(func(xm+dx)+func(xm-dx))
enddo ii
ss=xr*ss                      Scale the answer to the range of integration.
return
END

```

The above routine illustrates that one can use Gaussian quadratures without necessarily understanding the theory behind them: One just locates tabulated weights and abscissas in a book (e.g., [1] or [2]). However, the theory is very pretty, and it will come in handy if you ever need to construct your own tabulation of weights and abscissas for an unusual choice of $W(x)$. We will therefore give, without any proofs, some useful results that will enable you to do this. Several of the results assume that $W(x)$ does not change sign inside (a, b) , which is usually the case in practice.

The theory behind Gaussian quadratures goes back to Gauss in 1814, who used continued fractions to develop the subject. In 1826 Jacobi rederived Gauss's results by means of orthogonal polynomials. The systematic treatment of arbitrary weight functions $W(x)$ using orthogonal polynomials is largely due to Christoffel in 1877. To introduce these orthogonal polynomials, let us fix the interval of interest to be (a, b) . We can define the “scalar product of two functions f and g over a weight function W ” as

$$\langle f|g \rangle \equiv \int_a^b W(x)f(x)g(x)dx \quad (4.5.5)$$

The scalar product is a number, not a function of x . Two functions are said to be *orthogonal* if their scalar product is zero. A function is said to be *normalized* if its scalar product with itself is unity. A set of functions that are all mutually orthogonal and also all individually normalized is called an *orthonormal* set.

We can find a set of polynomials (i) that includes exactly one polynomial of order j , called $p_j(x)$, for each $j = 0, 1, 2, \dots$, and (ii) all of which are mutually orthogonal over the specified weight function $W(x)$. A constructive procedure for finding such a set is the recurrence relation

$$\begin{aligned} p_{-1}(x) &\equiv 0 \\ p_0(x) &\equiv 1 \\ p_{j+1}(x) &= (x - a_j)p_j(x) - b_j p_{j-1}(x) \quad j = 0, 1, 2, \dots \end{aligned} \quad (4.5.6)$$

where

$$\begin{aligned} a_j &= \frac{\langle xp_j | p_j \rangle}{\langle p_j | p_j \rangle} \quad j = 0, 1, \dots \\ b_j &= \frac{\langle p_j | p_j \rangle}{\langle p_{j-1} | p_{j-1} \rangle} \quad j = 1, 2, \dots \end{aligned} \quad (4.5.7)$$

The coefficient b_0 is arbitrary; we can take it to be zero.

The polynomials defined by (4.5.6) are *monic*, i.e., the coefficient of their leading term [x^j for $p_j(x)$] is unity. If we divide each $p_j(x)$ by the constant $[\langle p_j | p_j \rangle]^{1/2}$ we can render the set of polynomials orthonormal. One also encounters orthogonal polynomials with various other normalizations. You can convert from a given normalization to monic polynomials if you know that the coefficient of x^j in p_j is λ_j , say; then the monic polynomials are obtained by dividing each p_j by λ_j . Note that the coefficients in the recurrence relation (4.5.6) depend on the adopted normalization.

The polynomial $p_j(x)$ can be shown to have exactly j distinct roots in the interval (a, b) . Moreover, it can be shown that the roots of $p_j(x)$ “interleave” the $j - 1$ roots of $p_{j-1}(x)$, i.e., there is exactly one root of the former in between each two adjacent roots of the latter. This fact comes in handy if you need to find all the roots: You can start with the one root of $p_1(x)$ and then, in turn, bracket the roots of each higher j , pinning them down at each stage more precisely by Newton’s rule or some other root-finding scheme (see Chapter 9).

Why would you ever want to find all the roots of an orthogonal polynomial $p_j(x)$? Because the abscissas of the N -point Gaussian quadrature formulas (4.5.1) and (4.5.4) with weighting function $W(x)$ in the interval (a, b) are precisely the roots of the orthogonal polynomial $p_N(x)$ for the same interval and weighting function. This is the fundamental theorem of Gaussian quadratures, and lets you find the abscissas for any particular case.

Once you know the abscissas x_1, \dots, x_N , you need to find the weights w_j , $j = 1, \dots, N$. One way to do this (not the most efficient) is to solve the set of linear equations

$$\begin{bmatrix} p_0(x_1) & \dots & p_0(x_N) \\ p_1(x_1) & \dots & p_1(x_N) \\ \vdots & & \vdots \\ p_{N-1}(x_1) & \dots & p_{N-1}(x_N) \end{bmatrix} \begin{bmatrix} w_1 \\ w_2 \\ \vdots \\ w_N \end{bmatrix} = \begin{bmatrix} \int_a^b W(x)p_0(x)dx \\ 0 \\ \vdots \\ 0 \end{bmatrix} \quad (4.5.8)$$

Equation (4.5.8) simply solves for those weights such that the quadrature (4.5.1) gives the correct answer for the integral of the first N orthogonal polynomials. Note that the zeros on the right-hand side of (4.5.8) appear because $p_1(x), \dots, p_{N-1}(x)$ are all orthogonal to $p_0(x)$, which is a constant. It can be shown that, with those weights, the integral of the *next* $N - 1$ polynomials is also exact, so that the quadrature is exact for all polynomials of degree $2N - 1$ or less. Another way to evaluate the weights (though one whose proof is beyond our scope) is by the formula

$$w_j = \frac{\langle p_{N-1} | p_{N-1} \rangle}{p_{N-1}(x_j)p'_N(x_j)} \quad (4.5.9)$$

where $p'_N(x_j)$ is the derivative of the orthogonal polynomial at its zero x_j .

The computation of Gaussian quadrature rules thus involves two distinct phases: (i) the generation of the orthogonal polynomials p_0, \dots, p_N , i.e., the computation of the coefficients a_j, b_j in (4.5.6); (ii) the determination of the zeros of $p_N(x)$, and the computation of the associated weights. For the case of the “classical” orthogonal polynomials, the coefficients a_j and b_j are explicitly known (equations 4.5.10 –

4.5.14 below) and phase (i) can be omitted. However, if you are confronted with a “nonclassical” weight function $W(x)$, and you don’t know the coefficients a_j and b_j , the construction of the associated set of orthogonal polynomials is not trivial. We discuss it at the end of this section.

Computation of the Abscissas and Weights

This task can range from easy to difficult, depending on how much you already know about your weight function and its associated polynomials. In the case of classical, well-studied, orthogonal polynomials, practically everything is known, including good approximations for their zeros. These can be used as starting guesses, enabling Newton’s method (to be discussed in §9.4) to converge very rapidly. Newton’s method requires the derivative $p'_N(x)$, which is evaluated by standard relations in terms of p_N and p_{N-1} . The weights are then conveniently evaluated by equation (4.5.9). For the following named cases, this direct root-finding is faster, by a factor of 3 to 5, than any other method.

Here are the weight functions, intervals, and recurrence relations that generate the most commonly used orthogonal polynomials and their corresponding Gaussian quadrature formulas.

Gauss-Legendre:

$$W(x) = 1 \quad -1 < x < 1$$

$$(j+1)P_{j+1} = (2j+1)xP_j - jP_{j-1} \quad (4.5.10)$$

Gauss-Chebyshev:

$$W(x) = (1-x^2)^{-1/2} \quad -1 < x < 1$$

$$T_{j+1} = 2xT_j - T_{j-1} \quad (4.5.11)$$

Gauss-Laguerre:

$$W(x) = x^\alpha e^{-x} \quad 0 < x < \infty$$

$$(j+1)L_{j+1}^\alpha = (-x + 2j + \alpha + 1)L_j^\alpha - (j + \alpha)L_{j-1}^\alpha \quad (4.5.12)$$

Gauss-Hermite:

$$W(x) = e^{-x^2} \quad -\infty < x < \infty$$

$$H_{j+1} = 2xH_j - 2jH_{j-1} \quad (4.5.13)$$

Gauss-Jacobi:

$$W(x) = (1-x)^\alpha(1+x)^\beta \quad -1 < x < 1$$

$$c_j P_{j+1}^{(\alpha, \beta)} = (d_j + e_j x) P_j^{(\alpha, \beta)} - f_j P_{j-1}^{(\alpha, \beta)} \quad (4.5.14)$$

where the coefficients c_j , d_j , e_j , and f_j are given by

$$\begin{aligned} c_j &= 2(j+1)(j+\alpha+\beta+1)(2j+\alpha+\beta) \\ d_j &= (2j+\alpha+\beta+1)(\alpha^2-\beta^2) \\ e_j &= (2j+\alpha+\beta)(2j+\alpha+\beta+1)(2j+\alpha+\beta+2) \\ f_j &= 2(j+\alpha)(j+\beta)(2j+\alpha+\beta+2) \end{aligned} \quad (4.5.15)$$

We now give individual routines that calculate the abscissas and weights for these cases. First comes the most common set of abscissas and weights, those of Gauss-Legendre. The routine, due to G.B. Rybicki, uses equation (4.5.9) in the special form for the Gauss-Legendre case,

$$w_j = \frac{2}{(1-x_j^2)[P'_N(x_j)]^2} \quad (4.5.16)$$

The routine also scales the range of integration from (x_1, x_2) to $(-1, 1)$, and provides abscissas x_j and weights w_j for the Gaussian formula

$$\int_{x_1}^{x_2} f(x) dx = \sum_{j=1}^N w_j f(x_j) \quad (4.5.17)$$

```
SUBROUTINE gauleg(x1,x2,x,w,n)
INTEGER n

DOUBLE PRECISION EPS
PARAMETER (EPS=3.d-14)           EPS is the relative precision.
                                  Given the lower and upper limits of integration x1 and x2, and given n, this routine returns
arrays x(1:n) and w(1:n) of length n, containing the abscissas and weights of the Gauss-
Legendre n-point quadrature formula.
INTEGER i,m
DOUBLE PRECISION p1,p2,p3,pp,x1,xm,z,z1
      High precision is a good idea for this routine.
m=(n+1)/2                         The roots are symmetric in the interval, so we
xm=0.5d0*(x2+x1)                   only have to find half of them.
x1=0.5d0*(x2-x1)
do 12 i=1,m                         Loop over the desired roots.
z=cos(3.141592654d0*(i-.25d0)/(n+.5d0))
      Starting with the above approximation to the ith root, we enter the main loop of re-
finement by Newton's method.
1   continue
      p1=1.d0
      p2=0.d0
      do 11 j=1,n                       Loop up the recurrence relation to get the Leg-
                                         endre polynomial evaluated at z.
          p3=p2
          p2=p1
          p1=((2.d0*j-1.d0)*z*p2-(j-1.d0)*p3)/j
      enddo 11
      p1 is now the desired Legendre polynomial. We next compute pp, its derivative, by
      a standard relation involving also p2, the polynomial of one lower order.
      pp=n*(z*p1-p2)/(z*z-1.d0)
```

```

z1=z
z=z1-p1/pp
if(abs(z-z1).gt.EPS)goto 1
x(i)=xm-xl*z
x(n+1-i)=xm+xl*z
w(i)=2.d0*xl/((1.d0-z*z)*pp*pp)
w(n+1-i)=w(i)

enddo 12
return
END

```

Newton's method.

Scale the root to the desired interval,
and put in its symmetric counterpart.
Compute the weight
and its symmetric counterpart.

Next we give three routines that use initial approximations for the roots given by Stroud and Secrest [2]. The first is for Gauss-Laguerre abscissas and weights, to be used with the integration formula

$$\int_0^\infty x^\alpha e^{-x} f(x) dx = \sum_{j=1}^N w_j f(x_j) \quad (4.5.18)$$

```
w(i)=-exp(gammln(alf+n)-gammln(float(n)))/(pp*n*p2)
endo 13
return
END
```

Next is a routine for Gauss-Hermite abscissas and weights. If we use the “standard” normalization of these functions, as given in equation (4.5.13), we find that the computations overflow for large N because of various factorials that occur. We can avoid this by using instead the orthonormal set of polynomials \tilde{H}_j . They are generated by the recurrence

$$\tilde{H}_{-1} = 0, \quad \tilde{H}_0 = \frac{1}{\pi^{1/4}}, \quad \tilde{H}_{j+1} = x \sqrt{\frac{2}{j+1}} \tilde{H}_j - \sqrt{\frac{j}{j+1}} \tilde{H}_{j-1} \quad (4.5.19)$$

The formula for the weights becomes

$$w_j = \frac{2}{[\tilde{H}'_N(x_j)]^2} \quad (4.5.20)$$

while the formula for the derivative with this normalization is

$$\tilde{H}'_j = \sqrt{2j} \tilde{H}_{j-1} \quad (4.5.21)$$

The abscissas and weights returned by gauher are used with the integration formula

$$\int_{-\infty}^{\infty} e^{-x^2} f(x) dx = \sum_{j=1}^N w_j f(x_j) \quad (4.5.22)$$

```
SUBROUTINE gauher(x,w,n)
INTEGER n,MAXIT
REAL w(n),x(n)
DOUBLE PRECISION EPS,PIM4
PARAMETER (EPS=3.D-14,PIM4=.7511255444649425D0,MAXIT=10)
Given n, this routine returns arrays x(1:n) and w(1:n) containing the abscissas and
weights of the n-point Gauss-Hermite quadrature formula. The largest abscissa is returned
in x(1), the most negative in x(n).
Parameters: EPS is the relative precision, PIM4 =  $1/\pi^{1/4}$ , MAXIT = maximum iterations.
INTEGER i,its,j,m
DOUBLE PRECISION p1,p2,p3,pp,z,z1
High precision is a good idea for this routine.
m=(n+1)/2
The roots are symmetric about the origin, so we have to find only half of them.
do 13 i=1,m           Loop over the desired roots.
  if(i.eq.1)then        Initial guess for the largest root.
    z=sqrt(float(2*n+1))-1.85575*(2*n+1)**(-.16667)
  else if(i.eq.2)then        Initial guess for the second largest root.
    z=z-1.14*n**.426/z
  else if (i.eq.3)then        Initial guess for the third largest root.
    z=1.86*z-.86*x(1)
  else if (i.eq.4)then        Initial guess for the fourth largest root.
    z=1.91*z-.91*x(2)
  else                      Initial guess for the other roots.
  z=2.*z-x(i-2)
```

```

        endif
do 12 its=1,MAXIT      Refinement by Newton's method.
    p1=PIM4
    p2=0.d0
    do 11 j=1,n           Loop up the recurrence relation to get the Hermite poly-
                           nomial evaluated at z.
        p3=p2
        p2=p1
        p1=z*sqrt(2.d0/j)*p2-sqrt(db1e(j-1)/db1e(j))*p3
    enddo 11
    p1 is now the desired Hermite polynomial. We next compute pp, its derivative, by
    the relation (4.5.21) using p2, the polynomial of one lower order.
    pp=sqrt(2.d0*n)*p2
    z1=z
    z=z1-p1/pp            Newton's formula.
    if(abs(z-z1).le.EPS)goto 1
  enddo 12
  pause 'too many iterations in gauher'
  1   x(i)=z              Store the root
  x(n+1-i)=-z            and its symmetric counterpart.
  w(i)=2.d0/(pp*pp)       Compute the weight
  w(n+1-i)=w(i)          and its symmetric counterpart.
  enddo 13
  return
END

```

Finally, here is a routine for Gauss-Jacobi abscissas and weights, which implement the integration formula

$$\int_{-1}^1 (1-x)^\alpha (1+x)^\beta f(x) dx = \sum_{j=1}^N w_j f(x_j) \quad (4.5.23)$$

```

SUBROUTINE gaujac(x,w,n,alf,bet)
INTEGER n,MAXIT
REAL alf,bet,w(n),x(n)
DOUBLE PRECISION EPS
PARAMETER (EPS=3.D-14,MAXIT=10)      Increase EPS if you don't have this precision.
C USES gammln
Given alf and bet, the parameters  $\alpha$  and  $\beta$  of the Jacobi polynomials, this routine returns
arrays x(1:n) and w(1:n) containing the abscissas and weights of the n-point Gauss-Jacobi
quadrature formula. The largest abscissa is returned in x(1), the smallest in x(n).
INTEGER i,its,j
REAL alfbet,an,bn,r1,r2,r3,gammln
DOUBLE PRECISION a,b,c,p1,p2,p3,pp,temp,z,z1
High precision is a good idea for this routine.
do 13 i=1,n             Loop over the desired roots.
  if(i.eq.1)then          Initial guess for the largest root.
    an=alf/n
    bn=bet/n
    r1=(1.+alf)*(2.78/(4.+n*n)+.768*an/n)

Legendre polynomials are special cases of Jacobi polynomials with $\alpha = \beta = 0$, but it is worth having the separate routine for them, `gaulleg`, given above. Chebyshev polynomials correspond to $\alpha = \beta = -1/2$ (see §5.8). They have analytic abscissas and weights:

$$x_j = \cos\left(\frac{\pi(j - \frac{1}{2})}{N}\right)$$

$$w_j = \frac{\pi}{N} \quad (4.5.24)$$

Case of Known Recurrences

Turn now to the case where you do not know good initial guesses for the zeros of your orthogonal polynomials, but you do have available the coefficients a_j and b_j that generate them. As we have seen, the zeros of $p_N(x)$ are the abscissas for the N -point Gaussian quadrature formula. The most useful computational formula for the weights is equation (4.5.9) above, since the derivative p'_N can be efficiently computed by the derivative of (4.5.6) in the general case, or by special relations for the classical polynomials. Note that (4.5.9) is valid as written only for monic polynomials; for other normalizations, there is an extra factor of λ_N/λ_{N-1} , where λ_N is the coefficient of x^N in p_N .

Except in those special cases already discussed, the best way to find the abscissas is *not* to use a root-finding method like Newton's method on $p_N(x)$. Rather, it is generally faster to use the Golub-Welsch [3] algorithm, which is based on a result of Wilf [4]. This algorithm notes that if you bring the term xp_j to the left-hand side of (4.5.6) and the term p_{j+1} to the right-hand side, the recurrence relation can be written in matrix form as

$$x \begin{bmatrix} p_0 \\ p_1 \\ \vdots \\ p_{N-2} \\ p_{N-1} \end{bmatrix} = \begin{bmatrix} a_0 & 1 & & & \\ b_1 & a_1 & 1 & & \\ & \vdots & \vdots & \ddots & \\ & & b_{N-2} & a_{N-2} & 1 \\ & & & b_{N-1} & a_{N-1} \end{bmatrix} \cdot \begin{bmatrix} p_0 \\ p_1 \\ \vdots \\ p_{N-2} \\ p_{N-1} \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ \vdots \\ 0 \\ p_N \end{bmatrix}$$

or

$$x\mathbf{p} = \mathbf{T} \cdot \mathbf{p} + p_N \mathbf{e}_{N-1} \quad (4.5.25)$$

Here \mathbf{T} is a tridiagonal matrix, \mathbf{p} is a column vector of p_0, p_1, \dots, p_{N-1} , and \mathbf{e}_{N-1} is a unit vector with a 1 in the $(N-1)$ st (last) position and zeros elsewhere. The matrix \mathbf{T} can be symmetrized by a diagonal similarity transformation \mathbf{D} to give

$$\mathbf{J} = \mathbf{DTD}^{-1} = \begin{bmatrix} a_0 & \sqrt{b_1} & & & \\ \sqrt{b_1} & a_1 & \sqrt{b_2} & & \\ & \vdots & \vdots & \ddots & \\ & & \sqrt{b_{N-2}} & a_{N-2} & \sqrt{b_{N-1}} \\ & & & \sqrt{b_{N-1}} & a_{N-1} \end{bmatrix} \quad (4.5.26)$$

The matrix \mathbf{J} is called the *Jacobi matrix* (not to be confused with other matrices named after Jacobi that arise in completely different problems!). Now we see from (4.5.25) that $p_N(x_j) = 0$ is equivalent to x_j being an eigenvalue of \mathbf{T} . Since eigenvalues are preserved by a similarity transformation, x_j is an eigenvalue of the symmetric tridiagonal matrix \mathbf{J} . Moreover, Wilf [4] shows that if \mathbf{v}_j is the eigenvector corresponding to the eigenvalue x_j , normalized so that $\mathbf{v} \cdot \mathbf{v} = 1$, then

$$w_j = \mu_0 v_{j,1}^2 \quad (4.5.27)$$

where

$$\mu_0 = \int_a^b W(x) dx \quad (4.5.28)$$

and where $v_{j,1}$ is the first component of \mathbf{v} . As we shall see in Chapter 11, finding all eigenvalues and eigenvectors of a symmetric tridiagonal matrix is a relatively efficient and well-conditioned procedure. We accordingly give a routine, `gaucof`, for finding the abscissas and weights, given the coefficients a_j and b_j . Remember that if you know the recurrence relation for orthogonal polynomials that are not normalized to be monic, you can easily convert it to monic form by means of the quantities λ_j .

```

SUBROUTINE gaucof(n,a,b,amu0,x,w)
INTEGER n,NMAX
REAL amu0,a(n),b(n),w(n),x(n)
PARAMETER (NMAX=64)
C USES eigsrt,tqli
    Computes the abscissas and weights for a Gaussian quadrature formula from the Jacobi
    matrix. On input, a(1:n) and b(1:n) are the coefficients of the recurrence relation for
    the set of monic orthogonal polynomials. The quantity  $\mu_0 \equiv \int_a^b W(x) dx$  is input as amu0.
    The abscissas x(1:n) are returned in descending order, with the corresponding weights
    in w(1:n). The arrays a and b are modified. Execution can be speeded up by modifying
    tqli and eigsrt to compute only the first component of each eigenvector.
INTEGER i,j
REAL z(NMAX,NMAX)
do 12 i=1,n
    if(i.ne.1)b(i)=sqrt(b(i))      Set up superdiagonal of Jacobi matrix.
    do 11 j=1,n                    Set up identity matrix for tqli to compute eigenvectors.
        if(i.eq.j)then
            z(i,j)=1.
        else
            z(i,j)=0.
        endif
    enddo 11
  enddo 12
call tqli(a,b,n,NMAX,z)
call eigsrt(a,z,n,NMAX)      Sort eigenvalues into descending order.
do 13 i=1,n
    x(i)=a(i)
    w(i)=amu0*z(1,i)**2          Equation (4.5.12).
  enddo 13
return
END

```

Orthogonal Polynomials with Nonclassical Weights

This somewhat specialized subsection will tell you what to do if your weight function is not one of the classical ones dealt with above and you do not know the a_j 's and b_j 's of the recurrence relation (4.5.6) to use in `gaucof`. Then, a method of finding the a_j 's and b_j 's is needed.

The *procedure of Stieltjes* is to compute a_0 from (4.5.7), then $p_1(x)$ from (4.5.6). Knowing p_0 and p_1 , we can compute a_1 and b_1 from (4.5.7), and so on. But how are we to compute the inner products in (4.5.7)?

The textbook approach is to represent each $p_j(x)$ explicitly as a polynomial in x and to compute the inner products by multiplying out term by term. This will be feasible if we know the first $2N$ moments of the weight function,

$$\mu_j = \int_a^b x^j W(x) dx \quad j = 0, 1, \dots, 2N - 1 \quad (4.5.29)$$

However, the solution of the resulting set of algebraic equations for the coefficients a_j and b_j in terms of the moments μ_j is in general *extremely* ill-conditioned. Even in double precision, it is not unusual to lose all accuracy by the time $N = 12$. We thus reject any procedure based on the moments (4.5.29).

Sack and Donovan [5] discovered that the numerical stability is greatly improved if, instead of using powers of x as a set of basis functions to represent the p_j 's, one uses some other known set of orthogonal polynomials $\pi_j(x)$, say. Roughly speaking, the improved stability occurs because the polynomial basis "samples" the interval (a, b) better than the power basis when the inner product integrals are evaluated, especially if its weight function resembles $W(x)$.

So assume that we know the *modified moments*

$$\nu_j = \int_a^b \pi_j(x) W(x) dx \quad j = 0, 1, \dots, 2N - 1 \quad (4.5.30)$$

where the π_j 's satisfy a recurrence relation analogous to (4.5.6),

$$\begin{aligned} \pi_{-1}(x) &\equiv 0 \\ \pi_0(x) &\equiv 1 \\ \pi_{j+1}(x) &= (x - \alpha_j)\pi_j(x) - \beta_j\pi_{j-1}(x) \quad j = 0, 1, 2, \dots \end{aligned} \quad (4.5.31)$$

and the coefficients α_j , β_j are known explicitly. Then Wheeler [6] has given an efficient $O(N^2)$ algorithm equivalent to that of Sack and Donovan for finding a_j and b_j via a set of intermediate quantities

$$\sigma_{k,l} = \langle p_k | \pi_l \rangle \quad k, l \geq -1 \quad (4.5.32)$$

Initialize

$$\begin{aligned} \sigma_{-1,l} &= 0 & l &= 1, 2, \dots, 2N - 2 \\ \sigma_{0,l} &= \nu_l & l &= 0, 1, \dots, 2N - 1 \\ a_0 &= \alpha_0 + \frac{\nu_1}{\nu_0} & & \\ b_0 &= 0 & & \end{aligned} \quad (4.5.33)$$

Then, for $k = 1, 2, \dots, N - 1$, compute

$$\begin{aligned} \sigma_{k,l} &= \sigma_{k-1,l+1} - (a_{k-1} - \alpha_l)\sigma_{k-1,l} - b_{k-1}\sigma_{k-2,l} + \beta_l\sigma_{k-1,l-1} & l &= k, k+1, \dots, 2N-k-1 \\ a_k &= \alpha_k - \frac{\sigma_{k-1,k}}{\sigma_{k-1,k-1}} + \frac{\sigma_{k,k+1}}{\sigma_{k,k}} & & \\ b_k &= \frac{\sigma_{k,k}}{\sigma_{k-1,k-1}} & & \end{aligned} \quad (4.5.34)$$

Note that the normalization factors can also easily be computed if needed:

$$\begin{aligned} \langle p_0 | p_0 \rangle &= \nu_0 \\ \langle p_j | p_j \rangle &= b_j \langle p_{j-1} | p_{j-1} \rangle \quad j = 1, 2, \dots \end{aligned} \quad (4.5.35)$$

You can find a derivation of the above algorithm in Ref. [7].

Wheeler's algorithm requires that the modified moments (4.5.30) be accurately computed. In practical cases there is often a closed form, or else recurrence relations can be used. The algorithm is extremely successful for *finite* intervals (a, b) . For infinite intervals, the algorithm does not completely remove the ill-conditioning. In this case, Gautschi [8,9] recommends reducing the interval to a finite interval by a change of variable, and then using a suitable discretization procedure to compute the inner products. You will have to consult the references for details.

We give the routine `orthog` for generating the coefficients a_j and b_j by Wheeler's algorithm, given the coefficients α_j and β_j , and the modified moments ν_j . To conform to the usual FORTRAN convention for dimensioning subscripts, the indices of the σ matrix are increased by 2, i.e., $\text{sig}(k, 1) = \sigma_{k-2, l-2}$, while the indices of the vectors α , β , a and b are increased by 1.

```

SUBROUTINE orthog(n,anu,alpha,beta,a,b)
INTEGER n,NMAX
REAL a(n),alpha(2*n-1),anu(2*n),b(n),beta(2*n-1)
PARAMETER (NMAX=64)
Computes the coefficients  $a_j$  and  $b_j$ ,  $j = 0, \dots, N - 1$ , of the recurrence relation for monic orthogonal polynomials with weight function  $W(x)$  by Wheeler's algorithm. On input, alpha(1:2*n-1) and beta(1:2*n-1) are the coefficients  $\alpha_j$  and  $\beta_j$ ,  $j = 0, \dots, 2N - 2$ , of the recurrence relation for the chosen basis of orthogonal polynomials. The modified moments  $\nu_j$  are input in anu(1:2*n). The first  $n$  coefficients are returned in a(1:n) and b(1:n).
INTEGER k,l
REAL sig(2*NMAX+1,2*NMAX+1)
do 11 l=3,2*n                         Initialization, Equation (4.5.33).
    sig(1,l)=0.
  enddo 11
do 12 l=2,2*n+1
    sig(2,l)=anu(l-1)
  enddo 12
a(1)=alpha(1)+anu(2)/anu(1)
b(1)=0.
do 14 k=3,n+1                         Equation (4.5.34).
  do 13 l=k,2*n-k+3
    sig(k,l)=sig(k-1,l+1)+(alpha(l-1)-a(k-2))*sig(k-1,l)-
    b(k-2)*sig(k-2,l)+beta(l-1)*sig(k-1,l-1)
  enddo 13
  a(k-1)=alpha(k-1)+sig(k,k+1)/sig(k,k)-sig(k-1,k)/sig(k-1,k-1)
  b(k-1)=sig(k,k)/sig(k-1,k-1)
enddo 14
return
END

```

As an example of the use of `orthog`, consider the problem [7] of generating orthogonal polynomials with the weight function $W(x) = -\log x$ on the interval $(0, 1)$. A suitable set of π_j 's is the shifted Legendre polynomials

$$\pi_j = \frac{(j!)^2}{(2j)!} P_j(2x - 1) \quad (4.5.36)$$

The factor in front of P_j makes the polynomials monic. The coefficients in the recurrence relation (4.5.31) are

$$\begin{aligned} \alpha_j &= \frac{1}{2} & j &= 0, 1, \dots \\ \beta_j &= \frac{1}{4(4 - j^{-2})} & j &= 1, 2, \dots \end{aligned} \quad (4.5.37)$$

while the modified moments are

$$\nu_j = \begin{cases} 1 & j = 0 \\ \frac{(-1)^j (j!)^2}{j(j+1)(2j)!} & j \geq 1 \end{cases} \quad (4.5.38)$$

A call to `orthog` with this input allows one to generate the required polynomials to machine accuracy for very large N , and hence do Gaussian quadrature with this weight function. Before Sack and Donovan's observation, this seemingly simple problem was essentially intractable.

Extensions of Gaussian Quadrature

There are many different ways in which the ideas of Gaussian quadrature have been extended. One important extension is the case of *preassigned nodes*: Some points are required to be included in the set of abscissas, and the problem is to choose

the weights and the remaining abscissas to maximize the degree of exactness of the quadrature rule. The most common cases are *Gauss-Radau* quadrature, where one of the nodes is an endpoint of the interval, either a or b , and *Gauss-Lobatto* quadrature, where both a and b are nodes. Golub [10] has given an algorithm similar to `gaucof` for these cases.

The second important extension is the *Gauss-Kronrod* formulas. For ordinary Gaussian quadrature formulas, as N increases the sets of abscissas have no points in common. This means that if you compare results with increasing N as a way of estimating the quadrature error, you cannot reuse the previous function evaluations. Kronrod [11] posed the problem of searching for optimal sequences of rules, each of which reuses all abscissas of its predecessor. If one starts with $N = m$, say, and then adds n new points, one has $2n + m$ free parameters: the n new abscissas and weights, and m new weights for the fixed previous abscissas. The maximum degree of exactness one would expect to achieve would therefore be $2n + m - 1$. The question is whether this maximum degree of exactness can actually be achieved in practice, when the abscissas are required to all lie inside (a, b) . The answer to this question is not known in general.

Kronrod showed that if you choose $n = m + 1$, an optimal extension can be found for Gauss-Legendre quadrature. Patterson [12] showed how to compute continued extensions of this kind. Sequences such as $N = 10, 21, 43, 87, \dots$ are popular in automatic quadrature routines [13] that attempt to integrate a function until some specified accuracy has been achieved.

4.6 Multidimensional Integrals

Integrals of functions of several variables, over regions with dimension greater than one, are *not easy*. There are two reasons for this. First, the number of function evaluations needed to sample an N -dimensional space increases as the N th power of the number needed to do a one-dimensional integral. If you need 30 function evaluations to do a one-dimensional integral crudely, then you will likely need on the order of 30000 evaluations to reach the same crude level for a three-dimensional integral. Second, the region of integration in N -dimensional space is defined by an $N - 1$ dimensional boundary which can itself be terribly complicated: It need not be convex or simply connected, for example. By contrast, the boundary of a one-dimensional integral consists of two numbers, its upper and lower limits.

The first question to be asked, when faced with a multidimensional integral, is, “can it be reduced analytically to a lower dimensionality?” For example, so-called *iterated integrals* of a function of one variable $f(t)$ can be reduced to one-dimensional integrals by the formula

$$\int_0^x dt_n \int_0^{t_n} dt_{n-1} \cdots \int_0^{t_3} dt_2 \int_0^{t_2} f(t_1) dt_1 \\ = \frac{1}{(n-1)!} \int_0^x (x-t)^{n-1} f(t) dt \quad (4.6.1)$$

Alternatively, the function may have some special symmetry in the way it depends on its independent variables. If the boundary also has this symmetry, then the dimension can be reduced. In three dimensions, for example, the integration of a spherically symmetric function over a spherical region reduces, in polar coordinates, to a one-dimensional integral.

The next questions to be asked will guide your choice between two entirely different approaches to doing the problem. The questions are: Is the shape of the boundary of the region of integration simple or complicated? Inside the region, is the integrand smooth and simple, or complicated, or locally strongly peaked? Does the problem require high accuracy, or does it require an answer accurate only to a percent, or a few percent?

If your answers are that the boundary is complicated, the integrand is *not* strongly peaked in very small regions, and relatively low accuracy is tolerable, then your problem is a good candidate for *Monte Carlo integration*. This method is very straightforward to program, in its cruder forms. One needs only to know a region with simple boundaries that *includes* the complicated region of integration, plus a method of determining whether a random point is inside or outside the region of integration. Monte Carlo integration evaluates the function at a random sample of

Does the problem require high accuracy, or does it require an answer accurate only to a percent, or a few percent?

If your answers are that the boundary is complicated, the integrand is *not* strongly peaked in very small regions, and relatively low accuracy is tolerable, then your problem is a good candidate for *Monte Carlo integration*. This method is very straightforward to program, in its cruder forms. One needs only to know a region with simple boundaries that *includes* the complicated region of integration, plus a method of determining whether a random point is inside or outside the region of integration. Monte Carlo integration evaluates the function at a random sample of

points, and estimates its integral based on that random sample. We will discuss it in more detail, and with more sophistication, in Chapter 7.

If the boundary is simple, and the function is very smooth, then the remaining approaches, breaking up the problem into repeated one-dimensional integrals, or multidimensional Gaussian quadratures, will be effective and relatively fast [1]. If you require high accuracy, these approaches are in any case the *only* ones available to you, since Monte Carlo methods are by nature asymptotically slow to converge.

For low accuracy, use repeated one-dimensional integration or multidimensional Gaussian quadratures when the integrand is slowly varying and smooth in the region of integration, Monte Carlo when the integrand is oscillatory or discontinuous, but not strongly peaked in small regions.

If the integrand *is* strongly peaked in small regions, and you know where those regions are, break the integral up into several regions so that the integrand is smooth in each, and do each separately. If you don't know where the strongly peaked regions are, you might as well (at the level of sophistication of this book) quit: It is hopeless to expect an integration routine to search out unknown pockets of large contribution in a huge N -dimensional space. (But see §7.8.)

If, on the basis of the above guidelines, you decide to pursue the repeated one-dimensional integration approach, here is how it works. For definiteness, we will consider the case of a three-dimensional integral in x, y, z -space. Two dimensions, or more than three dimensions, are entirely analogous.

The first step is to specify the region of integration by (i) its lower and upper limits in x , which we will denote x_1 and x_2 ; (ii) its lower and upper limits in y at a specified value of x , denoted $y_1(x)$ and $y_2(x)$; and (iii) its lower and upper limits in z at specified x and y , denoted $z_1(x, y)$ and $z_2(x, y)$. In other words, find the numbers x_1 and x_2 , and the functions $y_1(x), y_2(x), z_1(x, y)$, and $z_2(x, y)$ such that

$$\begin{aligned} I &\equiv \int \int \int dx dy dz f(x, y, z) \\ &= \int_{x_1}^{x_2} dx \int_{y_1(x)}^{y_2(x)} dy \int_{z_1(x, y)}^{z_2(x, y)} dz f(x, y, z) \end{aligned} \quad (4.6.2)$$

For example, a two-dimensional integral over a circle of radius one centered on the origin becomes

$$\int_{-1}^1 dx \int_{-\sqrt{1-x^2}}^{\sqrt{1-x^2}} dy f(x, y) \quad (4.6.3)$$

Now we can define a function $G(x, y)$ that does the innermost integral,

$$G(x, y) \equiv \int_{z_1(x, y)}^{z_2(x, y)} f(x, y, z) dz \quad (4.6.4)$$

and a function $H(x)$ that does the integral of $G(x, y)$,

$$H(x) \equiv \int_{y_1(x)}^{y_2(x)} G(x, y) dy \quad (4.6.5)$$

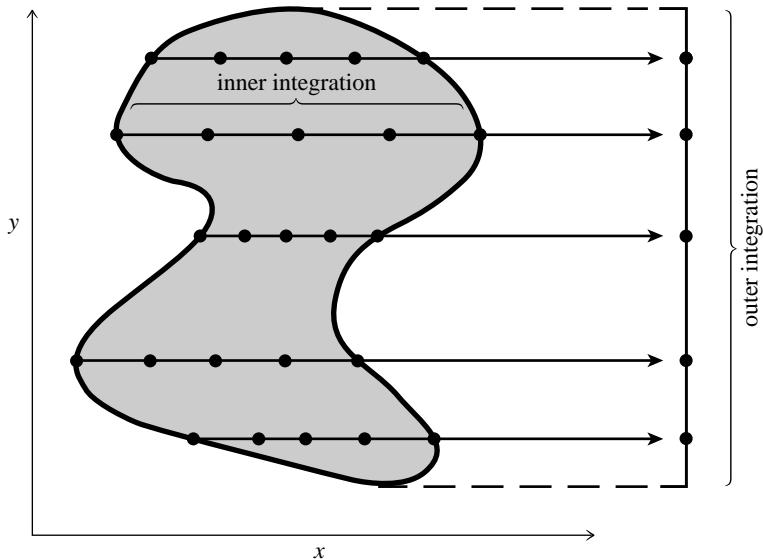

Figure 4.6.1. Function evaluations for a two-dimensional integral over an irregular region, shown schematically. The outer integration routine, in y , requests values of the inner, x , integral at locations along the y axis of its own choosing. The inner integration routine then evaluates the function at x locations suitable to it. This is more accurate in general than, e.g., evaluating the function on a Cartesian mesh of points.

and finally our answer as an integral over $H(x)$

$$I = \int_{x_1}^{x_2} H(x) dx \quad (4.6.6)$$

To implement equations (4.6.4)–(4.6.6) in a program, one needs three separate copies of a basic one-dimensional integration routine (and of any subroutines called by it), one each for the x , y , and z integrations. If you try to make do with only one copy, then it will call itself recursively, since (e.g.) the function evaluations of H for the x integration will themselves call the integration routine to do the y integration (see Figure 4.6.1). In our example, let us suppose that we plan to use the one-dimensional integrator qgaus of §4.5. Then we make three identical copies and call them qgausx, qgausy, and qgausz. The basic program for three-dimensional integration then is as follows:

```

SUBROUTINE quad3d(x1,x2,ss)
REAL ss,x1,x2,h
EXTERNAL h
C USES h,qgausx
      Returns as ss the integral of a user-supplied function func over a three-dimensional region
      specified by the limits x1, x2, and by the user-supplied functions y1, y2, z1, and z2, as
      defined in (4.6.2).
      call qgausx(h,x1,x2,ss)
      return
END

FUNCTION f(zz)
REAL f,zz,func,x,y,z

```

```

C COMMON /xyz/ x,y,z
C USES func
    Called by qgausz. Calls func.
z=zz
f=func(x,y,z)
return
END

FUNCTION g(yy)
REAL g,yy,f,z1,z2,x,y,z
EXTERNAL f
COMMON /xyz/ x,y,z
C USES f,qgausz,z1,z2
    Called by qgausy. Calls qgausz.
REAL ss
y=yy
call qgausz(f,z1(x,y),z2(x,y),ss)
g=ss
return
END

FUNCTION h(xx)
REAL h,xx,g,y1,y2,x,y,z
EXTERNAL g
COMMON /xyz/ x,y,z
C USES g,qgausy,y1,y2
    Called by qgausx. Calls qgausy.
REAL ss
x=xx
call qgausy(g,y1(x),y2(x),ss)
h=ss
return
END

```

The necessary user-supplied functions have the following calling sequences:

FUNCTION func(x,y,z) FUNCTION y1(x) FUNCTION y2(x) FUNCTION z1(x,y) FUNCTION z2(x,y)	The 3-dimensional function to be integrated
--	---

Chapter 5. Evaluation of Functions

5.0 Introduction

The purpose of this chapter is to acquaint you with a selection of the techniques that are frequently used in evaluating functions. In Chapter 6, we will apply and illustrate these techniques by giving routines for a variety of specific functions. The purposes of this chapter and the next are thus mostly in harmony, but there is nevertheless some tension between them: Routines that are clearest and most illustrative of the general techniques of this chapter are not always the methods of choice for a particular special function. By comparing this chapter to the next one, you should get some idea of the balance between “general” and “special” methods that occurs in practice.

Insofar as that balance favors general methods, this chapter should give you ideas about how to write your own routine for the evaluation of a function which, while “special” to you, is not so special as to be included in Chapter 6 or the standard program libraries.

5.1 Series and Their Convergence

Everybody knows that an analytic function can be expanded in the neighborhood of a point x_0 in a power series,

$$f(x) = \sum_{k=0}^{\infty} a_k (x - x_0)^k \quad (5.1.1)$$

Such series are straightforward to evaluate. You don’t, of course, evaluate the k th power of $x - x_0$ *ab initio* for each term; rather you keep the $k - 1$ st power and update it with a multiply. Similarly, the form of the coefficients a is often such as to make use of previous work: Terms like $k!$ or $(2k)!$ can be updated in a multiply or two.

5.1 Series and Their Convergence

Everybody knows that an analytic function can be expanded in the neighborhood of a point x_0 in a power series,

$$f(x) = \sum_{k=0}^{\infty} a_k (x - x_0)^k \quad (5.1.1)$$

Such series are straightforward to evaluate. You don’t, of course, evaluate the k th power of $x - x_0$ *ab initio* for each term; rather you keep the $k - 1$ st power and update it with a multiply. Similarly, the form of the coefficients a is often such as to make use of previous work: Terms like $k!$ or $(2k)!$ can be updated in a multiply or two.

How do you know when you have summed enough terms? In practice, the terms had better be getting small fast, otherwise the series is not a good technique to use in the first place. While not mathematically rigorous in all cases, standard practice is to quit when the term you have just added is smaller in magnitude than some small ϵ times the magnitude of the sum thus far accumulated. (But watch out if isolated instances of $a_k = 0$ are possible!).

A weakness of a power series representation is that it is guaranteed *not* to converge farther than that distance from x_0 at which a singularity is encountered *in the complex plane*. This catastrophe is not usually unexpected: When you find a power series in a book (or when you work one out yourself), you will generally also know the radius of convergence. An insidious problem occurs with series that converge everywhere (in the mathematical sense), but almost nowhere fast enough to be useful in a numerical method. Two familiar examples are the sine function and the Bessel function of the first kind,

$$\sin x = \sum_{k=0}^{\infty} \frac{(-1)^k}{(2k+1)!} x^{2k+1} \quad (5.1.2)$$

$$J_n(x) = \left(\frac{x}{2}\right)^n \sum_{k=0}^{\infty} \frac{(-\frac{1}{4}x^2)^k}{k!(k+n)!} \quad (5.1.3)$$

Both of these series converge for all x . But both don't even start to converge until $k \gg |x|$; before this, their terms are increasing. This makes these series useless for large x .

Accelerating the Convergence of Series

There are several tricks for accelerating the rate of convergence of a series (or, equivalently, of a sequence of partial sums). These tricks will *not* generally help in cases like (5.1.2) or (5.1.3) while the size of the terms is still increasing. For series with terms of decreasing magnitude, however, some accelerating methods can be startlingly good. *Aitken's δ^2 -process* is simply a formula for extrapolating the partial sums of a series whose convergence is approximately geometric. If S_{n-1}, S_n, S_{n+1} are three successive partial sums, then an improved estimate is

$$S'_n \equiv S_{n+1} - \frac{(S_{n+1} - S_n)^2}{S_{n+1} - 2S_n + S_{n-1}} \quad (5.1.4)$$

You can also use (5.1.4) with $n+1$ and $n-1$ replaced by $n+p$ and $n-p$ respectively, for any integer p . If you form the sequence of S'_i 's, you can apply (5.1.4) a second time to *that* sequence, and so on. (In practice, this iteration will only rarely do much for you after the first stage.) Note that equation (5.1.4) should be computed as written; there exist algebraically equivalent forms that are much more susceptible to roundoff error.

For *alternating series* (where the terms in the sum alternate in sign), *Euler's transformation* can be a powerful tool. Generally it is advisable to do a small number

of terms directly, through term $n - 1$ say, then apply the transformation to the rest of the series beginning with term n . The formula (for n even) is

$$\sum_{s=0}^{\infty} (-1)^s u_s = u_0 - u_1 + u_2 \dots - u_{n-1} + \sum_{s=0}^{\infty} \frac{(-1)^s}{2^{s+1}} [\Delta^s u_n] \quad (5.1.5)$$

Here Δ is the *forward difference operator*, i.e.,

$$\begin{aligned} \Delta u_n &\equiv u_{n+1} - u_n \\ \Delta^2 u_n &\equiv u_{n+2} - 2u_{n+1} + u_n \\ \Delta^3 u_n &\equiv u_{n+3} - 3u_{n+2} + 3u_{n+1} - u_n \quad \text{etc.} \end{aligned} \quad (5.1.6)$$

Of course you don't actually do the infinite sum on the right-hand side of (5.1.5), but only the first, say, p terms, thus requiring the first p differences (5.1.6) obtained from the terms starting at u_n .

Euler's transformation can be applied not only to convergent series. In some cases it will produce accurate answers from the first terms of a series that is formally divergent. It is widely used in the summation of asymptotic series. In this case it is generally wise not to sum farther than where the terms start increasing in magnitude; and you should devise some independent numerical check that the results are meaningful.

There is an elegant and subtle implementation of Euler's transformation due to van Wijngaarden [1]: It incorporates the terms of the original alternating series one at a time, in order. For each incorporation it *either* increases p by 1, equivalent to computing one further difference (5.1.6), or else *retroactively* increases n by 1, without having to redo all the difference calculations based on the old n value! The decision as to which to increase, n or p , is taken in such a way as to make the convergence most rapid. Van Wijngaarden's technique requires only one vector of saved partial differences. Here is the algorithm:

```
SUBROUTINE eulsum(sum,term,jterm,wksp)
INTEGER jterm
REAL sum,term,wksp(jterm)           Workspace, provided by the calling program.
Incorporates into sum the jterm'th term, with value term, of an alternating series. sum
is input as the previous partial sum, and is output as the new partial sum. The first call
to this routine, with the first term in the series, should be with jterm=1. On the second
call, term should be set to the second term of the series, with sign opposite to that of the
first call, and jterm should be 2. And so on.
INTEGER j,nterm
REAL dum,tmp
SAVE nterm
if(jterm.eq.1)then               Initialize:
  nterm=1                         Number of saved differences in wksp.
  wksp(1)=term
  sum=0.5*term
else                           Return first estimate.
  tmp=wksp(1)
  wksp(1)=term
  do ii j=1,nterm-1               Update saved quantities by van Wijngaarden's algo-
    dum=wksp(j+1)                 rithm.
    wksp(j+1)=0.5*(wksp(j)+tmp)
    tmp=dum
  enddo
```

```

enddo 11
wksp(nterm+1)=0.5*(wksp(nterm)+tmp)
if(abs(wksp(nterm+1)).le.abs(wksp(nterm)))then      Favorable to increase p,
    sum=sum+0.5*wksp(nterm+1)
    nterm=nterm+1
else
    sum=sum+wksp(nterm+1)           and the table becomes longer.
    nterm=nterm+1
endif
endif
return
END

```

The powerful Euler technique is not directly applicable to a series of positive terms. Occasionally it is useful to convert a series of positive terms into an alternating series, just so that the Euler transformation can be used! Van Wijngaarden has given a transformation for accomplishing this [1]:

$$\sum_{r=1}^{\infty} v_r = \sum_{r=1}^{\infty} (-1)^{r-1} w_r \quad (5.1.7)$$

where

$$w_r \equiv v_r + 2v_{2r} + 4v_{4r} + 8v_{8r} + \dots \quad (5.1.8)$$

Equations (5.1.7) and (5.1.8) replace a simple sum by a two-dimensional sum, each term in (5.1.7) being itself an infinite sum (5.1.8). This may seem a strange way to save on work! Since, however, the indices in (5.1.8) increase tremendously rapidly, as powers of 2, it often requires only a few terms to converge (5.1.8) to extraordinary accuracy. You do, however, need to be able to compute the v_r 's efficiently for "random" values r . The standard "updating" tricks for sequential r 's, mentioned above following equation (5.1.1), can't be used.

Actually, Euler's transformation is a special case of a more general transformation of power series. Suppose that some known function $g(z)$ has the series

$$g(z) = \sum_{n=0}^{\infty} b_n z^n \quad (5.1.9)$$

and that you want to sum the new, unknown, series

$$f(z) = \sum_{n=0}^{\infty} c_n b_n z^n \quad (5.1.10)$$

Then it is not hard to show (see [2]) that equation (5.1.10) can be written as

$$f(z) = \sum_{n=0}^{\infty} [\Delta^{(n)} c_0] \frac{g^{(n)}}{n!} z^n \quad (5.1.11)$$

which often converges much more rapidly. Here $\Delta^{(n)} c_0$ is the n th finite-difference operator (equation 5.1.6), with $\Delta^{(0)} c_0 \equiv c_0$, and $g^{(n)}$ is the n th derivative of $g(z)$. The usual Euler transformation (equation 5.1.5 with $n = 0$) can be obtained, for example, by substituting

$$g(z) = \frac{1}{1+z} = 1 - z + z^2 - z^3 + \dots \quad (5.1.12)$$

into equation (5.1.11), and then setting $z = 1$.

Sometimes you will want to compute a function from a series representation even when the computation is *not* efficient. For example, you may be using the values obtained to fit the function to an approximating form that you will use subsequently (cf. §5.8). If you are summing very large numbers of slowly convergent terms, pay attention to roundoff errors! In floating-point representation it is more accurate to sum a list of numbers in the order starting with the smallest one, rather than starting with the largest one. It is even better to group terms pairwise, then in pairs of pairs, etc., so that all additions involve operands of comparable magnitude.

5.2 Evaluation of Continued Fractions

Continued fractions are often powerful ways of evaluating functions that occur in scientific applications. A continued fraction looks like this:

$$f(x) = b_0 + \cfrac{a_1}{b_1 + \cfrac{a_2}{b_2 + \cfrac{a_3}{b_3 + \cfrac{a_4}{b_4 + \cfrac{a_5}{b_5 + \dots}}}}} \quad (5.2.1)$$

Printers prefer to write this as

$$f(x) = b_0 + \frac{a_1}{b_1} \frac{a_2}{b_2} \frac{a_3}{b_3} \frac{a_4}{b_4} \frac{a_5}{b_5} \dots \quad (5.2.2)$$

In either (5.2.1) or (5.2.2), the a 's and b 's can themselves be functions of x , usually linear or quadratic monomials at worst (i.e., constants times x or times x^2). For example, the continued fraction representation of the tangent function is

$$\tan x = \frac{x}{1 -} \frac{x^2}{3 -} \frac{x^2}{5 -} \frac{x^2}{7 -} \dots \quad (5.2.3)$$

Continued fractions frequently converge much more rapidly than power series expansions, and in a much larger domain in the complex plane (not necessarily including the domain of convergence of the series, however). Sometimes the continued fraction converges best where the series does worst, although this is not

into equation (5.1.11), and then setting $z = 1$.

Sometimes you will want to compute a function from a series representation even when the computation is *not* efficient. For example, you may be using the values obtained to fit the function to an approximating form that you will use subsequently (cf. §5.8). If you are summing very large numbers of slowly convergent terms, pay attention to roundoff errors! In floating-point representation it is more accurate to sum a list of numbers in the order starting with the smallest one, rather than starting with the largest one. It is even better to group terms pairwise, then in pairs of pairs, etc., so that all additions involve operands of comparable magnitude.

5.2 Evaluation of Continued Fractions

Continued fractions are often powerful ways of evaluating functions that occur in scientific applications. A continued fraction looks like this:

$$f(x) = b_0 + \cfrac{a_1}{b_1 + \cfrac{a_2}{b_2 + \cfrac{a_3}{b_3 + \cfrac{a_4}{b_4 + \cfrac{a_5}{b_5 + \dots}}}}} \quad (5.2.1)$$

Printers prefer to write this as

$$f(x) = b_0 + \frac{a_1}{b_1} \frac{a_2}{b_2} \frac{a_3}{b_3} \frac{a_4}{b_4} \frac{a_5}{b_5} \dots \quad (5.2.2)$$

In either (5.2.1) or (5.2.2), the a 's and b 's can themselves be functions of x , usually linear or quadratic monomials at worst (i.e., constants times x or times x^2). For example, the continued fraction representation of the tangent function is

$$\tan x = \frac{x}{1 -} \frac{x^2}{3 -} \frac{x^2}{5 -} \frac{x^2}{7 -} \dots \quad (5.2.3)$$

Continued fractions frequently converge much more rapidly than power series expansions, and in a much larger domain in the complex plane (not necessarily including the domain of convergence of the series, however). Sometimes the continued fraction converges best where the series does worst, although this is not

a general rule. Blanch [1] gives a good review of the most useful convergence tests for continued fractions.

There are standard techniques, including the important *quotient-difference algorithm*, for going back and forth between continued fraction approximations, power series approximations, and rational function approximations. Consult Acton [2] for an introduction to this subject, and Fike [3] for further details and references.

How do you tell how far to go when evaluating a continued fraction? Unlike a series, you can't just evaluate equation (5.2.1) from left to right, stopping when the change is small. Written in the form of (5.2.1), the only way to evaluate the continued fraction is from right to left, first (blindly!) guessing how far out to start. This is not the right way.

The right way is to use a result that relates continued fractions to rational approximations, and that gives a means of evaluating (5.2.1) or (5.2.2) from left to right. Let f_n denote the result of evaluating (5.2.2) with coefficients through a_n and b_n . Then

$$f_n = \frac{A_n}{B_n} \quad (5.2.4)$$

where A_n and B_n are given by the following recurrence:

$$\begin{aligned} A_{-1} &\equiv 1 & B_{-1} &\equiv 0 \\ A_0 &\equiv b_0 & B_0 &\equiv 1 \\ A_j &= b_j A_{j-1} + a_j A_{j-2} & B_j &= b_j B_{j-1} + a_j B_{j-2} & j &= 1, 2, \dots, n \end{aligned} \quad (5.2.5)$$

This method was invented by J. Wallis in 1655 (!), and is discussed in his *Arithmetica Infinitorum* [4]. You can easily prove it by induction.

In practice, this algorithm has some unattractive features: The recurrence (5.2.5) frequently generates very large or very small values for the partial numerators and denominators A_j and B_j . There is thus the danger of overflow or underflow of the floating-point representation. However, the recurrence (5.2.5) is linear in the A 's and B 's. At any point you can rescale the currently saved two levels of the recurrence, e.g., divide A_j , B_j , A_{j-1} , and B_{j-1} all by B_j . This incidentally makes $A_j = f_j$ and is convenient for testing whether you have gone far enough: See if f_j and f_{j-1} from the last iteration are as close as you would like them to be. (If B_j happens to be zero, which can happen, just skip the renormalization for this cycle. A fancier level of optimization is to renormalize only when an overflow is imminent, saving the unnecessary divides. All this complicates the program logic.)

Two newer algorithms have been proposed for evaluating continued fractions. *Steed's method* does not use A_j and B_j explicitly, but only the ratio $D_j = B_{j-1}/B_j$. One calculates D_j and $\Delta f_j = f_j - f_{j-1}$ recursively using

$$D_j = 1/(b_j + a_j D_{j-1}) \quad (5.2.6)$$

$$\Delta f_j = (b_j D_j - 1) \Delta f_{j-1} \quad (5.2.7)$$

Steed's method (see, e.g., [5]) avoids the need for rescaling of intermediate results. However, for certain continued fractions you can occasionally run into a situation

where the denominator in (5.2.6) approaches zero, so that D_j and Δf_j are very large. The next Δf_{j+1} will typically cancel this large change, but with loss of accuracy in the numerical running sum of the f_j 's. It is awkward to program around this, so Steed's method can be recommended only for cases where you know in advance that no denominator can vanish. We will use it for a special purpose in the routine `bessik` (§6.7).

The best general method for evaluating continued fractions seems to be the *modified Lentz's method* [6]. The need for rescaling intermediate results is avoided by using *both* the ratios

$$C_j = A_j/A_{j-1}, \quad D_j = B_{j-1}/B_j \quad (5.2.8)$$

and calculating f_j by

$$f_j = f_{j-1} C_j D_j \quad (5.2.9)$$

From equation (5.2.5), one easily shows that the ratios satisfy the recurrence relations

$$D_j = 1/(b_j + a_j D_{j-1}), \quad C_j = b_j + a_j/C_{j-1} \quad (5.2.10)$$

In this algorithm there is the danger that the denominator in the expression for D_j , or the quantity C_j itself, might approach zero. Either of these conditions invalidates (5.2.10). However, Thompson and Barnett [5] show how to modify Lentz's algorithm to fix this: Just shift the offending term by a small amount, e.g., 10^{-30} . If you work through a cycle of the algorithm with this prescription, you will see that f_{j+1} is accurately calculated.

In detail, the modified Lentz's algorithm is this:

- Set $f_0 = b_0$; if $b_0 = 0$ set $f_0 = \text{tiny}$.
- Set $C_0 = f_0$.
- Set $D_0 = 0$.
- For $j = 1, 2, \dots$
 - Set $D_j = b_j + a_j D_{j-1}$.
 - If $D_j = 0$, set $D_j = \text{tiny}$.
 - Set $C_j = b_j + a_j/C_{j-1}$.
 - If $C_j = 0$ set $C_j = \text{tiny}$.
 - Set $D_j = 1/D_j$.
 - Set $\Delta_j = C_j D_j$.
 - Set $f_j = f_{j-1} \Delta_j$.
 - If $|\Delta_j - 1| < \text{eps}$ then exit.

Here eps is your floating-point precision, say 10^{-7} or 10^{-15} . The parameter tiny should be less than typical values of $\text{eps}|b_j|$, say 10^{-30} .

The above algorithm assumes that you can terminate the evaluation of the continued fraction when $|f_j - f_{j-1}|$ is sufficiently small. This is usually the case, but by no means guaranteed. Jones [7] gives a list of theorems that can be used to justify this termination criterion for various kinds of continued fractions.

There is at present no rigorous analysis of error propagation in Lentz's algorithm. However, empirical tests suggest that it is at least as good as other methods.

Manipulating Continued Fractions

Several important properties of continued fractions can be used to rewrite them in forms that can speed up numerical computation. An *equivalence transformation*

$$a_n \rightarrow \lambda a_n, \quad b_n \rightarrow \lambda b_n, \quad a_{n+1} \rightarrow \lambda a_{n+1} \quad (5.2.11)$$

leaves the value of a continued fraction unchanged. By a suitable choice of the scale factor λ you can often simplify the form of the a 's and the b 's. Of course, you can carry out successive equivalence transformations, possibly with different λ 's, on successive terms of the continued fraction.

The *even* and *odd* parts of a continued fraction are continued fractions whose successive convergents are f_{2n} and f_{2n+1} , respectively. Their main use is that they converge twice as fast as the original continued fraction, and so if their terms are not much more complicated than the terms in the original there can be a big savings in computation. The formula for the even part of (5.2.2) is

$$f_{\text{even}} = d_0 + \frac{c_1}{d_1 +} \frac{c_2}{d_2 +} \dots \quad (5.2.12)$$

where in terms of intermediate variables

$$\begin{aligned} \alpha_1 &= \frac{a_1}{b_1} \\ \alpha_n &= \frac{a_n}{b_n b_{n-1}}, \quad n \geq 2 \end{aligned} \quad (5.2.13)$$

we have

$$\begin{aligned} d_0 &= b_0, \quad c_1 = \alpha_1, \quad d_1 = 1 + \alpha_2 \\ c_n &= -\alpha_{2n-1} \alpha_{2n-2}, \quad d_n = 1 + \alpha_{2n-1} + \alpha_{2n}, \quad n \geq 2 \end{aligned} \quad (5.2.14)$$

You can find the similar formula for the odd part in the review by Blanch [1]. Often a combination of the transformations (5.2.14) and (5.2.11) is used to get the best form for numerical work.

We will make frequent use of continued fractions in the next chapter.

5.3 Polynomials and Rational Functions

A polynomial of degree $N - 1$ is represented numerically as a stored array of coefficients, $c(j)$ with $j = 1, \dots, N$. We will always take $c(1)$ to be the constant term in the polynomial, $c(N)$ the coefficient of x^{N-1} ; but of course other conventions are possible. There are two kinds of manipulations that you can do with a polynomial: *numerical* manipulations (such as evaluation), where you are given the numerical value of its argument, or *algebraic* manipulations, where you want to transform the coefficient array in some way without choosing any particular argument. Let's start with the numerical.

We assume that you know enough *never* to evaluate a polynomial this way:

```
p=c(1)+c(2)*x+c(3)*x**2+c(4)*x**3+c(5)*x**4
```

Come the (computer) revolution, all persons found guilty of such criminal behavior will be summarily executed, and their programs won't be! It is a matter of taste, however, whether to write

```
p=c(1)+x*(c(2)+x*(c(3)+x*(c(4)+x*c(5))))
```

or

```
p=((c(5)*x+c(4))*x+c(3))*x+c(2))*x+c(1)
```

If the number of coefficients is a large number n , one writes

```
p=c(n)
do :: j=n-1,1,-1
    p=p*x+c(j)
enddo ::
```

Another useful trick is for evaluating a polynomial $P(x)$ and its derivative $dP(x)/dx$ simultaneously:

```
p=c(n)
dp=0.
do :: j=n-1,1,-1
    dp=dp*x+p
    p=p*x+c(j)
enddo ::
```

which returns the polynomial as p and its derivative as dp .

The above trick, which is basically *synthetic division* [1,2], generalizes to the evaluation of the polynomial and $nd-1$ of its derivatives simultaneously:

Thompson, I.J., and Barnett, A.R. 1986, *Journal of Computational Physics*, vol. 64, pp. 490–509.

5.3 Polynomials and Rational Functions

A polynomial of degree $N - 1$ is represented numerically as a stored array of coefficients, $c(j)$ with $j = 1, \dots, N$. We will always take $c(1)$ to be the constant term in the polynomial, $c(N)$ the coefficient of x^{N-1} ; but of course other conventions are possible. There are two kinds of manipulations that you can do with a polynomial: *numerical* manipulations (such as evaluation), where you are given the numerical value of its argument, or *algebraic* manipulations, where you want to transform the coefficient array in some way without choosing any particular argument. Let's start with the numerical.

We assume that you know enough *never* to evaluate a polynomial this way:

```
p=c(1)+c(2)*x+c(3)*x**2+c(4)*x**3+c(5)*x**4
```

Come the (computer) revolution, all persons found guilty of such criminal behavior will be summarily executed, and their programs won't be! It is a matter of taste, however, whether to write

```
p=c(1)+x*(c(2)+x*(c(3)+x*(c(4)+x*c(5))))
```

or

```
p=((c(5)*x+c(4))*x+c(3))*x+c(2))*x+c(1)
```

If the number of coefficients is a large number n , one writes

```
p=c(n)
do :: j=n-1,1,-1
    p=p*x+c(j)
enddo ::
```

Another useful trick is for evaluating a polynomial $P(x)$ and its derivative $dP(x)/dx$ simultaneously:

```
p=c(n)
dp=0.
do :: j=n-1,1,-1
    dp=dp*x+p
    p=p*x+c(j)
enddo ::
```

which returns the polynomial as p and its derivative as dp .

The above trick, which is basically *synthetic division* [1,2], generalizes to the evaluation of the polynomial and $nd-1$ of its derivatives simultaneously:

```

SUBROUTINE ddpoly(c,nc,x,pd,nd)
INTEGER nc,nd
REAL x,c(nc),pd(nd)
Given the coefficients of a polynomial of degree nc-1 as an array c(1:nc) with c(1) being
the constant term, and given a value x, and given a value nd>1, this routine returns the
polynomial evaluated at x as pd(1) and nd-1 derivatives as pd(2:nd).
INTEGER i,j,nd
REAL const
pd(1)=c(nc)
do 11 j=2,nd
    pd(j)=0.
  enddo 11
do 13 i=nc-1,1,-1
    nnd=min(nd,nc+1-i)
    do 12 j=nnd,2,-1
        pd(j)=pd(j)*x+pd(j-1)
    enddo 12
    pd(1)=pd(1)*x+c(i)
  enddo 13
const=2.                                After the first derivative, factorial constants come in.
do 14 i=3,nd
    pd(i)=const*pd(i)
    const=const*i
  enddo 14
return
END

```

As a curiosity, you might be interested to know that polynomials of degree $n > 3$ can be evaluated in fewer than n multiplications, at least if you are willing to precompute some auxiliary coefficients and, in some cases, do an extra addition. For example, the polynomial

$$P(x) = a_0 + a_1x + a_2x^2 + a_3x^3 + a_4x^4 \quad (5.3.1)$$

where $a_4 > 0$, can be evaluated with 3 multiplications and 5 additions as follows:

$$P(x) = [(Ax + B)^2 + Ax + C][(Ax + B)^2 + D] + E \quad (5.3.2)$$

where A, B, C, D , and E are to be precomputed by

$$\begin{aligned} A &= (a_4)^{1/4} \\ B &= \frac{a_3 - A^3}{4A^3} \\ D &= 3B^2 + 8B^3 + \frac{a_1A - 2a_2B}{A^2} \\ C &= \frac{a_2}{A^2} - 2B - 6B^2 - D \\ E &= a_0 - B^4 - B^2(C + D) - CD \end{aligned} \quad (5.3.3)$$

Fifth degree polynomials can be evaluated in 4 multiplies and 5 adds; sixth degree polynomials can be evaluated in 4 multiplies and 7 adds; if any of this strikes you as interesting, consult references [3-5]. The subject has something of the same entertaining, if impractical, flavor as that of fast matrix multiplication, discussed in §2.11.

Turn now to algebraic manipulations. You multiply a polynomial of degree $n - 1$ (array of length n) by a monomial factor $x - a$ by a bit of code like the following,

```
c(n+1)=c(n)
do 11 j=n,2,-1
    c(j)=c(j-1)-c(j)*a
11 enddo
c(1)=-c(1)*a
```

Likewise, you divide a polynomial of degree $n - 1$ by a monomial factor $x - a$ (synthetic division again) using

```
rem=c(n)
c(n)=0.
do 11 i=n-1,1,-1
    swap=c(i)
    c(i)=rem
    rem=swap+rem*a
11 enddo
```

which leaves you with a new polynomial array and a numerical remainder `rem`.

Multiplication of two general polynomials involves straightforward summing of the products, each involving one coefficient from each polynomial. Division of two general polynomials, while it can be done awkwardly in the fashion taught using pencil and paper, is susceptible to a good deal of streamlining. Witness the following routine based on the algorithm in [3].

```
SUBROUTINE poldiv(u,n,v,nv,q,r)
INTEGER n,nv
REAL q(n),r(n),u(n),v(nv)
Given the n coefficients of a polynomial in u(1:n), and the nv coefficients of another
polynomial in v(1:nv), divide the polynomial u by the polynomial v ("u"/"v") giving
a quotient polynomial whose coefficients are returned in q(1:n-nv+1), and a remainder
polynomial whose coefficients are returned in r(1:nv-1). The arrays q and r are dimensioned
with lengths n, but the elements r(nv)...r(n) and q(n-nv+2)...q(n) will be
returned as zero.
INTEGER j,k
do 11 j=1,n
    r(j)=u(j)
    q(j)=0.
11 enddo
do 13 k=n-nv,0,-1
    q(k+1)=r(nv+k)/v(nv)
    do 12 j=nv+k-1,k+1,-1
        r(j)=r(j)-q(k+1)*v(j-k)
    12 enddo
13 enddo
do 14 j=nv,n
    r(j)=0.
14 enddo
return
END
```

Rational Functions

You evaluate a rational function like

$$R(x) = \frac{P_\mu(x)}{Q_\nu(x)} = \frac{p_0 + p_1x + \cdots + p_\mu x^\mu}{q_0 + q_1x + \cdots + q_\nu x^\nu} \quad (5.3.4)$$

in the obvious way, namely as two separate polynomials followed by a divide. As a matter of convention one usually chooses $q_0 = 1$, obtained by dividing numerator and denominator by any other q_0 . It is often convenient to have both sets of coefficients stored in a single array, and to have a standard subroutine available for doing the evaluation:

```
FUNCTION ratval(x,cof,mm,kk)
INTEGER kk,mm
DOUBLE PRECISION ratval,x,cof(mm+kk+1)      Note precision! Change to REAL if desired.
      Given mm, kk, and cof(1:mm+kk+1), evaluate and return the rational function (cof(1) +
      cof(2)x + ... + cof(mm+1)xmm)/(1 + cof(mm+2)x + ... + cof(mm+kk+1)xkk).
INTEGER j
DOUBLE PRECISION sumd,sumn
sumn=cof(mm+1)
do 11 j=mm,1,-1
      sumn=sumn*x+cof(j)
enddo 11
sumd=0.d0
do 12 j=mm+kk+1,mm+2,-1
      sumd=(sumd+cof(j))*x
enddo 12
ratval=sumn/(1.d0+sumd)
return
END
```

5.4 Complex Arithmetic

Since FORTRAN has the built-in data type COMPLEX, you can generally let the compiler and intrinsic function library take care of complex arithmetic for you. Generally, but not always. For a program with only a small number of complex operations, you may want to code these yourself, in-line. Or, you may find that your compiler is not up to snuff: It is disconcertingly common to encounter complex operations that produce overflows or underflows when both the complex operands and the complex result are perfectly representable. This occurs, we think, because software companies assign inexperienced programmers to what they believe to be the perfectly trivial task of implementing complex arithmetic.

Actually, complex arithmetic is not *quite* trivial. Addition and subtraction are done in the obvious way, performing the operation separately on the real and imaginary parts of the operands. Multiplication can also be done in the obvious way, with 4 multiplications, one addition, and one subtraction,

$$(a + ib)(c + id) = (ac - bd) + i(bc + ad) \quad (5.4.1)$$

(the addition before the i doesn't count; it just separates the real and imaginary parts notationally). But it is sometimes faster to multiply via

$$(a + ib)(c + id) = (ac - bd) + i[(a + b)(c + d) - ac - bd] \quad (5.4.2)$$

which has only three multiplications (ac , bd , $(a + b)(c + d)$), plus two additions and three subtractions. The total operations count is higher by two, but multiplication is a slow operation on some machines.

While it is true that intermediate results in equations (5.4.1) and (5.4.2) can overflow even when the final result is representable, this happens only when the final answer is on the edge of representability. Not so for the complex modulus, if you or your compiler are misguided enough to compute it as

$$|a + ib| = \sqrt{a^2 + b^2} \quad (\text{bad!}) \quad (5.4.3)$$

whose intermediate result will overflow if either a or b is as large as the square root of the largest representable number (e.g., 10^{19} as compared to 10^{38}). The right way to do the calculation is

$$|a + ib| = \begin{cases} |a| \sqrt{1 + (b/a)^2} & |a| \geq |b| \\ |b| \sqrt{1 + (a/b)^2} & |a| < |b| \end{cases} \quad (5.4.4)$$

Complex division should use a similar trick to prevent avoidable overflows, underflow, or loss of precision,

$$\frac{a + ib}{c + id} = \begin{cases} \frac{[a + b(d/c)] + i[b - a(d/c)]}{c + d(d/c)} & |c| \geq |d| \\ \frac{[a(c/d) + b] + i[b(c/d) - a]}{c(c/d) + d} & |c| < |d| \end{cases} \quad (5.4.5)$$

5.4 Complex Arithmetic

Since FORTRAN has the built-in data type COMPLEX, you can generally let the compiler and intrinsic function library take care of complex arithmetic for you. Generally, but not always. For a program with only a small number of complex operations, you may want to code these yourself, in-line. Or, you may find that your compiler is not up to snuff: It is disconcertingly common to encounter complex operations that produce overflows or underflows when both the complex operands and the complex result are perfectly representable. This occurs, we think, because software companies assign inexperienced programmers to what they believe to be the perfectly trivial task of implementing complex arithmetic.

Actually, complex arithmetic is not *quite* trivial. Addition and subtraction are done in the obvious way, performing the operation separately on the real and imaginary parts of the operands. Multiplication can also be done in the obvious way, with 4 multiplications, one addition, and one subtraction,

$$(a + ib)(c + id) = (ac - bd) + i(bc + ad) \quad (5.4.1)$$

(the addition before the i doesn't count; it just separates the real and imaginary parts notationally). But it is sometimes faster to multiply via

$$(a + ib)(c + id) = (ac - bd) + i[(a + b)(c + d) - ac - bd] \quad (5.4.2)$$

which has only three multiplications (ac , bd , $(a + b)(c + d)$), plus two additions and three subtractions. The total operations count is higher by two, but multiplication is a slow operation on some machines.

While it is true that intermediate results in equations (5.4.1) and (5.4.2) can overflow even when the final result is representable, this happens only when the final answer is on the edge of representability. Not so for the complex modulus, if you or your compiler are misguided enough to compute it as

$$|a + ib| = \sqrt{a^2 + b^2} \quad (\text{bad!}) \quad (5.4.3)$$

whose intermediate result will overflow if either a or b is as large as the square root of the largest representable number (e.g., 10^{19} as compared to 10^{38}). The right way to do the calculation is

$$|a + ib| = \begin{cases} |a| \sqrt{1 + (b/a)^2} & |a| \geq |b| \\ |b| \sqrt{1 + (a/b)^2} & |a| < |b| \end{cases} \quad (5.4.4)$$

Complex division should use a similar trick to prevent avoidable overflows, underflow, or loss of precision,

$$\frac{a + ib}{c + id} = \begin{cases} \frac{[a + b(d/c)] + i[b - a(d/c)]}{c + d(d/c)} & |c| \geq |d| \\ \frac{[a(c/d) + b] + i[b(c/d) - a]}{c(c/d) + d} & |c| < |d| \end{cases} \quad (5.4.5)$$

Of course you should calculate repeated subexpressions, like c/d or d/c , only once.

Complex square root is even more complicated, since we must both guard intermediate results, and also enforce a chosen branch cut (here taken to be the negative real axis). To take the square root of $c + id$, first compute

$$w \equiv \begin{cases} 0 & c = d = 0 \\ \sqrt{|c|} \sqrt{\frac{1 + \sqrt{1 + (d/c)^2}}{2}} & |c| \geq |d| \\ \sqrt{|d|} \sqrt{\frac{|c/d| + \sqrt{1 + (c/d)^2}}{2}} & |c| < |d| \end{cases} \quad (5.4.6)$$

Then the answer is

$$\sqrt{c + id} = \begin{cases} 0 & w = 0 \\ w + i \left(\frac{d}{2w} \right) & w \neq 0, c \geq 0 \\ \frac{|d|}{2w} + iw & w \neq 0, c < 0, d \geq 0 \\ \frac{|d|}{2w} - iw & w \neq 0, c < 0, d < 0 \end{cases} \quad (5.4.7)$$

5.5 Recurrence Relations and Clenshaw's Recurrence Formula

Many useful functions satisfy recurrence relations, e.g.,

$$(n+1)P_{n+1}(x) = (2n+1)xP_n(x) - nP_{n-1}(x) \quad (5.5.1)$$

$$J_{n+1}(x) = \frac{2n}{x} J_n(x) - J_{n-1}(x) \quad (5.5.2)$$

$$nE_{n+1}(x) = e^{-x} - xE_n(x) \quad (5.5.3)$$

$$\cos n\theta = 2 \cos \theta \cos(n-1)\theta - \cos(n-2)\theta \quad (5.5.4)$$

$$\sin n\theta = 2 \cos \theta \sin(n-1)\theta - \sin(n-2)\theta \quad (5.5.5)$$

where the first three functions are Legendre polynomials, Bessel functions of the first kind, and exponential integrals, respectively. (For notation see [1].) These relations

Of course you should calculate repeated subexpressions, like c/d or d/c , only once.

Complex square root is even more complicated, since we must both guard intermediate results, and also enforce a chosen branch cut (here taken to be the negative real axis). To take the square root of $c + id$, first compute

$$w \equiv \begin{cases} 0 & c = d = 0 \\ \sqrt{|c|} \sqrt{\frac{1 + \sqrt{1 + (d/c)^2}}{2}} & |c| \geq |d| \\ \sqrt{|d|} \sqrt{\frac{|c/d| + \sqrt{1 + (c/d)^2}}{2}} & |c| < |d| \end{cases} \quad (5.4.6)$$

Then the answer is

$$\sqrt{c + id} = \begin{cases} 0 & w = 0 \\ w + i \left(\frac{d}{2w} \right) & w \neq 0, c \geq 0 \\ \frac{|d|}{2w} + iw & w \neq 0, c < 0, d \geq 0 \\ \frac{|d|}{2w} - iw & w \neq 0, c < 0, d < 0 \end{cases} \quad (5.4.7)$$

5.5 Recurrence Relations and Clenshaw's Recurrence Formula

Many useful functions satisfy recurrence relations, e.g.,

$$(n+1)P_{n+1}(x) = (2n+1)xP_n(x) - nP_{n-1}(x) \quad (5.5.1)$$

$$J_{n+1}(x) = \frac{2n}{x} J_n(x) - J_{n-1}(x) \quad (5.5.2)$$

$$nE_{n+1}(x) = e^{-x} - xE_n(x) \quad (5.5.3)$$

$$\cos n\theta = 2 \cos \theta \cos(n-1)\theta - \cos(n-2)\theta \quad (5.5.4)$$

$$\sin n\theta = 2 \cos \theta \sin(n-1)\theta - \sin(n-2)\theta \quad (5.5.5)$$

where the first three functions are Legendre polynomials, Bessel functions of the first kind, and exponential integrals, respectively. (For notation see [1].) These relations

are useful for extending computational methods from two successive values of n to other values, either larger or smaller.

Equations (5.5.4) and (5.5.5) motivate us to say a few words about trigonometric functions. If your program's running time is dominated by evaluating trigonometric functions, you are probably doing something wrong. Trig functions whose arguments form a linear sequence $\theta = \theta_0 + n\delta$, $n = 0, 1, 2, \dots$, are efficiently calculated by the following recurrence,

$$\begin{aligned}\cos(\theta + \delta) &= \cos \theta - [\alpha \cos \theta + \beta \sin \theta] \\ \sin(\theta + \delta) &= \sin \theta - [\alpha \sin \theta - \beta \cos \theta]\end{aligned}\tag{5.5.6}$$

where α and β are the precomputed coefficients

$$\alpha \equiv 2 \sin^2 \left(\frac{\delta}{2} \right) \quad \beta \equiv \sin \delta \tag{5.5.7}$$

The reason for doing things this way, rather than with the standard (and equivalent) identities for sums of angles, is that here α and β do not lose significance if the incremental δ is small. Likewise, the adds in equation (5.5.6) should be done in the order indicated by square brackets. We will use (5.5.6) repeatedly in Chapter 12, when we deal with Fourier transforms.

Another trick, occasionally useful, is to note that both $\sin \theta$ and $\cos \theta$ can be calculated via a single call to \tan :

$$t \equiv \tan \left(\frac{\theta}{2} \right) \quad \cos \theta = \frac{1 - t^2}{1 + t^2} \quad \sin \theta = \frac{2t}{1 + t^2} \tag{5.5.8}$$

The cost of getting both \sin and \cos , if you need them, is thus the cost of \tan plus 2 multiplies, 2 divides, and 2 adds. On machines with slow trig functions, this can be a savings. *However*, note that special treatment is required if $\theta \rightarrow \pm\pi$. And also note that many modern machines have *very fast* trig functions; so you should not assume that equation (5.5.8) is faster without testing.

Stability of Recurrences

You need to be aware that recurrence relations are not necessarily *stable* against roundoff error in the direction that you propose to go (either increasing n or decreasing n). A three-term linear recurrence relation

$$y_{n+1} + a_n y_n + b_n y_{n-1} = 0, \quad n = 1, 2, \dots \tag{5.5.9}$$

has two linearly independent solutions, f_n and g_n say. Only one of these corresponds to the sequence of functions f_n that you are trying to generate. The other one g_n may be exponentially growing in the direction that you want to go, or exponentially damped, or exponentially neutral (growing or dying as some power law, for example). If it is exponentially growing, then the recurrence relation is of little or no practical use in that direction. This is the case, e.g., for (5.5.2) in the direction of increasing n , when $x < n$. You cannot generate Bessel functions of high n by forward recurrence on (5.5.2).

To state things a bit more formally, if

$$f_n/g_n \rightarrow 0 \quad \text{as} \quad n \rightarrow \infty \quad (5.5.10)$$

then f_n is called the *minimal* solution of the recurrence relation (5.5.9). Nonminimal solutions like g_n are called *dominant* solutions. The minimal solution is unique, if it exists, but dominant solutions are not — you can add an arbitrary multiple of f_n to a given g_n . You can evaluate any dominant solution by forward recurrence, *but not the minimal solution*. (Unfortunately it is sometimes the one you want.)

Abramowitz and Stegun (in their Introduction) [1] give a list of recurrences that are stable in the increasing or decreasing directions. That list does not contain all possible formulas, of course. Given a recurrence relation for some function $f_n(x)$ you can test it yourself with about five minutes of (human) labor: For a fixed x in your range of interest, start the recurrence not with true values of $f_j(x)$ and $f_{j+1}(x)$, but (first) with the values 1 and 0, respectively, and then (second) with 0 and 1, respectively. Generate 10 or 20 terms of the recursive sequences in the direction that you want to go (increasing or decreasing from j), for each of the two starting conditions. Look at the difference between the corresponding members of the two sequences. If the differences stay of order unity (absolute value less than 10, say), then the recurrence is stable. If they increase slowly, then the recurrence may be mildly unstable but quite tolerably so. If they increase catastrophically, then there is an exponentially growing solution of the recurrence. If you know that the function that you want actually corresponds to the growing solution, then you can keep the recurrence formula anyway e.g., the case of the Bessel function $Y_n(x)$ for increasing n , see §6.5; if you don't know which solution your function corresponds to, you must at this point reject the recurrence formula. Notice that you can do this test *before* you go to the trouble of finding a numerical method for computing the two starting functions $f_j(x)$ and $f_{j+1}(x)$: stability is a property of the recurrence, not of the starting values.

An alternative heuristic procedure for testing stability is to replace the recurrence relation by a similar one that is linear with constant coefficients. For example, the relation (5.5.2) becomes

$$y_{n+1} - 2\gamma y_n + y_{n-1} = 0 \quad (5.5.11)$$

where $\gamma \equiv n/x$ is treated as a constant. You solve such recurrence relations by trying solutions of the form $y_n = a^n$. Substituting into the above recurrence gives

$$a^2 - 2\gamma a + 1 = 0 \quad \text{or} \quad a = \gamma \pm \sqrt{\gamma^2 - 1} \quad (5.5.12)$$

The recurrence is stable if $|a| \leq 1$ for all solutions a . This holds (as you can verify) if $|\gamma| \leq 1$ or $n \leq x$. The recurrence (5.5.2) thus cannot be used, starting with $J_0(x)$ and $J_1(x)$, to compute $J_n(x)$ for large n .

Possibly you would at this point like the security of some real theorems on this subject (although we ourselves always follow one of the heuristic procedures). Here are two theorems, due to Perron [2]:

Theorem A. If in (5.5.9) $a_n \sim an^\alpha$, $b_n \sim bn^\beta$ as $n \rightarrow \infty$, and $\beta < 2\alpha$, then

$$g_{n+1}/g_n \sim -an^\alpha, \quad f_{n+1}/f_n \sim -(b/a)n^{\beta-\alpha} \quad (5.5.13)$$

and f_n is the minimal solution to (5.5.9).

Theorem B. Under the same conditions as Theorem A, but with $\beta = 2\alpha$, consider the *characteristic polynomial*

$$t^2 + at + b = 0 \quad (5.5.14)$$

If the roots t_1 and t_2 of (5.5.14) have distinct moduli, $|t_1| > |t_2|$ say, then

$$g_{n+1}/g_n \sim t_1 n^\alpha, \quad f_{n+1}/f_n \sim t_2 n^\alpha \quad (5.5.15)$$

and f_n is again the minimal solution to (5.5.9). Cases other than those in these two theorems are inconclusive for the existence of minimal solutions. (For more on the stability of recurrences, see [3].)

How do you proceed if the solution that you desire *is* the minimal solution? The answer lies in that old aphorism, that every cloud has a silver lining: If a recurrence relation is catastrophically unstable in one direction, then that (undesired) solution will decrease very rapidly in the reverse direction. This means that you can start with *any* seed values for the consecutive f_j and f_{j+1} and (when you have gone enough steps in the stable direction) you will converge to the sequence of functions that you want, times an unknown normalization factor. If there is some other way to normalize the sequence (e.g., by a formula for the sum of the f_n 's), then this can be a practical means of function evaluation. The method is called *Miller's algorithm*. An example often given [1,4] uses equation (5.5.2) in just this way, along with the normalization formula

$$1 = J_0(x) + 2J_2(x) + 2J_4(x) + 2J_6(x) + \dots \quad (5.5.16)$$

Incidentally, there is an important relation between three-term recurrence relations and *continued fractions*. Rewrite the recurrence relation (5.5.9) as

$$\frac{y_n}{y_{n-1}} = -\frac{b_n}{a_n + y_{n+1}/y_n} \quad (5.5.17)$$

Iterating this equation, starting with n , gives

$$\frac{y_n}{y_{n-1}} = -\frac{b_n}{a_n} \frac{b_{n+1}}{a_{n+1}} \dots \quad (5.5.18)$$

Pincherle's Theorem [2] tells us that (5.5.18) converges if and only if (5.5.9) has a minimal solution f_n , in which case it converges to f_n/f_{n-1} . This result, usually for the case $n = 1$ and combined with some way to determine f_0 , underlies many of the practical methods for computing special functions that we give in the next chapter.

Clenshaw's Recurrence Formula

Clenshaw's recurrence formula [5] is an elegant and efficient way to evaluate a sum of coefficients times functions that obey a recurrence formula, e.g.,

$$f(\theta) = \sum_{k=0}^N c_k \cos k\theta \quad \text{or} \quad f(x) = \sum_{k=0}^N c_k P_k(x)$$

Here is how it works: Suppose that the desired sum is

$$f(x) = \sum_{k=0}^N c_k F_k(x) \tag{5.5.19}$$

and that F_k obeys the recurrence relation

$$F_{n+1}(x) = \alpha(n, x)F_n(x) + \beta(n, x)F_{n-1}(x) \tag{5.5.20}$$

for some functions $\alpha(n, x)$ and $\beta(n, x)$. Now define the quantities y_k ($k = N, N-1, \dots, 1$) by the following recurrence:

$$\begin{aligned} y_{N+2} &= y_{N+1} = 0 \\ y_k &= \alpha(k, x)y_{k+1} + \beta(k+1, x)y_{k+2} + c_k \quad (k = N, N-1, \dots, 1) \end{aligned} \tag{5.5.21}$$

If you solve equation (5.5.21) for c_k on the left, and then write out explicitly the sum (5.5.19), it will look (in part) like this:

$$\begin{aligned} f(x) &= \dots \\ &\quad + [y_8 - \alpha(8, x)y_9 - \beta(9, x)y_{10}]F_8(x) \\ &\quad + [y_7 - \alpha(7, x)y_8 - \beta(8, x)y_9]F_7(x) \\ &\quad + [y_6 - \alpha(6, x)y_7 - \beta(7, x)y_8]F_6(x) \\ &\quad + [y_5 - \alpha(5, x)y_6 - \beta(6, x)y_7]F_5(x) \\ &\quad + \dots \\ &\quad + [y_2 - \alpha(2, x)y_3 - \beta(3, x)y_4]F_2(x) \\ &\quad + [y_1 - \alpha(1, x)y_2 - \beta(2, x)y_3]F_1(x) \\ &\quad + [c_0 + \beta(1, x)y_2 - \beta(1, x)y_2]F_0(x) \end{aligned} \tag{5.5.22}$$

Notice that we have added and subtracted $\beta(1, x)y_2$ in the last line. If you examine the terms containing a factor of y_8 in (5.5.22), you will find that they sum to zero as a consequence of the recurrence relation (5.5.20); similarly all the other y_k 's down through y_2 . The only surviving terms in (5.5.22) are

$$f(x) = \beta(1, x)F_0(x)y_2 + F_1(x)y_1 + F_0(x)c_0 \tag{5.5.23}$$

Equations (5.5.21) and (5.5.23) are *Clenshaw's recurrence formula* for doing the sum (5.5.19): You make one pass down through the y_k 's using (5.5.21); when you have reached y_2 and y_1 you apply (5.5.23) to get the desired answer.

Clenshaw's recurrence as written above incorporates the coefficients c_k in a downward order, with k decreasing. At each stage, the effect of all previous c_k 's is "remembered" as two coefficients which multiply the functions F_{k+1} and F_k (ultimately F_0 and F_1). If the functions F_k are small when k is large, *and* if the coefficients c_k are small when k is *small*, then the sum can be dominated by small F_k 's. In this case the remembered coefficients will involve a delicate cancellation and there can be a catastrophic loss of significance. An example would be to sum the trivial series

$$J_{15}(1) = 0 \times J_0(1) + 0 \times J_1(1) + \dots + 0 \times J_{14}(1) + 1 \times J_{15}(1) \quad (5.5.24)$$

Here J_{15} , which is tiny, ends up represented as a canceling linear combination of J_0 and J_1 , which are of order unity.

The solution in such cases is to use an alternative Clenshaw recurrence that incorporates c_k 's in an upward direction. The relevant equations are

$$y_{-2} = y_{-1} = 0 \quad (5.5.25)$$

$$y_k = \frac{1}{\beta(k+1, x)} [y_{k-2} - \alpha(k, x)y_{k-1} - c_k], \quad (k = 0, 1, \dots, N-1) \quad (5.5.26)$$

$$f(x) = c_N F_N(x) - \beta(N, x) F_{N-1}(x) y_{N-1} - F_N(x) y_{N-2} \quad (5.5.27)$$

The rare case where equations (5.5.25)–(5.5.27) should be used instead of equations (5.5.21) and (5.5.23) can be detected automatically by testing whether the operands in the first sum in (5.5.23) are opposite in sign and nearly equal in magnitude. Other than in this special case, Clenshaw's recurrence is always stable, independent of whether the recurrence for the functions F_k is stable in the upward or downward direction.

5.6 Quadratic and Cubic Equations

The roots of simple algebraic equations can be viewed as being functions of the equations' coefficients. We are taught these functions in elementary algebra. Yet, surprisingly many people don't know the right way to solve a quadratic equation with two real roots, or to obtain the roots of a cubic equation.

There are two ways to write the solution of the *quadratic equation*

$$ax^2 + bx + c = 0 \quad (5.6.1)$$

with real coefficients a, b, c , namely

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \quad (5.6.2)$$

and

$$x = \frac{2c}{-b \pm \sqrt{b^2 - 4ac}} \quad (5.6.3)$$

If you use *either* (5.6.2) *or* (5.6.3) to get the two roots, you are asking for trouble: If either a or c (or both) are small, then one of the roots will involve the subtraction of b from a very nearly equal quantity (the discriminant); you will get that root very inaccurately. The correct way to compute the roots is

$$q \equiv -\frac{1}{2} \left[b + \text{sgn}(b) \sqrt{b^2 - 4ac} \right] \quad (5.6.4)$$

Then the two roots are

$$x_1 = \frac{q}{a} \quad \text{and} \quad x_2 = \frac{c}{q} \quad (5.6.5)$$

If the coefficients a, b, c , are complex rather than real, then the above formulas still hold, except that in equation (5.6.4) the sign of the square root should be chosen so as to make

$$\text{Re}(b^* \sqrt{b^2 - 4ac}) \geq 0 \quad (5.6.6)$$

where Re denotes the real part and asterisk denotes complex conjugation.

Apropos of quadratic equations, this seems a convenient place to recall that the inverse hyperbolic functions \sinh^{-1} and \cosh^{-1} are in fact just logarithms of solutions to such equations,

$$\sinh^{-1}(x) = \ln(x + \sqrt{x^2 + 1}) \quad (5.6.7)$$

$$\cosh^{-1}(x) = \pm \ln(x + \sqrt{x^2 - 1}) \quad (5.6.8)$$

Equation (5.6.7) is numerically robust for $x \geq 0$. For negative x , use the symmetry $\sinh^{-1}(-x) = -\sinh^{-1}(x)$. Equation (5.6.8) is of course valid only for $x \geq 1$. Since FORTRAN mysteriously omits the inverse hyperbolic functions from its list of intrinsic functions, equations (5.6.7)–(5.6.8) are sometimes quite essential.

5.6 Quadratic and Cubic Equations

The roots of simple algebraic equations can be viewed as being functions of the equations' coefficients. We are taught these functions in elementary algebra. Yet, surprisingly many people don't know the right way to solve a quadratic equation with two real roots, or to obtain the roots of a cubic equation.

There are two ways to write the solution of the *quadratic equation*

$$ax^2 + bx + c = 0 \quad (5.6.1)$$

with real coefficients a, b, c , namely

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} \quad (5.6.2)$$

and

$$x = \frac{2c}{-b \pm \sqrt{b^2 - 4ac}} \quad (5.6.3)$$

If you use *either* (5.6.2) *or* (5.6.3) to get the two roots, you are asking for trouble: If either a or c (or both) are small, then one of the roots will involve the subtraction of b from a very nearly equal quantity (the discriminant); you will get that root very inaccurately. The correct way to compute the roots is

$$q \equiv -\frac{1}{2} \left[b + \operatorname{sgn}(b) \sqrt{b^2 - 4ac} \right] \quad (5.6.4)$$

Then the two roots are

$$x_1 = \frac{q}{a} \quad \text{and} \quad x_2 = \frac{c}{q} \quad (5.6.5)$$

If the coefficients a, b, c , are complex rather than real, then the above formulas still hold, except that in equation (5.6.4) the sign of the square root should be chosen so as to make

$$\operatorname{Re}(b^* \sqrt{b^2 - 4ac}) \geq 0 \quad (5.6.6)$$

where Re denotes the real part and asterisk denotes complex conjugation.

Apropos of quadratic equations, this seems a convenient place to recall that the inverse hyperbolic functions \sinh^{-1} and \cosh^{-1} are in fact just logarithms of solutions to such equations,

$$\sinh^{-1}(x) = \ln(x + \sqrt{x^2 + 1}) \quad (5.6.7)$$

$$\cosh^{-1}(x) = \pm \ln(x + \sqrt{x^2 - 1}) \quad (5.6.8)$$

Equation (5.6.7) is numerically robust for $x \geq 0$. For negative x , use the symmetry $\sinh^{-1}(-x) = -\sinh^{-1}(x)$. Equation (5.6.8) is of course valid only for $x \geq 1$. Since FORTRAN mysteriously omits the inverse hyperbolic functions from its list of intrinsic functions, equations (5.6.7)–(5.6.8) are sometimes quite essential.

For the *cubic equation*

$$x^3 + ax^2 + bx + c = 0 \quad (5.6.9)$$

with real or complex coefficients a, b, c , first compute

$$Q \equiv \frac{a^2 - 3b}{9} \quad \text{and} \quad R \equiv \frac{2a^3 - 9ab + 27c}{54} \quad (5.6.10)$$

If Q and R are real (always true when a, b, c are real) and $R^2 < Q^3$, then the cubic equation has three real roots. Find them by computing

$$\theta = \arccos(R/\sqrt{Q^3}) \quad (5.6.11)$$

in terms of which the three roots are

$$\begin{aligned} x_1 &= -2\sqrt{Q} \cos\left(\frac{\theta}{3}\right) - \frac{a}{3} \\ x_2 &= -2\sqrt{Q} \cos\left(\frac{\theta + 2\pi}{3}\right) - \frac{a}{3} \\ x_3 &= -2\sqrt{Q} \cos\left(\frac{\theta - 2\pi}{3}\right) - \frac{a}{3} \end{aligned} \quad (5.6.12)$$

(This equation first appears in Chapter VI of François Viète's treatise "De emendatione," published in 1615!)

Otherwise, compute

$$A = -\left[R + \sqrt{R^2 - Q^3}\right]^{1/3} \quad (5.6.13)$$

where the sign of the square root is chosen to make

$$\operatorname{Re}(R^* \sqrt{R^2 - Q^3}) \geq 0 \quad (5.6.14)$$

(asterisk again denoting complex conjugation). If Q and R are both real, equations (5.6.13)–(5.6.14) are equivalent to

$$A = -\operatorname{sgn}(R) \left[|R| + \sqrt{R^2 - Q^3}\right]^{1/3} \quad (5.6.15)$$

where the positive square root is assumed. Next compute

$$B = \begin{cases} Q/A & (A \neq 0) \\ 0 & (A = 0) \end{cases} \quad (5.6.16)$$

in terms of which the three roots are

$$x_1 = (A + B) - \frac{a}{3} \quad (5.6.17)$$

(the single real root when a, b, c are real) and

$$\begin{aligned}x_2 &= -\frac{1}{2}(A + B) - \frac{a}{3} + i\frac{\sqrt{3}}{2}(A - B) \\x_3 &= -\frac{1}{2}(A + B) - \frac{a}{3} - i\frac{\sqrt{3}}{2}(A - B)\end{aligned}\tag{5.6.18}$$

(in that same case, a complex conjugate pair). Equations (5.6.13)–(5.6.16) are arranged both to minimize roundoff error, and also (as pointed out by A.J. Glassman) to ensure that no choice of branch for the complex cube root can result in the spurious loss of a distinct root.

If you need to solve many cubic equations with only slightly different coefficients, it is more efficient to use Newton's method (§9.4).

5.7 Numerical Derivatives

Imagine that you have a procedure which computes a function $f(x)$, and now you want to compute its derivative $f'(x)$. Easy, right? The definition of the derivative, the limit as $h \rightarrow 0$ of

$$f'(x) \approx \frac{f(x + h) - f(x)}{h}\tag{5.7.1}$$

practically suggests the program: Pick a small value h ; evaluate $f(x + h)$; you probably have $f(x)$ already evaluated, but if not, do it too; finally apply equation (5.7.1). What more needs to be said?

Quite a lot, actually. Applied uncritically, the above procedure is almost guaranteed to produce inaccurate results. Applied properly, it can be the right way to compute a derivative only when the function f is *fiercely* expensive to compute, when you already have invested in computing $f(x)$, and when, therefore, you want to get the derivative in no more than a single additional function evaluation. In such a situation, the remaining issue is to choose h properly, an issue we now discuss:

There are two sources of error in equation (5.7.1), truncation error and roundoff error. The truncation error comes from higher terms in the Taylor series expansion,

$$f(x + h) = f(x) + hf'(x) + \frac{1}{2}h^2f''(x) + \frac{1}{6}h^3f'''(x) + \dots\tag{5.7.2}$$

whence

$$\frac{f(x + h) - f(x)}{h} = f' + \frac{1}{2}hf'' + \dots\tag{5.7.3}$$

(the single real root when a, b, c are real) and

$$\begin{aligned}x_2 &= -\frac{1}{2}(A + B) - \frac{a}{3} + i\frac{\sqrt{3}}{2}(A - B) \\x_3 &= -\frac{1}{2}(A + B) - \frac{a}{3} - i\frac{\sqrt{3}}{2}(A - B)\end{aligned}\tag{5.6.18}$$

(in that same case, a complex conjugate pair). Equations (5.6.13)–(5.6.16) are arranged both to minimize roundoff error, and also (as pointed out by A.J. Glassman) to ensure that no choice of branch for the complex cube root can result in the spurious loss of a distinct root.

If you need to solve many cubic equations with only slightly different coefficients, it is more efficient to use Newton's method (§9.4).

5.7 Numerical Derivatives

Imagine that you have a procedure which computes a function $f(x)$, and now you want to compute its derivative $f'(x)$. Easy, right? The definition of the derivative, the limit as $h \rightarrow 0$ of

$$f'(x) \approx \frac{f(x + h) - f(x)}{h}\tag{5.7.1}$$

practically suggests the program: Pick a small value h ; evaluate $f(x + h)$; you probably have $f(x)$ already evaluated, but if not, do it too; finally apply equation (5.7.1). What more needs to be said?

Quite a lot, actually. Applied uncritically, the above procedure is almost guaranteed to produce inaccurate results. Applied properly, it can be the right way to compute a derivative only when the function f is *fiercely* expensive to compute, when you already have invested in computing $f(x)$, and when, therefore, you want to get the derivative in no more than a single additional function evaluation. In such a situation, the remaining issue is to choose h properly, an issue we now discuss:

There are two sources of error in equation (5.7.1), truncation error and roundoff error. The truncation error comes from higher terms in the Taylor series expansion,

$$f(x + h) = f(x) + hf'(x) + \frac{1}{2}h^2f''(x) + \frac{1}{6}h^3f'''(x) + \dots\tag{5.7.2}$$

whence

$$\frac{f(x + h) - f(x)}{h} = f' + \frac{1}{2}hf'' + \dots\tag{5.7.3}$$

The roundoff error has various contributions. First there is roundoff error in h : Suppose, by way of an example, that you are at a point $x = 10.3$ and you blindly choose $h = 0.0001$. Neither $x = 10.3$ nor $x + h = 10.30001$ is a number with an exact representation in binary; each is therefore represented with some fractional error characteristic of the machine's floating-point format, ϵ_m , whose value in single precision may be $\sim 10^{-7}$. The error in the *effective* value of h , namely the difference between $x + h$ and x as represented in the machine, is therefore on the order of $\epsilon_m x$, which implies a fractional error in h of order $\sim \epsilon_m x / h \sim 10^{-2}$! By equation (5.7.1) this immediately implies at least the same large fractional error in the derivative.

We arrive at Lesson 1: Always choose h so that $x + h$ and x differ by an exactly representable number. This can usually be accomplished by the program steps

$$\begin{aligned} \text{temp} &= x + h \\ h &= \text{temp} - x \end{aligned} \tag{5.7.4}$$

Some optimizing compilers, and some computers whose floating-point chips have higher internal accuracy than is stored externally, can foil this trick; if so, it is usually enough to call a dummy subroutine `donothing(temp)` between the two equations (5.7.4). This forces `temp` into and out of addressable memory.

With h an “exact” number, the roundoff error in equation (5.7.1) is $e_r \sim \epsilon_f |f(x)/h|$. Here ϵ_f is the fractional accuracy with which f is computed; for a simple function this may be comparable to the machine accuracy, $\epsilon_f \approx \epsilon_m$, but for a complicated calculation with additional sources of inaccuracy it may be larger. The truncation error in equation (5.7.3) is on the order of $e_t \sim |h f''(x)|$. Varying h to minimize the sum $e_r + e_t$ gives the optimal choice of h ,

$$h \sim \sqrt{\frac{\epsilon_f f}{f''}} \approx \sqrt{\epsilon_f} x_c \tag{5.7.5}$$

where $x_c \equiv (f/f'')^{1/2}$ is the “curvature scale” of the function f , or “characteristic scale” over which it changes. In the absence of any other information, one often assumes $x_c = x$ (except near $x = 0$ where some other estimate of the typical x scale should be used).

With the choice of equation (5.7.5), the fractional accuracy of the computed derivative is

$$(e_r + e_t) / |f'| \sim \sqrt{\epsilon_f} (ff''/f'^2)^{1/2} \sim \sqrt{\epsilon_f} \tag{5.7.6}$$

Here the last order-of-magnitude equality assumes that f , f' , and f'' all share the same characteristic length scale, usually the case. One sees that the simple finite-difference equation (5.7.1) gives *at best* only the square root of the machine accuracy ϵ_m .

If you can afford two function evaluations for each derivative calculation, then it is significantly better to use the symmetrized form

$$f'(x) \approx \frac{f(x+h) - f(x-h)}{2h} \tag{5.7.7}$$

In this case, by equation (5.7.2), the truncation error is $e_t \sim h^2 f'''$. The roundoff error e_r is about the same as before. The optimal choice of h , by a short calculation analogous to the one above, is now

$$h \sim \left(\frac{\epsilon_f f}{f'''} \right)^{1/3} \sim (\epsilon_f)^{1/3} x_c \quad (5.7.8)$$

and the fractional error is

$$(e_r + e_t) / |f'| \sim (\epsilon_f)^{2/3} f^{2/3} (f''')^{1/3} / f' \sim (\epsilon_f)^{2/3} \quad (5.7.9)$$

which will typically be an order of magnitude (single precision) or two orders of magnitude (double precision) *better* than equation (5.7.6). We have arrived at Lesson 2: Choose h to be *the correct power* of ϵ_f or ϵ_m times a characteristic scale x_c .

You can easily derive the correct powers for other cases [1]. For a function of two dimensions, for example, and the mixed derivative formula

$$\frac{\partial^2 f}{\partial x \partial y} = \frac{[f(x+h, y+h) - f(x+h, y-h)] - [f(x-h, y+h) - f(x-h, y-h)]}{4h^2} \quad (5.7.10)$$

the correct scaling is $h \sim \epsilon_f^{1/4} x_c$.

It is disappointing, certainly, that no simple finite-difference formula like equation (5.7.1) or (5.7.7) gives an accuracy comparable to the machine accuracy ϵ_m , or even the lower accuracy to which f is evaluated, ϵ_f . Are there no better methods?

Yes, there are. All, however, involve exploration of the function's behavior over scales comparable to x_c , plus some assumption of smoothness, or analyticity, so that the high-order terms in a Taylor expansion like equation (5.7.2) have some meaning. Such methods also involve multiple evaluations of the function f , so their increased accuracy must be weighed against increased cost.

The general idea of “Richardson’s deferred approach to the limit” is particularly attractive. For numerical integrals, that idea leads to so-called Romberg integration (for review, see §4.3). For derivatives, one seeks to extrapolate, to $h \rightarrow 0$, the result of finite-difference calculations with smaller and smaller finite values of h . By the use of Neville’s algorithm (§3.1), one uses each new finite-difference calculation to produce both an extrapolation of higher order, and also extrapolations of previous, lower, orders but with smaller scales h . Ridders [2] has given a nice implementation of this idea; the following program, `dfridr`, is based on his algorithm, modified by an improved termination criterion. Input to the routine is a function f (called `func`), a position x , and a *largest* stepsize h (more analogous to what we have called x_c above than to what we have called h). Output is the returned value of the derivative, and an estimate of its error, `err`.

```
FUNCTION dfridr(func,x,h,err)
INTEGER NTAB
REAL dfridr,err,h,x,func,CON,CON2,BIG,SAFE
PARAMETER (CON=1.4,CON2=CON*CON,BIG=1.E30,NTAB=10,SAFE=2.)
EXTERNAL func
```

C USES func

Returns the derivative of a function `func` at a point `x` by Ridders’ method of polynomial extrapolation. The value `h` is input as an estimated initial stepsize; it need not be small,

but rather should be an increment in x over which `func` changes *substantially*. An estimate of the error in the derivative is returned as `err`.

Parameters: Step size is decreased by `CON` at each iteration. Max size of tableau is set by `NTAB`. Return when error is `SAFE` worse than the best so far.

```

INTEGER i,j
REAL errt,fac,hh,a(NTAB,NTAB)
if(h.eq.0.) pause 'h must be nonzero in dfridr'
hh=h
a(1,1)=(func(x+hh)-func(x-hh))/(2.0*hh)
err=BIG
do 12 i=2,NTAB
      Successive columns in the Neville tableau will go to smaller
      hh=hh/CON           stepsizes and higher orders of extrapolation.
      a(1,i)=(func(x+hh)-func(x-hh))/(2.0*hh)   Try new, smaller stepsize.
      fac=CON2
      do 11 j=2,i           Compute extrapolations of various orders, requiring no new
      a(j,i)=(a(j-1,i)*fac-a(j-1,i-1))/(fac-1.)    function evaluations.
      fac=CON2*fac
      errt=max(abs(a(j,i)-a(j-1,i)),abs(a(j,i)-a(j-1,i-1)))
      The error strategy is to compare each new extrapolation to one order lower, both at
      the present stepsize and the previous one.
      if (errt.le.err) then           If error is decreased, save the improved answer.
          err=errt
          dfridr=a(j,i)
      endif
  enddo 11
  if(abs(a(i,i)-a(i-1,i-1)).ge.SAFE*err) return
      If higher order is worse by a significant factor SAFE, then quit early.
enddo 12
return
END

```

In `dfridr`, the number of evaluations of `func` is typically 6 to 12, but is allowed to be as great as $2 \times \text{NTAB}$. As a function of input h , it is typical for the accuracy to get *better* as h is made larger, until a sudden point is reached where nonsensical extrapolation produces early return with a large error. You should therefore choose a fairly large value for h , but monitor the returned value `err`, decreasing h if it is not small. For functions whose characteristic x scale is of order unity, we typically take h to be a few tenths.

Besides Ridders' method, there are other possible techniques. If your function is fairly smooth, and you know that you will want to evaluate its derivative many times at arbitrary points in some interval, then it makes sense to construct a Chebyshev polynomial approximation to the function in that interval, and to evaluate the derivative directly from the resulting Chebyshev coefficients. This method is described in §§5.8–5.9, following.

Another technique applies when the function consists of data that is tabulated at equally spaced intervals, and perhaps also noisy. One might then want, at each point, to least-squares *fit* a polynomial of some degree M , using an additional number n_L of points to the left and some number n_R of points to the right of each desired x value. The estimated derivative is then the derivative of the resulting fitted polynomial. A very efficient way to do this construction is via Savitzky-Golay smoothing filters, which will be discussed later, in §14.8. There we will give a routine for getting filter coefficients that not only construct the fitting polynomial but, in the accumulation of a single sum of data points times filter coefficients, evaluate it as well. In fact, the routine given, `savgol`, has an argument `1d` that determines which derivative of the fitted polynomial is evaluated. For the first derivative, the

appropriate setting is `1d=1`, and the value of the derivative is the accumulated sum divided by the sampling interval h .

5.8 Chebyshev Approximation

The Chebyshev polynomial of degree n is denoted $T_n(x)$, and is given by the explicit formula

$$T_n(x) = \cos(n \arccos x) \quad (5.8.1)$$

This may look trigonometric at first glance (and there is in fact a close relation between the Chebyshev polynomials and the discrete Fourier transform); however (5.8.1) can be combined with trigonometric identities to yield explicit expressions for $T_n(x)$ (see Figure 5.8.1),

$$\begin{aligned} T_0(x) &= 1 \\ T_1(x) &= x \\ T_2(x) &= 2x^2 - 1 \\ T_3(x) &= 4x^3 - 3x \\ T_4(x) &= 8x^4 - 8x^2 + 1 \\ &\dots \\ T_{n+1}(x) &= 2xT_n(x) - T_{n-1}(x) \quad n \geq 1. \end{aligned} \quad (5.8.2)$$

(There also exist inverse formulas for the powers of x in terms of the T_n 's — see equations 5.11.2–5.11.3.)

The Chebyshev polynomials are orthogonal in the interval $[-1, 1]$ over a weight $(1 - x^2)^{-1/2}$. In particular,

$$\int_{-1}^1 \frac{T_i(x)T_j(x)}{\sqrt{1-x^2}} dx = \begin{cases} 0 & i \neq j \\ \pi/2 & i = j \neq 0 \\ \pi & i = j = 0 \end{cases} \quad (5.8.3)$$

The polynomial $T_n(x)$ has n zeros in the interval $[-1, 1]$, and they are located at the points

$$x = \cos\left(\frac{\pi(k - \frac{1}{2})}{n}\right) \quad k = 1, 2, \dots, n \quad (5.8.4)$$

appropriate setting is `1d=1`, and the value of the derivative is the accumulated sum divided by the sampling interval h .

5.8 Chebyshev Approximation

The Chebyshev polynomial of degree n is denoted $T_n(x)$, and is given by the explicit formula

$$T_n(x) = \cos(n \arccos x) \quad (5.8.1)$$

This may look trigonometric at first glance (and there is in fact a close relation between the Chebyshev polynomials and the discrete Fourier transform); however (5.8.1) can be combined with trigonometric identities to yield explicit expressions for $T_n(x)$ (see Figure 5.8.1),

$$\begin{aligned} T_0(x) &= 1 \\ T_1(x) &= x \\ T_2(x) &= 2x^2 - 1 \\ T_3(x) &= 4x^3 - 3x \\ T_4(x) &= 8x^4 - 8x^2 + 1 \\ &\dots \\ T_{n+1}(x) &= 2xT_n(x) - T_{n-1}(x) \quad n \geq 1. \end{aligned} \quad (5.8.2)$$

(There also exist inverse formulas for the powers of x in terms of the T_n 's — see equations 5.11.2–5.11.3.)

The Chebyshev polynomials are orthogonal in the interval $[-1, 1]$ over a weight $(1 - x^2)^{-1/2}$. In particular,

$$\int_{-1}^1 \frac{T_i(x)T_j(x)}{\sqrt{1-x^2}} dx = \begin{cases} 0 & i \neq j \\ \pi/2 & i = j \neq 0 \\ \pi & i = j = 0 \end{cases} \quad (5.8.3)$$

The polynomial $T_n(x)$ has n zeros in the interval $[-1, 1]$, and they are located at the points

$$x = \cos\left(\frac{\pi(k - \frac{1}{2})}{n}\right) \quad k = 1, 2, \dots, n \quad (5.8.4)$$

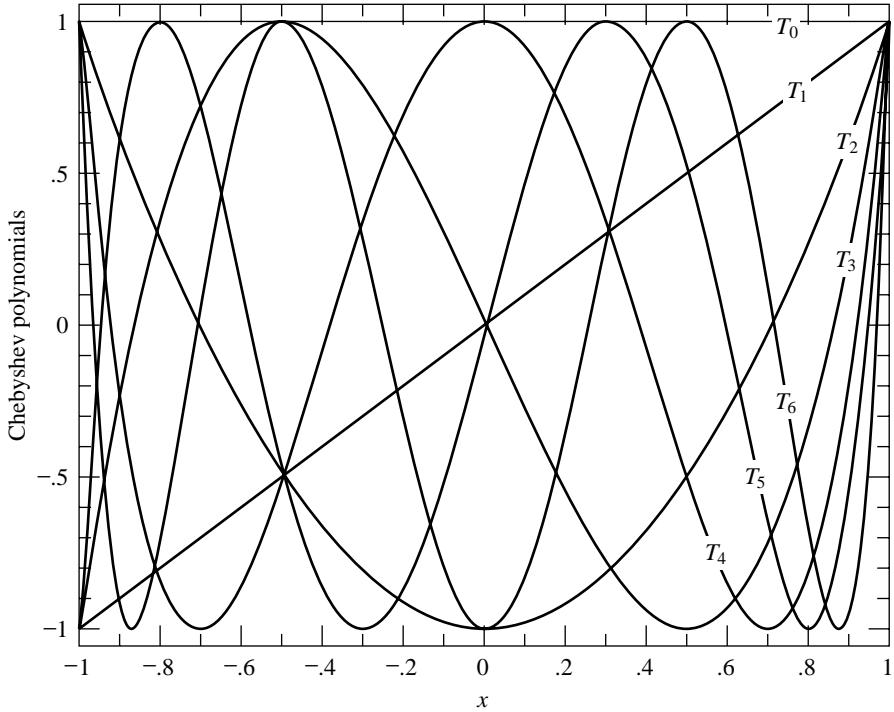

Figure 5.8.1. Chebyshev polynomials $T_0(x)$ through $T_6(x)$. Note that T_j has j roots in the interval $(-1, 1)$ and that all the polynomials are bounded between ± 1 .

In this same interval there are $n + 1$ extrema (maxima and minima), located at

$$x = \cos\left(\frac{\pi k}{n}\right) \quad k = 0, 1, \dots, n \quad (5.8.5)$$

At all of the maxima $T_n(x) = 1$, while at all of the minima $T_n(x) = -1$; it is precisely this property that makes the Chebyshev polynomials so useful in polynomial approximation of functions.

The Chebyshev polynomials satisfy a discrete orthogonality relation as well as the continuous one (5.8.3): If x_k ($k = 1, \dots, m$) are the m zeros of $T_m(x)$ given by (5.8.4), and if $i, j < m$, then

$$\sum_{k=1}^m T_i(x_k) T_j(x_k) = \begin{cases} 0 & i \neq j \\ m/2 & i = j \neq 0 \\ m & i = j = 0 \end{cases} \quad (5.8.6)$$

It is not too difficult to combine equations (5.8.1), (5.8.4), and (5.8.6) to prove the following theorem: If $f(x)$ is an arbitrary function in the interval $[-1, 1]$, and if N coefficients $c_j, j = 1, \dots, N$, are defined by

$$\begin{aligned} c_j &= \frac{2}{N} \sum_{k=1}^N f(x_k) T_{j-1}(x_k) \\ &= \frac{2}{N} \sum_{k=1}^N f \left[\cos\left(\frac{\pi(k-\frac{1}{2})}{N}\right) \right] \cos\left(\frac{\pi(j-1)(k-\frac{1}{2})}{N}\right) \end{aligned} \quad (5.8.7)$$

then the approximation formula

$$f(x) \approx \left[\sum_{k=1}^N c_k T_{k-1}(x) \right] - \frac{1}{2}c_1 \quad (5.8.8)$$

is *exact* for x equal to all of the N zeros of $T_N(x)$.

For a fixed N , equation (5.8.8) is a polynomial in x which approximates the function $f(x)$ in the interval $[-1, 1]$ (where all the zeros of $T_N(x)$ are located). Why is this particular approximating polynomial better than any other one, exact on some other set of N points? The answer is *not* that (5.8.8) is necessarily more accurate than some other approximating polynomial of the same order N (for some specified definition of “accurate”), but rather that (5.8.8) can be truncated to a polynomial of *lower* degree $m \ll N$ in a very graceful way, one that *does* yield the “most accurate” approximation of degree m (in a sense that can be made precise). Suppose N is so large that (5.8.8) is virtually a perfect approximation of $f(x)$. Now consider the truncated approximation

$$f(x) \approx \left[\sum_{k=1}^m c_k T_{k-1}(x) \right] - \frac{1}{2}c_1 \quad (5.8.9)$$

with the same c_j ’s, computed from (5.8.7). Since the $T_k(x)$ ’s are all bounded between ± 1 , the difference between (5.8.9) and (5.8.8) can be no larger than the sum of the neglected c_k ’s ($k = m+1, \dots, N$). In fact, if the c_k ’s are rapidly decreasing (which is the typical case), then the error is dominated by $c_{m+1}T_m(x)$, an oscillatory function with $m+1$ equal extrema distributed smoothly over the interval $[-1, 1]$. This smooth spreading out of the error is a very important property: The Chebyshev approximation (5.8.9) is very nearly the same polynomial as that holy grail of approximating polynomials the *minimax polynomial*, which (among all polynomials of the same degree) has the smallest maximum deviation from the true function $f(x)$. The minimax polynomial is very difficult to find; the Chebyshev approximating polynomial is almost identical and is very easy to compute!

So, given some (perhaps difficult) means of computing the function $f(x)$, we now need algorithms for implementing (5.8.7) and (after inspection of the resulting c_k ’s and choice of a truncating value m) evaluating (5.8.9). The latter equation then becomes an easy way of computing $f(x)$ for all subsequent time.

The first of these tasks is straightforward. A generalization of equation (5.8.7) that is here implemented is to allow the range of approximation to be between two arbitrary limits a and b , instead of just -1 to 1 . This is effected by a change of variable

$$y \equiv \frac{x - \frac{1}{2}(b+a)}{\frac{1}{2}(b-a)} \quad (5.8.10)$$

and by the approximation of $f(x)$ by a Chebyshev polynomial in y .

```
SUBROUTINE chebft(a,b,c,n,func)
INTEGER n,NMAX
REAL a,b,c(n),func
DOUBLE PRECISION PI
EXTERNAL func
PARAMETER (NMAX=50, PI=3.141592653589793d0)
```

Chebyshev fit: Given a function `func`, lower and upper limits of the interval $[a,b]$, and a maximum degree n , this routine computes the n coefficients c_k such that $func(x) \approx$

$[\sum_{k=1}^n c_k T_{k-1}(y)] - c_1/2$, where y and x are related by (5.8.10). This routine is to be used with moderately large n (e.g., 30 or 50), the array of c 's subsequently to be truncated at the smaller value m such that c_{m+1} and subsequent elements are negligible.

Parameters: Maximum expected value of n , and π .

```

INTEGER j,k

    y=cos(PI*(k-0.5d0)/n)
    f(k)=func(y*bma+bpa)
  enddo 11
fac=2./n
do 13 j=1,n
    sum=0.d0
    do 12 k=1,n
        sum=sum+f(k)*cos((PI*(j-1))*((k-0.5d0)/n))
      enddo 12
    c(j)=fac*sum
  enddo 13
return
END

```

We evaluate the function at the n points required by (5.8.7).

We will accumulate the sum in double precision, a nicety that you can ignore.

(If you find that the execution time of `chebft` is dominated by the calculation of N^2 cosines, rather than by the N evaluations of your function, then you should look ahead to §12.3, especially equation 12.3.22, which shows how fast cosine transform methods can be used to evaluate equation 5.8.7.)

Now that we have the Chebyshev coefficients, how do we evaluate the approximation? One could use the recurrence relation of equation (5.8.2) to generate values for $T_k(x)$ from $T_0 = 1, T_1 = x$, while also accumulating the sum of (5.8.9). It is better to use Clenshaw's recurrence formula (§5.5), effecting the two processes simultaneously. Applied to the Chebyshev series (5.8.9), the recurrence is

$$\begin{aligned}
 d_{m+2} &\equiv d_{m+1} \equiv 0 \\
 d_j &= 2xd_{j+1} - d_{j+2} + c_j \quad j = m, m-1, \dots, 2 \\
 f(x) &\equiv d_0 = xd_2 - d_3 + \frac{1}{2}c_1
 \end{aligned} \tag{5.8.11}$$

```

FUNCTION chebev(a,b,c,m,x)
INTEGER m
REAL chebev,a,b,x,c(m)
Chebyshev evaluation: All arguments are input. c(1:m) is an array of Chebyshev coefficients, the first m elements of c output from chebft (which must have been called with the same a and b). The Chebyshev polynomial  $\sum_{k=1}^m c_k T_{k-1}(y) - c_1/2$  is evaluated at a point  $y = [x - (b + a)/2]/[(b - a)/2]$ , and the result is returned as the function value.
INTEGER j
REAL d,dd,sv,y,y2
if ((x-a)*(x-b).gt.0.) pause 'x not in range in chebev'
d=0.
dd=0.
y=(2.*x-a-b)/(b-a)           Change of variable.
y2=2.*y
do 11 j=m,2,-1
    sv=d
    Clenshaw's recurrence.

```

```

d=y2*d-dd+c(j)
dd=sv
enddo !!
chebev=y*d-dd+0.5*c(1)      Last step is different.
return
END

```

If we are approximating an *even* function on the interval $[-1, 1]$, its expansion will involve only even Chebyshev polynomials. It is wasteful to call `chebev` with all the odd coefficients zero [1]. Instead, using the half-angle identity for the cosine in equation (5.8.1), we get the relation

$$T_{2n}(x) = T_n(2x^2 - 1) \quad (5.8.12)$$

Thus we can evaluate a series of even Chebyshev polynomials by calling `chebev` with the even coefficients stored consecutively in the array `c`, but with the argument x replaced by $2x^2 - 1$.

An odd function will have an expansion involving only odd Chebyshev polynomials. It is best to rewrite it as an expansion for the function $f(x)/x$, which involves only even Chebyshev polynomials. This will give accurate values for $f(x)/x$ near $x = 0$. The coefficients c'_n for $f(x)/x$ can be found from those for $f(x)$ by recurrence:

$$\begin{aligned} c'_{N+1} &= 0 \\ c'_{n-1} &= 2c_n - c'_{n+1}, \quad n = N, N-2, \dots \end{aligned} \quad (5.8.13)$$

Equation (5.8.13) follows from the recurrence relation in equation (5.8.2).

If you insist on evaluating an odd Chebyshev series, the efficient way is to once again use `chebev` with x replaced by $y = 2x^2 - 1$, and with the odd coefficients stored consecutively in the array `c`. Now, however, you must also change the last formula in equation (5.8.11) to be

$$f(x) = x[(2y - 1)d_2 - d_3 + c_1] \quad (5.8.14)$$

and change the corresponding line in `chebev`.

5.9 Derivatives or Integrals of a Chebyshev-approximated Function

If you have obtained the Chebyshev coefficients that approximate a function in a certain range (e.g., from `chebft` in §5.8), then it is a simple matter to transform them to Chebyshev coefficients corresponding to the derivative or integral of the function. Having done this, you can evaluate the derivative or integral just as if it were a function that you had Chebyshev-fitted *ab initio*.

The relevant formulas are these: If c_i , $i = 1, \dots, m$ are the coefficients that approximate a function f in equation (5.8.9), C_i are the coefficients that approximate the indefinite integral of f , and c'_i are the coefficients that approximate the derivative of f , then

$$C_i = \frac{c_{i-1} - c_{i+1}}{2(i-1)} \quad (i > 1) \quad (5.9.1)$$

$$c'_{i-1} = c'_{i+1} + 2(i-1)c_i \quad (i = m, m-1, \dots, 2) \quad (5.9.2)$$

Equation (5.9.1) is augmented by an arbitrary choice of C_1 , corresponding to an arbitrary constant of integration. Equation (5.9.2), which is a recurrence, is started with the values $c'_m = c'_{m+1} = 0$, corresponding to no information about the $m+1$ st Chebyshev coefficient of the original function f .

Here are routines for implementing equations (5.9.1) and (5.9.2).

5.9 Derivatives or Integrals of a Chebyshev-approximated Function

If you have obtained the Chebyshev coefficients that approximate a function in a certain range (e.g., from `chebft` in §5.8), then it is a simple matter to transform them to Chebyshev coefficients corresponding to the derivative or integral of the function. Having done this, you can evaluate the derivative or integral just as if it were a function that you had Chebyshev-fitted *ab initio*.

The relevant formulas are these: If c_i , $i = 1, \dots, m$ are the coefficients that approximate a function f in equation (5.8.9), C_i are the coefficients that approximate the indefinite integral of f , and c'_i are the coefficients that approximate the derivative of f , then

$$C_i = \frac{c_{i-1} - c_{i+1}}{2(i-1)} \quad (i > 1) \quad (5.9.1)$$

$$c'_{i-1} = c'_{i+1} + 2(i-1)c_i \quad (i = m, m-1, \dots, 2) \quad (5.9.2)$$

Equation (5.9.1) is augmented by an arbitrary choice of C_1 , corresponding to an arbitrary constant of integration. Equation (5.9.2), which is a recurrence, is started with the values $c'_m = c'_{m+1} = 0$, corresponding to no information about the $m+1$ st Chebyshev coefficient of the original function f .

Here are routines for implementing equations (5.9.1) and (5.9.2).

```
SUBROUTINE chder(a,b,c,cder,n)
INTEGER n
REAL a,b,c(1:n),cder(n)
Given a,b,c(1:n), as output from routine chebft §5.8, and given n, the desired degree
of approximation (length of c to be used), this routine returns the array cder(1:n), the
Chebyshev coefficients of the derivative of the function whose coefficients are c(1:n).
INTEGER j
REAL con
cder(n)=0.                                     n and n-1 are special cases.
cder(n-1)=2*(n-1)*c(n)
do 11 j=n-2,1,-1
    cder(j)=cder(j+2)+2*j*c(j+1)           Equation (5.9.2).
11 enddo
con=2./(b-a)
do 12 j=1,n
    cder(j)=cder(j)*con                   Normalize to the interval b-a.
12 enddo
return
END
```

```
SUBROUTINE chint(a,b,c,cint,n)
INTEGER n
REAL a,b,c(1:n),cint(n)
Given a,b,c(1:n), as output from routine chebft §5.8, and given n, the desired degree
of approximation (length of c to be used), this routine returns the array cint(1:n), the
Chebyshev coefficients of the integral of the function whose coefficients are c. The constant
of integration is set so that the integral vanishes at a.
INTEGER j
REAL con,fac,sum
```

```

con=0.25*(b-a)          Factor that normalizes to the interval b-a.
sum=0.                   Accumulates the constant of integration.
fac=1.                   Will equal ±1.
do :: j=2,n-1
    cint(j)=con*(c(j-1)-c(j+1))/(j-1)      Equation (5.9.1).
    sum=sum+fac*cint(j)
    fac=-fac
endo :: 
cint(n)=con*c(n-1)/(n-1)  Special case of (5.9.1) for n.
sum=sum+fac*cint(n)
cint(1)=2.*sum            Set the constant of integration.
return
END

```

Clenshaw-Curtis Quadrature

Since a smooth function's Chebyshev coefficients c_i decrease rapidly, generally exponentially, equation (5.9.1) is often quite efficient as the basis for a quadrature scheme. The routines `chebft` and `chint`, used in that order, can be followed by repeated calls to `chebev` if $\int_a^x f(x)dx$ is required for many different values of x in the range $a \leq x \leq b$.

If only the single definite integral $\int_a^b f(x)dx$ is required, then `chint` and `chebev` are replaced by the simpler formula, derived from equation (5.9.1),

$$\int_a^b f(x)dx = (b-a) \left[\frac{1}{2}c_1 - \frac{1}{3}c_3 - \frac{1}{15}c_5 - \cdots - \frac{1}{(2k+1)(2k-1)}c_{2k+1} - \cdots \right] \quad (5.9.3)$$

where the c_i 's are as returned by `chebft`. The series can be truncated when c_{2k+1} becomes negligible, and the first neglected term gives an error estimate.

This scheme is known as *Clenshaw-Curtis quadrature* [1]. It is often combined with an adaptive choice of N , the number of Chebyshev coefficients calculated via equation (5.8.7), which is also the number of function evaluations of $f(x)$. If a modest choice of N does not give a sufficiently small c_{2k+1} in equation (5.9.3), then a larger value is tried. In this adaptive case, it is even better to replace equation (5.8.7) by the so-called "trapezoidal" or Gauss-Lobatto (§4.5) variant,

$$c_j = \frac{2}{N} \sum_{k=0}^{N-1} f \left[\cos \left(\frac{\pi k}{N} \right) \right] \cos \left(\frac{\pi(j-1)k}{N} \right) \quad j = 1, \dots, N \quad (5.9.4)$$

where (N.B.!) the two primes signify that the first and last terms in the sum are to be multiplied by 1/2. If N is doubled in equation (5.9.4), then half of the new function evaluation points are identical to the old ones, allowing the previous function evaluations to be reused. This feature, plus the analytic weights and abscissas (cosine functions in 5.9.4), give Clenshaw-Curtis quadrature an edge over high-order adaptive Gaussian quadrature (cf. §4.5), which the method otherwise resembles.

If your problem forces you to large values of N , you should be aware that equation (5.9.4) can be evaluated rapidly, and simultaneously for all the values of j , by a fast cosine transform. (See §12.3, especially equation 12.3.17.) (We already remarked that the nontrapezoidal form (5.8.7) can also be done by fast cosine methods, cf. equation 12.3.22.)

5.10 Polynomial Approximation from Chebyshev Coefficients

You may well ask after reading the preceding two sections, “Must I store and evaluate my Chebyshev approximation as an array of Chebyshev coefficients for a transformed variable y ? Can’t I convert the c_k ’s into actual polynomial coefficients in the original variable x and have an approximation of the following form?”

$$f(x) \approx \sum_{k=1}^m g_k x^{k-1} \quad (5.10.1)$$

Yes, you can do this (and we will give you the algorithm to do it), but we caution you against it: Evaluating equation (5.10.1), where the coefficient g ’s reflect an underlying Chebyshev approximation, usually requires more significant figures than evaluation of the Chebyshev sum directly (as by chebev). This is because the Chebyshev polynomials themselves exhibit a rather delicate cancellation: The leading coefficient of $T_n(x)$, for example, is 2^{n-1} ; other coefficients of $T_n(x)$ are even bigger; yet they all manage to combine into a polynomial that lies between ± 1 . Only when m is no larger than 7 or 8 should you contemplate writing a Chebyshev fit as a direct polynomial, and even in those cases you should be willing to tolerate two or so significant figures less accuracy than the roundoff limit of your machine.

You get the g ’s in equation (5.10.1) from the c ’s output from chebft (suitably truncated at a modest value of m) by calling in sequence the following two procedures:

```
SUBROUTINE chebpc(c,d,n)
INTEGER n,NMAX
REAL c(n),d(n)
PARAMETER (NMAX=50)           Maximum anticipated value of n.
Chebyshev polynomial coefficients. Given a coefficient array c(1:n) of length n, this routine
generates a coefficient array d(1:n) such that  $\sum_{k=1}^n d_k y^{k-1} = \sum_{k=1}^n c_k T_{k-1}(y) - c_1/2$ .
The method is Clenshaw’s recurrence (5.8.11), but now applied algebraically rather than
arithmetically.
INTEGER j,k
REAL sv,dd(NMAX)
do 11 j=1,n
    d(j)=0.
    dd(j)=0.
1endo 11
d(1)=c(n)
do 13 j=n-1,2,-1
    do 12 k=n-j+1,2,-1
        sv=d(k)
        d(k)=2.*d(k-1)-dd(k)
        dd(k)=sv
    enddo 12
    sv=d(1)
    d(1)=-dd(1)+c(j)
    dd(1)=sv
1endo 13
do 14 j=n,2,-1
    d(j)=d(j-1)-dd(j)
1endo 14
d(1)=-dd(1)+0.5*c(1)
return
END
```

5.11 Economization of Power Series

One particular application of Chebyshev methods, the *economization of power series*, is an occasionally useful technique, with a flavor of getting something for nothing.

Suppose that you are already computing a function by the use of a convergent power series, for example

$$f(x) \equiv 1 - \frac{x}{3!} + \frac{x^2}{5!} - \frac{x^3}{7!} + \dots \quad (5.11.1)$$

(This function is actually $\sin(\sqrt{x})/\sqrt{x}$, but pretend you don't know that.) You might be doing a problem that requires evaluating the series many times in some particular interval, say $[0, (2\pi)^2]$. Everything is fine, except that the series requires a large number of terms before its error (approximated by the first neglected term, say) is tolerable. In our example, with $x = (2\pi)^2$, the first term smaller than 10^{-7} is $x^{13}/(27!)$. This then approximates the error of the finite series whose last term is $x^{12}/(25!)$.

Notice that because of the large exponent in x^{13} , the error is *much smaller* than 10^{-7} everywhere in the interval except at the very largest values of x . This is the feature that allows “economization”: if we are willing to let the error elsewhere in the interval rise to about the same value that the first neglected term has at the extreme end of the interval, then we can replace the 13-term series by one that is significantly shorter.

Here are the steps for doing so:

1. Change variables from x to y , as in equation (5.8.10), to map the x interval into $-1 \leq y \leq 1$.
2. Find the coefficients of the Chebyshev sum (like equation 5.8.8) that exactly equals your truncated power series (the one with enough terms for accuracy).

```

SUBROUTINE pcshft(a,b,d,n)
INTEGER n
REAL a,b,d(n)
  Polynomial coefficient shift. Given a coefficient array d(1:n), this routine generates a

5.11 Economization of Power Series

One particular application of Chebyshev methods, the *economization of power series*, is an occasionally useful technique, with a flavor of getting something for nothing.

Suppose that you are already computing a function by the use of a convergent power series, for example

$$f(x) \equiv 1 - \frac{x}{3!} + \frac{x^2}{5!} - \frac{x^3}{7!} + \dots \quad (5.11.1)$$

(This function is actually $\sin(\sqrt{x})/\sqrt{x}$, but pretend you don't know that.) You might be doing a problem that requires evaluating the series many times in some particular interval, say $[0, (2\pi)^2]$. Everything is fine, except that the series requires a large number of terms before its error (approximated by the first neglected term, say) is tolerable. In our example, with $x = (2\pi)^2$, the first term smaller than 10^{-7} is $x^{13}/(27!)$. This then approximates the error of the finite series whose last term is $x^{12}/(25!)$.

Notice that because of the large exponent in x^{13} , the error is *much smaller* than 10^{-7} everywhere in the interval except at the very largest values of x . This is the feature that allows “economization”: if we are willing to let the error elsewhere in the interval rise to about the same value that the first neglected term has at the extreme end of the interval, then we can replace the 13-term series by one that is significantly shorter.

Here are the steps for doing so:

1. Change variables from x to y , as in equation (5.8.10), to map the x interval into $-1 \leq y \leq 1$.
2. Find the coefficients of the Chebyshev sum (like equation 5.8.8) that exactly equals your truncated power series (the one with enough terms for accuracy).

3. Truncate this Chebyshev series to a smaller number of terms, using the coefficient of the first neglected Chebyshev polynomial as an estimate of the error.
4. Convert back to a polynomial in y .
5. Change variables back to x .

All of these steps can be done numerically, given the coefficients of the original power series expansion. The first step is exactly the inverse of the routine `pcshft` (§5.10), which mapped a polynomial from y (in the interval $[-1, 1]$) to x (in the interval $[a, b]$). But since equation (5.8.10) is a linear relation between x and y , one can also use `pcshft` for the inverse. The inverse of

`pcshft(a,b,d,n)`

turns out to be (you can check this)

$$\text{pcshft}\left(\frac{-2-b-a}{b-a}, \frac{2-b-a}{b-a}, d, n\right)$$

The second step requires the inverse operation to that done by the routine `chebpc` (which took Chebyshev coefficients into polynomial coefficients). The following routine, `pccheb`, accomplishes this, using the formula [1]

$$x^k = \frac{1}{2^{k-1}} \left[T_k(x) + \binom{k}{1} T_{k-2}(x) + \binom{k}{2} T_{k-4}(x) + \dots \right] \quad (5.11.2)$$

where the last term depends on whether k is even or odd,

$$\dots + \binom{k}{(k-1)/2} T_1(x) \quad (k \text{ odd}), \quad \dots + \frac{1}{2} \binom{k}{k/2} T_0(x) \quad (k \text{ even}). \quad (5.11.3)$$

```
SUBROUTINE pccheb(d,c,n)
INTEGER n
REAL c(n),d(n)
Inverse of routine chebpc: given an array of polynomial coefficients d(1:n), returns an
equivalent array of Chebyshev coefficients c(1:n).
INTEGER j,jm,jp,k
REAL fac,pow
pow=1.                                Will be powers of 2.
c(1)=2.*d(1)
do 12 k=2,n                            Loop over orders of x in the polynomial.
  c(k)=0.                                Zero corresponding order of Chebyshev.
  fac=d(k)/pow
  jm=k-1
  jp=1
  do 11 j=k,1,-2                      Increment this and lower orders of Chebyshev with the com-
    c(j)=c(j)+fac                      binatorial coefficient times d(k); see text for formula.
    fac=fac*float(jm)/float(jp)
    jm=jm-1
    jp=jp+1
  enddo 11
  pow=2.*pow
enddo 12
return
END
```

The fourth and fifth steps are accomplished by the routines `chebpc` and `pcshft`, respectively. Here is how the procedure looks all together:

```

INTEGER NMANY,NFEW
REAL e(NMANY),d(NFEW),c(NMANY),a,b
Economize NMANY power series coefficients e(1:NMANY) in the range (a,b) into NFEW
coefficients d(1:NFEW).
call pcshft((-2.-b-a)/(b-a),(2.-b-a)/(b-a),e,NMANY)
call pccheb(e,c,NMANY)
...
Here one would normally examine the Chebyshev coefficients c(1:NMANY) to decide how
small NFEW can be.
call chebpc(c,d,NFEW)
call pcshft(a,b,d,NFEW)

```

In our example, by the way, the 8th through 10th Chebyshev coefficients turn out to be on the order of -7×10^{-6} , 3×10^{-7} , and -9×10^{-9} , so reasonable truncations (for single precision calculations) are somewhere in this range, yielding a polynomial with 8 – 10 terms instead of the original 13.

Replacing a 13-term polynomial with a (say) 10-term polynomial without any loss of accuracy — that does seem to be getting something for nothing. Is there some magic in this technique? Not really. The 13-term polynomial defined a function $f(x)$. Equivalent to economizing the series, we could instead have evaluated $f(x)$ at enough points to construct its Chebyshev approximation in the interval of interest, by the methods of §5.8. We would have obtained just the same lower-order polynomial. The principal lesson is that the rate of convergence of Chebyshev coefficients has nothing to do with the rate of convergence of power series coefficients; and it is the *former* that dictates the number of terms needed in a polynomial approximation. A function might have a *divergent* power series in some region of interest, but if the function itself is well-behaved, it will have perfectly good polynomial approximations. These can be found by the methods of §5.8, but *not* by economization of series. There is slightly less to economization of series than meets the eye.

5.12 Padé Approximants

A *Padé approximant*, so called, is that rational function (of a specified order) whose power series expansion agrees with a given power series to the highest possible order. If the rational function is

$$R(x) \equiv \frac{\sum_{k=0}^M a_k x^k}{1 + \sum_{k=1}^N b_k x^k} \quad (5.12.1)$$

then $R(x)$ is said to be a Padé approximant to the series

$$f(x) \equiv \sum_{k=0}^{\infty} c_k x^k \quad (5.12.2)$$

if

$$R(0) = f(0) \quad (5.12.3)$$

and also

$$\left. \frac{d^k}{dx^k} R(x) \right|_{x=0} = \left. \frac{d^k}{dx^k} f(x) \right|_{x=0}, \quad k = 1, 2, \dots, M + N \quad (5.12.4)$$

Equations (5.12.3) and (5.12.4) furnish $M + N + 1$ equations for the unknowns a_0, \dots, a_M and b_1, \dots, b_N . The easiest way to see what these equations are is to equate (5.12.1) and (5.12.2), multiply both by the denominator of equation (5.12.1), and equate all powers of x that have either a 's or b 's in their coefficients. If we consider only the special case of a diagonal rational approximation, $M = N$ (cf. §3.2), then we have $a_0 = c_0$, with the remaining a 's and b 's satisfying

$$\sum_{m=1}^N b_m c_{N-m+k} = -c_{N+k}, \quad k = 1, \dots, N \quad (5.12.5)$$

$$\sum_{m=0}^k b_m c_{k-m} = a_k, \quad k = 1, \dots, N \quad (5.12.6)$$

(note, in equation 5.12.1, that $b_0 = 1$). To solve these, start with equations (5.12.5), which are a set of linear equations for all the unknown b 's. Although the set is in the form of a Toeplitz matrix (compare equation 2.8.8), experience shows that the equations are frequently close to singular, so that one should not solve them by the methods of §2.8, but rather by full *LU* decomposition. Additionally, it is a good idea to refine the solution by iterative improvement (routine `mprove` in §2.5) [1].

Once the b 's are known, then equation (5.12.6) gives an explicit formula for the unknown a 's, completing the solution.

Padé approximants are typically used when there is some unknown underlying function $f(x)$. We suppose that you are able somehow to compute, perhaps by laborious analytic expansions, the values of $f(x)$ and a few of its derivatives at $x = 0$: $f(0)$, $f'(0)$, $f''(0)$, and so on. These are of course the first few coefficients in the power series expansion of $f(x)$; but they are not necessarily getting small, and you have no idea where (or whether) the power series is convergent.

By contrast with techniques like Chebyshev approximation (§5.8) or economization of power series (§5.11) that only condense the information that you already know about a function, Padé approximants can give you genuinely new information about your function's values. It is sometimes quite mysterious how well this can work. (Like other mysteries in mathematics, it relates to *analyticity*.) An example will illustrate.

Imagine that, by extraordinary labors, you have ground out the first five terms in the power series expansion of an unknown function $f(x)$,

$$f(x) \approx 2 + \frac{1}{9}x + \frac{1}{81}x^2 - \frac{49}{8748}x^3 + \frac{175}{78732}x^4 + \dots \quad (5.12.7)$$

(It is not really necessary that you know the coefficients in exact rational form — numerical values are just as good. We here write them as rationals to give you the impression that they derive from some side analytic calculation.) Equation (5.12.7) is plotted as the curve labeled “power series” in Figure 5.12.1. One sees that for $x \gtrsim 4$ it is dominated by its largest, quartic, term.

We now take the five coefficients in equation (5.12.7) and run them through the routine `pade` listed below. It returns five rational coefficients, three a 's and two b 's, for use in equation (5.12.1) with $M = N = 2$. The curve in the figure labeled “Padé” plots the resulting rational function. Note that both solid curves derive from the *same* five original coefficient values.

To evaluate the results, we need *Deus ex machina* (a useful fellow, when he is available) to tell us that equation (5.12.7) is in fact the power series expansion of the function

$$f(x) = [7 + (1 + x)^{4/3}]^{1/3} \quad (5.12.8)$$

which is plotted as the dotted curve in the figure. This function has a branch point at $x = -1$, so its power series is convergent only in the range $-1 < x < 1$. In most of the range shown in the figure, the series is divergent, and the value of its truncation to five terms is

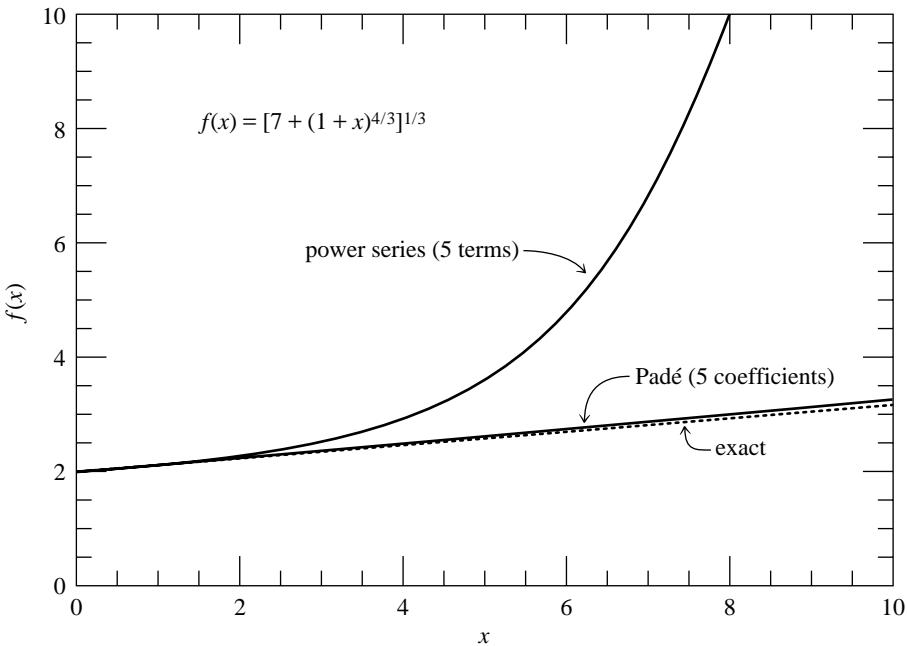

Figure 5.12.1. The five-term power series expansion and the derived five-coefficient Padé approximant for a sample function $f(x)$. The full power series converges only for $x < 1$. Note that the Padé approximant maintains accuracy far outside the radius of convergence of the series.

rather meaningless. Nevertheless, those five terms, converted to a Padé approximant, give a remarkably good representation of the function up to at least $x \sim 10$.

Why does this work? Are there not other functions with the same first five terms in their power series, but completely different behavior in the range (say) $2 < x < 10$? Indeed there are. Padé approximation has the uncanny knack of picking the function *you had in mind* from among all the possibilities. *Except when it doesn't!* That is the downside of Padé approximation: it is uncontrolled. There is, in general, no way to tell how accurate it is, or how far out in x it can usefully be extended. It is a powerful, but in the end still mysterious, technique.

Here is the routine that gets a 's and b 's from your c 's. Note that the routine is specialized to the case $M = N$, and also that, on output, the rational coefficients are arranged in a format for use with the evaluation routine `ratval` (§5.3). (Also for consistency with that routine, the array of c 's is passed in double precision.)

```

SUBROUTINE pade(cof,n,resid)
INTEGER n,NMAX
REAL resid,BIG
DOUBLE PRECISION cof(2*n+1)          For consistency with ratval.
PARAMETER (NMAX=20,BIG=1.E30)         Max expected value of n, and a big number.
C USES lubksb,ludcmp,mprove
      Given cof(1:2*n+1), the leading terms in the power series expansion of a function, solve
      the linear Padé equations to return the coefficients of a diagonal rational function approxi-
      mation to the same function, namely (cof(1) + cof(2)x + ... + cof(n+1)xN)/(1 +
      cof(n+2)x + ... + cof(2*n+1)xN). The value resid is the norm of the residual vector;
      a small value indicates a well-converged solution.
      INTEGER j,k,indx(NMAX)
      REAL d,rr,rrold,sum,q(NMAX,NMAX),qlu(NMAX,NMAX),x(NMAX),
      y(NMAX),z(NMAX)
*      Set up matrix for solving.
      do 12 j=1,n

5.13 Rational Chebyshev Approximation

In §5.8 and §5.10 we learned how to find good polynomial approximations to a given function $f(x)$ in a given interval $a \leq x \leq b$. Here, we want to generalize the task to find good approximations that are rational functions (see §5.3). The reason for doing so is that, for some functions and some intervals, the optimal rational function approximation is able to achieve substantially higher accuracy than the optimal polynomial approximation with the same number of coefficients. This must be weighed against the fact that finding a rational function approximation is not as straightforward as finding a polynomial approximation, which, as we saw, could be done elegantly via Chebyshev polynomials.

5.13 Rational Chebyshev Approximation

In §5.8 and §5.10 we learned how to find good polynomial approximations to a given function $f(x)$ in a given interval $a \leq x \leq b$. Here, we want to generalize the task to find good approximations that are rational functions (see §5.3). The reason for doing so is that, for some functions and some intervals, the optimal rational function approximation is able to achieve substantially higher accuracy than the optimal polynomial approximation with the same number of coefficients. This must be weighed against the fact that finding a rational function approximation is not as straightforward as finding a polynomial approximation, which, as we saw, could be done elegantly via Chebyshev polynomials.

Let the desired rational function $R(x)$ have numerator of degree m and denominator of degree k . Then we have

$$R(x) \equiv \frac{p_0 + p_1 x + \cdots + p_m x^m}{1 + q_1 x + \cdots + q_k x^k} \approx f(x) \quad \text{for } a \leq x \leq b \quad (5.13.1)$$

The unknown quantities that we need to find are p_0, \dots, p_m and q_1, \dots, q_k , that is, $m+k+1$ quantities in all. Let $r(x)$ denote the deviation of $R(x)$ from $f(x)$, and let r denote its maximum absolute value,

$$r(x) \equiv R(x) - f(x) \quad r \equiv \max_{a \leq x \leq b} |r(x)| \quad (5.13.2)$$

The ideal *minimax* solution would be that choice of p 's and q 's that minimizes r . Obviously there is *some* minimax solution, since r is bounded below by zero. How can we find it, or a reasonable approximation to it?

A first hint is furnished by the following fundamental theorem: If $R(x)$ is nondegenerate (has no common polynomial factors in numerator and denominator), then there is a unique choice of p 's and q 's that minimizes r ; for this choice, $r(x)$ has $m+k+2$ extrema in $a \leq x \leq b$, *all of magnitude r and with alternating sign*. (We have omitted some technical assumptions in this theorem. See Ralston [1] for a precise statement.) We thus learn that the situation with rational functions is quite analogous to that for minimax polynomials: In §5.8 we saw that the error term of an n th order approximation, with $n+1$ Chebyshev coefficients, was generally dominated by the first neglected Chebyshev term, namely T_{n+1} , which itself has $n+2$ extrema of equal magnitude and alternating sign. So, here, the number of rational coefficients, $m+k+1$, plays the same role of the number of polynomial coefficients, $n+1$.

A different way to see why $r(x)$ should have $m+k+2$ extrema is to note that $R(x)$ can be made exactly equal to $f(x)$ at any $m+k+1$ points x_i . Multiplying equation (5.13.1) by its denominator gives the equations

$$\begin{aligned} p_0 + p_1 x_i + \cdots + p_m x_i^m &= f(x_i)(1 + q_1 x_i + \cdots + q_k x_i^k) \\ i &= 1, 2, \dots, m+k+1 \end{aligned} \quad (5.13.3)$$

This is a set of $m+k+1$ linear equations for the unknown p 's and q 's, which can be solved by standard methods (e.g., *LU* decomposition). If we choose the x_i 's to all be in the interval (a, b) , then there will generically be an extremum between each chosen x_i and x_{i+1} , plus also extrema where the function goes out of the interval at a and b , for a total of $m+k+2$ extrema. For arbitrary x_i 's, the extrema will not have the same magnitude. The theorem says that, for one particular choice of x_i 's, the magnitudes can be beaten down to the identical, minimal, value of r .

Instead of making $f(x_i)$ and $R(x_i)$ equal at the points x_i , one can instead force the residual $r(x_i)$ to any desired values y_i by solving the linear equations

$$\begin{aligned} p_0 + p_1 x_i + \cdots + p_m x_i^m &= [f(x_i) - y_i](1 + q_1 x_i + \cdots + q_k x_i^k) \\ i &= 1, 2, \dots, m+k+1 \end{aligned} \quad (5.13.4)$$

In fact, if the x_i 's are chosen to be the extrema (not the zeros) of the minimax solution, then the equations satisfied will be

$$\begin{aligned} p_0 + p_1 x_i + \cdots + p_m x_i^m &= [f(x_i) \pm r](1 + q_1 x_i + \cdots + q_k x_i^k) \\ i &= 1, 2, \dots, m+k+2 \end{aligned} \quad (5.13.5)$$

where the \pm alternates for the alternating extrema. Notice that equation (5.13.5) is satisfied at $m+k+2$ extrema, while equation (5.13.4) was satisfied only at $m+k+1$ arbitrary points. How can this be? The answer is that r in equation (5.13.5) is an additional unknown, so that the number of both equations and unknowns is $m+k+2$. True, the set is mildly nonlinear (in r), but in general it is still perfectly soluble by methods that we will develop in Chapter 9.

We thus see that, given only the *locations* of the extrema of the minimax rational function, we can solve for its coefficients and maximum deviation. Additional theorems,

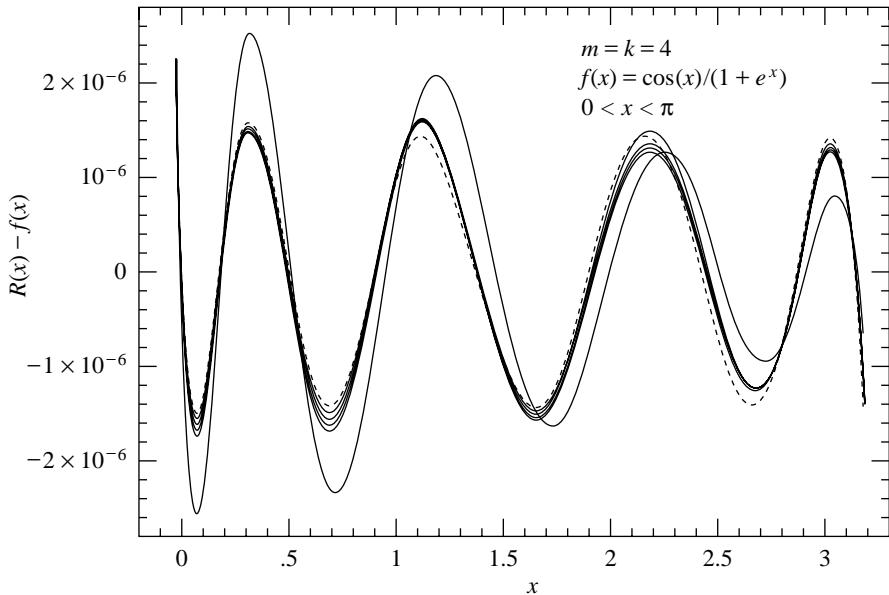

Figure 5.13.1. Solid curves show deviations $r(x)$ for five successive iterations of the routine `ratlsg` for an arbitrary test problem. The algorithm does not converge to exactly the minimax solution (shown as the dotted curve). But, after one iteration, the discrepancy is a small fraction of the last significant bit of accuracy.

leading up to the so-called *Remes algorithms* [1], tell how to converge to these locations by an iterative process. For example, here is a (slightly simplified) statement of *Remes' Second Algorithm*: (1) Find an initial rational function with $m + k + 2$ extrema x_i (not having equal deviation). (2) Solve equation (5.13.5) for new rational coefficients and r . (3) Evaluate the resulting $R(x)$ to find its actual extrema (which will not be the same as the guessed values). (4) Replace each guessed value with the nearest actual extremum of the same sign. (5) Go back to step 2 and iterate to convergence. Under a broad set of assumptions, this method will converge. Ralston [1] fills in the necessary details, including how to find the initial set of x_i 's.

Up to this point, our discussion has been textbook-standard. We now reveal ourselves as heretics. We don't much like the elegant Remes algorithm. Its two nested iterations (on r in the nonlinear set 5.13.5, and on the new sets of x_i 's) are finicky and require a lot of special logic for degenerate cases. Even more heretical, we doubt that compulsive searching for the *exactly best*, equal deviation, approximation is worth the effort — except perhaps for those few people in the world whose business it is to find optimal approximations that get built into compilers and microchips.

When we use rational function approximation, the goal is usually much more pragmatic: Inside some inner loop we are evaluating some function a zillion times, and we want to speed up its evaluation. Almost never do we need this function to the last bit of machine accuracy. Suppose (heresy!) we use an approximation whose error has $m + k + 2$ extrema whose deviations differ by a factor of 2. The theorems on which the Remes algorithms are based guarantee that the perfect minimax solution will have extrema somewhere within this factor of 2 range — forcing down the higher extrema will cause the lower ones to rise, until all are equal. So our "sloppy" approximation is in fact within a fraction of a least significant bit of the minimax one.

That is good enough for us, especially when we have available a very robust method for finding the so-called "sloppy" approximation. Such a method is the least-squares solution of overdetermined linear equations by singular value decomposition (§2.6 and §15.4). We proceed as follows: First, solve (in the least-squares sense) equation (5.13.3), not just for $m + k + 1$ values of x_i , but for a significantly larger number of x_i 's, spaced approximately

like the zeros of a high-order Chebyshev polynomial. This gives an initial guess for $R(x)$. Second, tabulate the resulting deviations, find the mean absolute deviation, call it r , and then solve (again in the least-squares sense) equation (5.13.5) with r fixed and the \pm chosen to be the sign of the observed deviation at each point x_i . Third, repeat the second step a few times.

You can spot some Remes orthodoxy lurking in our algorithm: The equations we solve are trying to bring the deviations not to zero, but rather to plus-or-minus some consistent value. However, we dispense with keeping track of actual extrema; and we solve only linear equations at each stage. One additional trick is to solve a *weighted* least-squares problem, where the weights are chosen to beat down the largest deviations fastest.

Here is a program implementing these ideas. Notice that the only calls to the function `fn` occur in the initial filling of the table `fs`s. You could easily modify the code to do this filling outside of the routine. It is not even necessary that your abscissas `xs` be exactly the ones that we use, though the quality of the fit will deteriorate if you do not have several abscissas between each extremum of the (underlying) minimax solution. Notice that the rational coefficients are output in a format suitable for evaluation by the routine `ratval` in §5.3.

```

SUBROUTINE ratlsq(fn,a,b,mm,kk,cof ,dev)
INTEGER kk,mm,NPFAC,MAXC,MAXP,MAXIT
DOUBLE PRECISION a,b,dev,cof (mm+kk+1),fn,PIO2,BIG
PARAMETER (NPFAC=8,MAXC=20,MAXP=NPFAC*MAXC+1,

Figure 5.13.1 shows the discrepancies for the first five iterations of `ratlsq` when it is applied to find the $m = k = 4$ rational fit to the function $f(x) = \cos x / (1 + e^x)$ in the interval $(0, \pi)$. One sees that after the first iteration, the results are virtually as good as the minimax solution. The iterations do not converge in the order that the figure suggests: In fact, it is the second iteration that is best (has smallest maximum deviation). The routine `ratlsq` accordingly returns the best of its iterations, not necessarily the last one; there is no advantage in doing more than five iterations.

5.14 Evaluation of Functions by Path Integration

In computer programming, the technique of choice is not necessarily the most efficient, or elegant, or fastest executing one. Instead, it may be the one that is quick to implement, general, and easy to check.

One sometimes needs only a few, or a few thousand, evaluations of a special function, perhaps a complex valued function of a complex variable, that has many different parameters, or asymptotic regimes, or both. Use of the usual tricks (series, continued fractions, rational function approximations, recurrence relations, and so forth) may result in a patchwork program with tests and branches to different formulas. While such a program may be highly efficient in execution, it is often not the shortest way to the answer from a standing start.

A different technique of considerable generality is direct integration of a function's defining differential equation – an ab initio integration for each desired

Figure 5.13.1 shows the discrepancies for the first five iterations of `ratlsq` when it is applied to find the $m = k = 4$ rational fit to the function $f(x) = \cos x / (1 + e^x)$ in the interval $(0, \pi)$. One sees that after the first iteration, the results are virtually as good as the minimax solution. The iterations do not converge in the order that the figure suggests: In fact, it is the second iteration that is best (has smallest maximum deviation). The routine `ratlsq` accordingly returns the best of its iterations, not necessarily the last one; there is no advantage in doing more than five iterations.

5.14 Evaluation of Functions by Path Integration

In computer programming, the technique of choice is not necessarily the most efficient, or elegant, or fastest executing one. Instead, it may be the one that is quick to implement, general, and easy to check.

One sometimes needs only a few, or a few thousand, evaluations of a special function, perhaps a complex valued function of a complex variable, that has many different parameters, or asymptotic regimes, or both. Use of the usual tricks (series, continued fractions, rational function approximations, recurrence relations, and so forth) may result in a patchwork program with tests and branches to different formulas. While such a program may be highly efficient in execution, it is often not the shortest way to the answer from a standing start.

A different technique of considerable generality is direct integration of a function's defining differential equation – an ab initio integration for each desired

function value — along a path in the complex plane if necessary. While this may at first seem like swatting a fly with a golden brick, it turns out that when you already have the brick, and the fly is asleep right under it, all you have to do is let it fall!

As a specific example, let us consider the complex hypergeometric function ${}_2F_1(a, b, c; z)$, which is defined as the analytic continuation of the so-called hypergeometric series,

$$\begin{aligned} {}_2F_1(a, b, c; z) = & 1 + \frac{ab}{c} \frac{z}{1!} + \frac{a(a+1)b(b+1)}{c(c+1)} \frac{z^2}{2!} + \dots \\ & + \frac{a(a+1)\dots(a+j-1)b(b+1)\dots(b+j-1)}{c(c+1)\dots(c+j-1)} \frac{z^j}{j!} + \dots \end{aligned} \quad (5.14.1)$$

The series converges only within the unit circle $|z| < 1$ (see [1]), but one's interest in the function is often not confined to this region.

The hypergeometric function ${}_2F_1$ is a solution (in fact *the* solution that is regular at the origin) of the hypergeometric differential equation, which we can write as

$$z(1-z)F'' = abF - [c - (a+b+1)z]F' \quad (5.14.2)$$

Here prime denotes d/dz . One can see that the equation has regular singular points at $z = 0, 1$, and ∞ . Since the desired solution is regular at $z = 0$, the values 1 and ∞ will in general be branch points. If we want ${}_2F_1$ to be a single valued function, we must have a branch cut connecting these two points. A conventional position for this cut is along the positive real axis from 1 to ∞ , though we may wish to keep open the possibility of altering this choice for some applications.

Our golden brick consists of a collection of routines for the integration of sets of ordinary differential equations, which we will develop in detail later, in Chapter 16. For now, we need only a high-level, “black-box” routine that integrates such a set from initial conditions at one value of a (real) independent variable to final conditions at some other value of the independent variable, while automatically adjusting its internal stepsize to maintain some specified accuracy. That routine is called `odeint` and, in one particular invocation, calculates its individual steps with a sophisticated Bulirsch-Stoer technique.

Suppose that we know values for F and its derivative F' at some value z_0 , and that we want to find F at some other point z_1 in the complex plane. The straight-line path connecting these two points is parametrized by

$$z(s) = z_0 + s(z_1 - z_0) \quad (5.14.3)$$

with s a real parameter. The differential equation (5.14.2) can now be written as a set of two first-order equations,

$$\begin{aligned} \frac{dF}{ds} &= (z_1 - z_0)F' \\ \frac{dF'}{ds} &= (z_1 - z_0) \left(\frac{abF - [c - (a+b+1)z]F'}{z(1-z)} \right) \end{aligned} \quad (5.14.4)$$

to be integrated from $s = 0$ to $s = 1$. Here F and F' are to be viewed as two independent complex variables. The fact that prime means d/dz can be ignored; it

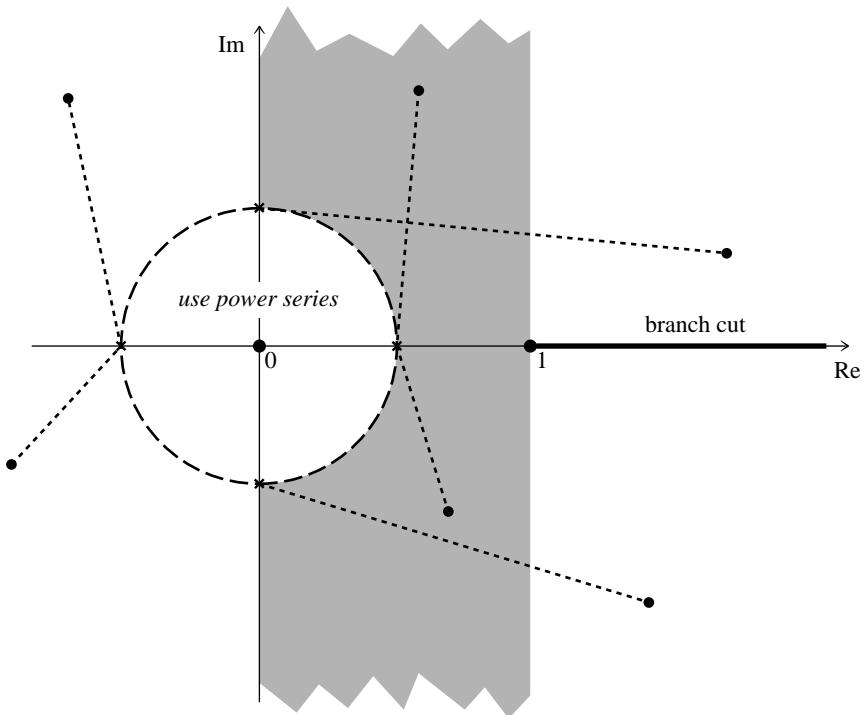

Figure 5.14.1. Complex plane showing the singular points of the hypergeometric function, its branch cut, and some integration paths from the circle $|z| = 1/2$ (where the power series converges rapidly) to other points in the plane.

will emerge as a consequence of the first equation in (5.14.4). Moreover, the real and imaginary parts of equation (5.14.4) define a set of four *real* differential equations, with independent variable s . The complex arithmetic on the right-hand side can be viewed as mere shorthand for how the four components are to be coupled. It is precisely this point of view that gets passed to the routine `odeint`, since it knows nothing of either complex functions or complex independent variables.

It remains only to decide where to start, and what path to take in the complex plane, to get to an arbitrary point z . This is where consideration of the function's singularities, and the adopted branch cut, enter. Figure 5.14.1 shows the strategy that we adopt. For $|z| \leq 1/2$, the series in equation (5.14.1) will in general converge rapidly, and it makes sense to use it directly. Otherwise, we integrate along a straight line path from one of the starting points $(\pm 1/2, 0)$ or $(0, \pm 1/2)$. The former choices are natural for $0 < \text{Re}(z) < 1$ and $\text{Re}(z) < 0$, respectively. The latter choices are used for $\text{Re}(z) > 1$, above and below the branch cut; the purpose of starting away from the real axis in these cases is to avoid passing too close to the singularity at $z = 1$ (see Figure 5.14.1). The location of the branch cut is *defined* by the fact that our adopted strategy never integrates across the real axis for $\text{Re}(z) > 1$.

An implementation of this algorithm is given in §6.12 as the routine `hypgeo`.

A number of variants on the procedure described thus far are possible, and easy to program. If successively called values of z are close together (with identical values of a , b , and c), then you can save the state vector (F, F') and the corresponding value

of z on each call, and use these as starting values for the next call. The incremental integration may then take only one or two steps. Avoid integrating across the branch cut unintentionally: the function value will be “correct,” but not the one you want.

Alternatively, you may wish to integrate to some position z by a dog-leg path that *does* cross the real axis $\text{Re } z > 1$, as a means of *moving* the branch cut. For example, in some cases you might want to integrate from $(0, 1/2)$ to $(3/2, 1/2)$, and go from there to any point with $\text{Re } z > 1$ — with either sign of $\text{Im } z$. (If you are, for example, finding roots of a function by an iterative method, you do not want the integration for nearby values to take different paths around a branch point. If it does, your root-finder will see discontinuous function values, and will likely not converge correctly!)

In any case, be aware that a loss of numerical accuracy can result if you integrate through a region of large function value on your way to a final answer where the function value is small. (For the hypergeometric function, a particular case of this is when a and b are both large and positive, with c and $x \gtrsim 1$.) In such cases, you’ll need to find a better dog-leg path.

The general technique of evaluating a function by integrating its differential equation in the complex plane can also be applied to other special functions. For example, the complex Bessel function, Airy function, Coulomb wave function, and Weber function are all special cases of the *confluent hypergeometric function*, with a differential equation similar to the one used above (see, e.g., [1] §13.6, for a table of special cases). The confluent hypergeometric function has no singularities at finite z : That makes it easy to integrate. However, its essential singularity at infinity means that it can have, along some paths and for some parameters, highly oscillatory or exponentially decreasing behavior: That makes it hard to integrate. Some case by case judgment (or experimentation) is therefore required.

Chapter 6. Special Functions

6.0 Introduction

There is nothing particularly special about a *special function*, except that some person in authority or textbook writer (not the same thing!) has decided to bestow the moniker. Special functions are sometimes called *higher transcendental functions* (higher than what?) or *functions of mathematical physics* (but they occur in other fields also) or *functions that satisfy certain frequently occurring second-order differential equations* (but not all special functions do). One might simply call them “useful functions” and let it go at that; it is surely only a matter of taste which functions we have chosen to include in this chapter.

Good commercially available program libraries, such as NAG or IMSL, contain routines for a number of special functions. These routines are intended for users who will have no idea what goes on inside them. Such state of the art “black boxes” are often very messy things, full of branches to completely different methods depending on the value of the calling arguments. Black boxes have, or should have, careful control of accuracy, to some stated uniform precision in all regimes.

We will not be quite so fastidious in our examples, in part because we want to illustrate techniques from Chapter 5, and in part because we *want* you to understand what goes on in the routines presented. Some of our routines have an accuracy parameter that can be made as small as desired, while others (especially those involving polynomial fits) give only a certain accuracy, one that we believe serviceable (typically six significant figures or more). We do *not* certify that the routines are perfect black boxes. We do hope that, if you ever encounter trouble in a routine, you will be able to diagnose and correct the problem on the basis of the information that we have given.

In short, the special function routines of this chapter are meant to be used — we use them all the time — but we also want you to be prepared to understand their inner workings.

6.1 Gamma Function, Beta Function, Factorials, Binomial Coefficients

The gamma function is defined by the integral

$$\Gamma(z) = \int_0^\infty t^{z-1} e^{-t} dt \quad (6.1.1)$$

When the argument z is an integer, the gamma function is just the familiar factorial function, but offset by one,

$$n! = \Gamma(n+1) \quad (6.1.2)$$

The gamma function satisfies the recurrence relation

$$\Gamma(z+1) = z\Gamma(z) \quad (6.1.3)$$

If the function is known for arguments $z > 1$ or, more generally, in the half complex plane $\text{Re}(z) > 1$ it can be obtained for $z < 1$ or $\text{Re}(z) < 1$ by the reflection formula

$$\Gamma(1-z) = \frac{\pi}{\Gamma(z) \sin(\pi z)} = \frac{\pi z}{\Gamma(1+z) \sin(\pi z)} \quad (6.1.4)$$

Notice that $\Gamma(z)$ has a pole at $z = 0$, and at all negative integer values of z .

There are a variety of methods in use for calculating the function $\Gamma(z)$ numerically, but none is quite as neat as the approximation derived by Lanczos [1]. This scheme is entirely specific to the gamma function, seemingly plucked from thin air. We will not attempt to derive the approximation, but only state the resulting formula: For certain integer choices of γ and N , and for certain coefficients c_1, c_2, \dots, c_N , the gamma function is given by

$$\begin{aligned} \Gamma(z+1) &= (z + \gamma + \frac{1}{2})^{z+\frac{1}{2}} e^{-(z+\gamma+\frac{1}{2})} \\ &\times \sqrt{2\pi} \left[c_0 + \frac{c_1}{z+1} + \frac{c_2}{z+2} + \cdots + \frac{c_N}{z+N} + \epsilon \right] \quad (z > 0) \end{aligned} \quad (6.1.5)$$

You can see that this is a sort of take-off on Stirling's approximation, but with a series of corrections that take into account the first few poles in the left complex plane. The constant c_0 is very nearly equal to 1. The error term is parametrized by ϵ . For $\gamma = 5$, $N = 6$, and a certain set of c 's, the error is smaller than $|\epsilon| < 2 \times 10^{-10}$. Impressed? If not, then perhaps you will be impressed by the fact that (with these

6.1 Gamma Function, Beta Function, Factorials, Binomial Coefficients

The gamma function is defined by the integral

$$\Gamma(z) = \int_0^\infty t^{z-1} e^{-t} dt \quad (6.1.1)$$

When the argument z is an integer, the gamma function is just the familiar factorial function, but offset by one,

$$n! = \Gamma(n+1) \quad (6.1.2)$$

The gamma function satisfies the recurrence relation

$$\Gamma(z+1) = z\Gamma(z) \quad (6.1.3)$$

If the function is known for arguments $z > 1$ or, more generally, in the half complex plane $\text{Re}(z) > 1$ it can be obtained for $z < 1$ or $\text{Re}(z) < 1$ by the reflection formula

$$\Gamma(1-z) = \frac{\pi}{\Gamma(z) \sin(\pi z)} = \frac{\pi z}{\Gamma(1+z) \sin(\pi z)} \quad (6.1.4)$$

Notice that $\Gamma(z)$ has a pole at $z = 0$, and at all negative integer values of z .

There are a variety of methods in use for calculating the function $\Gamma(z)$ numerically, but none is quite as neat as the approximation derived by Lanczos [1]. This scheme is entirely specific to the gamma function, seemingly plucked from thin air. We will not attempt to derive the approximation, but only state the resulting formula: For certain integer choices of γ and N , and for certain coefficients c_1, c_2, \dots, c_N , the gamma function is given by

$$\begin{aligned} \Gamma(z+1) &= (z + \gamma + \frac{1}{2})^{z+\frac{1}{2}} e^{-(z+\gamma+\frac{1}{2})} \\ &\times \sqrt{2\pi} \left[c_0 + \frac{c_1}{z+1} + \frac{c_2}{z+2} + \cdots + \frac{c_N}{z+N} + \epsilon \right] \quad (z > 0) \end{aligned} \quad (6.1.5)$$

You can see that this is a sort of take-off on Stirling's approximation, but with a series of corrections that take into account the first few poles in the left complex plane. The constant c_0 is very nearly equal to 1. The error term is parametrized by ϵ . For $\gamma = 5$, $N = 6$, and a certain set of c 's, the error is smaller than $|\epsilon| < 2 \times 10^{-10}$. Impressed? If not, then perhaps you will be impressed by the fact that (with these

same parameters) the formula (6.1.5) and bound on ϵ apply for the *complex* gamma function, *everywhere in the half complex plane* $\text{Re } z > 0$.

It is better to implement $\ln \Gamma(x)$ than $\Gamma(x)$, since the latter will overflow many computers' floating-point representation at quite modest values of x . Often the gamma function is used in calculations where the large values of $\Gamma(x)$ are divided by other large numbers, with the result being a perfectly ordinary value. Such operations would normally be coded as subtraction of logarithms. With (6.1.5) in hand, we can compute the logarithm of the gamma function with two calls to a logarithm and 25 or so arithmetic operations. This makes it not much more difficult than other built-in functions that we take for granted, such as $\sin x$ or e^x :

```
FUNCTION gammln(xx)
REAL gammln,xx
    Returns the value  $\ln[\Gamma(xx)]$  for  $xx > 0$ .
INTEGER j
DOUBLE PRECISION ser,stp,tmp,x,y,cof(6)
    Internal arithmetic will be done in double precision, a nicety that you can omit if five-figure
    accuracy is good enough.
SAVE cof,stp
DATA cof,stp/76.18009172947146d0,-86.50532032941677d0,
*   24.01409824083091d0,-1.231739572450155d0,.1208650973866179d-2,
*   -.5395239384953d-5,2.5066282746310005d0/
x=xx
y=x
tmp=x+5.5d0
tmp=(x+0.5d0)*log(tmp)-tmp
ser=1.000000000190015d0
do !! j=1,6
    y=y+1.d0
    ser=ser+cof(j)/y
enddo !!
gammln=tmp+log(stp*ser/x)
return
END
```

How shall we write a routine for the factorial function $n!$? Generally the factorial function will be called for small integer values (for large values it will overflow anyway!), and in most applications the same integer value will be called for many times. It is a profligate waste of computer time to call `exp(gammln(n+1.0))` for each required factorial. Better to go back to basics, holding `gammln` in reserve for unlikely calls:

```
C FUNCTION factrl(n)
INTEGER n
REAL factrl
USES gammln
    Returns the value  $n!$  as a floating-point number.
INTEGER j,ntop
REAL a(33),gammln          Table to be filled in only as required.
SAVE ntop,a
DATA ntop,a(1)/0,1./        Table initialized with  $0!$  only.
if (n.lt.0) then
    pause 'negative factorial in factrl'
else if (n.le.ntop) then    Already in table.
    factrl=a(n+1)
else if (n.le.32) then      Fill in table up to desired value.
    do !! j=ntop+1,n
```

```

        a(j+1)=j*a(j)
    enddo 11
    ntop=n
    factrl=a(n+1)
else                                Larger value than size of table is required. Actually, this big
    factrl=exp(gammln(n+1.))      a value is going to overflow on many computers, but no
endif                               harm in trying.
return
END

```

A useful point is that `factrl` will be *exact* for the smaller values of n , since floating-point multiplies on small integers are exact on all computers. This exactness will not hold if we turn to the logarithm of the factorials. For binomial coefficients, however, we must do exactly this, since the individual factorials in a binomial coefficient will overflow long before the coefficient itself will.

The binomial coefficient is defined by

$$\binom{n}{k} = \frac{n!}{k!(n-k)!} \quad 0 \leq k \leq n \quad (6.1.6)$$

```

FUNCTION bico(n,k)
INTEGER k,n
REAL bico
C   USES factln
      Returns the binomial coefficient  $\binom{n}{k}$  as a floating-point number.
REAL factln
bico=nint(exp(factln(n)-factln(k)-factln(n-k)))
return The nearest-integer function cleans up roundoff error for smaller values of n and k.
END

```

which uses

```

FUNCTION factln(n)
INTEGER n
REAL factln
C   USES gammln
      Returns  $\ln(n!)$ .
REAL a(100),gammln
SAVE a
DATA a/100*-1./                         Initialize the table to negative values.
if (n.lt.0) pause 'negative factorial in factln'
if (n.le.99) then                         In range of the table.
    if (a(n+1).lt.0.) a(n+1)=gammln(n+1.)   If not already in the table, put it in.
    factln=a(n+1)
else                                         Out of range of the table.
    factln=gammln(n+1.)
endif
return
END

```

If your problem requires a series of related binomial coefficients, a good idea is to use recurrence relations, for example

$$\begin{aligned}\binom{n+1}{k} &= \frac{n+1}{n-k+1} \binom{n}{k} = \binom{n}{k} + \binom{n}{k-1} \\ \binom{n}{k+1} &= \frac{n-k}{k+1} \binom{n}{k}\end{aligned}\quad (6.1.7)$$

Finally, turning away from the combinatorial functions with integer valued arguments, we come to the beta function,

$$B(z, w) = B(w, z) = \int_0^1 t^{z-1} (1-t)^{w-1} dt \quad (6.1.8)$$

which is related to the gamma function by

$$B(z, w) = \frac{\Gamma(z)\Gamma(w)}{\Gamma(z+w)} \quad (6.1.9)$$

hence

```
FUNCTION beta(z,w)
REAL beta,w,z
C USES gammln
    Returns the value of the beta function B(z,w).
REAL gammln
beta=exp(gammln(z)+gammln(w)-gammln(z+w))
return
END
```

6.2 Incomplete Gamma Function, Error Function, Chi-Square Probability Function, Cumulative Poisson Function

The incomplete gamma function is defined by

$$P(a, x) \equiv \frac{\gamma(a, x)}{\Gamma(a)} \equiv \frac{1}{\Gamma(a)} \int_0^x e^{-t} t^{a-1} dt \quad (a > 0) \quad (6.2.1)$$

If your problem requires a series of related binomial coefficients, a good idea is to use recurrence relations, for example

$$\begin{aligned}\binom{n+1}{k} &= \frac{n+1}{n-k+1} \binom{n}{k} = \binom{n}{k} + \binom{n}{k-1} \\ \binom{n}{k+1} &= \frac{n-k}{k+1} \binom{n}{k}\end{aligned}\quad (6.1.7)$$

Finally, turning away from the combinatorial functions with integer valued arguments, we come to the beta function,

$$B(z, w) = B(w, z) = \int_0^1 t^{z-1} (1-t)^{w-1} dt \quad (6.1.8)$$

which is related to the gamma function by

$$B(z, w) = \frac{\Gamma(z)\Gamma(w)}{\Gamma(z+w)} \quad (6.1.9)$$

hence

```
FUNCTION beta(z,w)
REAL beta,w,z
C USES gammln
    Returns the value of the beta function B(z,w).
REAL gammln
beta=exp(gammln(z)+gammln(w)-gammln(z+w))
return
END
```

6.2 Incomplete Gamma Function, Error Function, Chi-Square Probability Function, Cumulative Poisson Function

The incomplete gamma function is defined by

$$P(a, x) \equiv \frac{\gamma(a, x)}{\Gamma(a)} \equiv \frac{1}{\Gamma(a)} \int_0^x e^{-t} t^{a-1} dt \quad (a > 0) \quad (6.2.1)$$

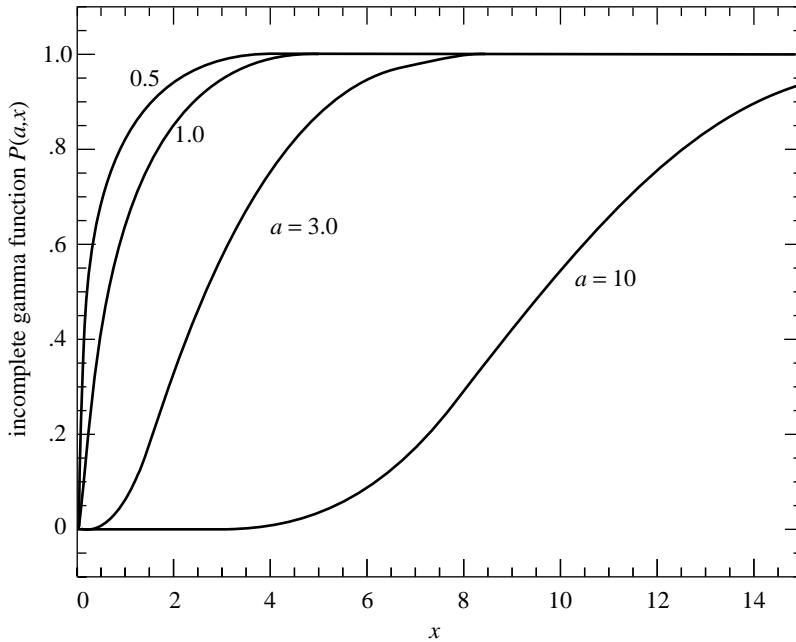

Figure 6.2.1. The incomplete gamma function $P(a, x)$ for four values of a .

It has the limiting values

$$P(a, 0) = 0 \quad \text{and} \quad P(a, \infty) = 1 \quad (6.2.2)$$

The incomplete gamma function $P(a, x)$ is monotonic and (for a greater than one or so) rises from “near-zero” to “near-unity” in a range of x centered on about $a - 1$, and of width about \sqrt{a} (see Figure 6.2.1).

The complement of $P(a, x)$ is also confusingly called an incomplete gamma function,

$$Q(a, x) \equiv 1 - P(a, x) \equiv \frac{\Gamma(a, x)}{\Gamma(a)} \equiv \frac{1}{\Gamma(a)} \int_x^\infty e^{-t} t^{a-1} dt \quad (a > 0) \quad (6.2.3)$$

It has the limiting values

$$Q(a, 0) = 1 \quad \text{and} \quad Q(a, \infty) = 0 \quad (6.2.4)$$

The notations $P(a, x)$, $\gamma(a, x)$, and $\Gamma(a, x)$ are standard; the notation $Q(a, x)$ is specific to this book.

There is a series development for $\gamma(a, x)$ as follows:

$$\gamma(a, x) = e^{-x} x^a \sum_{n=0}^{\infty} \frac{\Gamma(a)}{\Gamma(a + 1 + n)} x^n \quad (6.2.5)$$

One does not actually need to compute a new $\Gamma(a + 1 + n)$ for each n ; one rather uses equation (6.1.3) and the previous coefficient.

A continued fraction development for $\Gamma(a, x)$ is

$$\Gamma(a, x) = e^{-x} x^a \left(\frac{1}{x +} \frac{1-a}{1+} \frac{1}{x+} \frac{2-a}{1+} \frac{2}{x+} \dots \right) \quad (x > 0) \quad (6.2.6)$$

It is computationally better to use the even part of (6.2.6), which converges twice as fast (see §5.2):

$$\Gamma(a, x) = e^{-x} x^a \left(\frac{1}{x+1-a-} \frac{1 \cdot (1-a)}{x+3-a-} \frac{2 \cdot (2-a)}{x+5-a-} \dots \right) \quad (x > 0) \quad (6.2.7)$$

It turns out that (6.2.5) converges rapidly for x less than about $a + 1$, while (6.2.6) or (6.2.7) converges rapidly for x greater than about $a + 1$. In these respective regimes each requires at most a few times \sqrt{a} terms to converge, and this many only near $x = a$, where the incomplete gamma functions are varying most rapidly. Thus (6.2.5) and (6.2.7) together allow evaluation of the function for all positive a and x . An extra dividend is that we never need compute a function value near zero by subtracting two nearly equal numbers. The higher-level functions that return $P(a, x)$ and $Q(a, x)$ are

```

FUNCTION gammp(a,x)
REAL a,gammp,x
C USES gcf,gser
    Returns the incomplete gamma function  $P(a, x)$ .
REAL gammcf,gamser,gln
if(x.lt.0..or.a.le.0.)pause 'bad arguments in gammp'
if(x.lt.a+1.)then           Use the series representation.
    call gser(gamser,a,x,gln)
    gammcp=gamser
else                         Use the continued fraction representation
    call gcf(gammcf,a,x,gln)
    gammcp=1.-gammcf           and take its complement.
endif
return
END

FUNCTION gammq(a,x)
REAL a,gammq,x
C USES gcf,gser
    Returns the incomplete gamma function  $Q(a, x) \equiv 1 - P(a, x)$ .
REAL gammcf,gamser,gln
if(x.lt.0..or.a.le.0.)pause 'bad arguments in gammq'
if(x.lt.a+1.)then           Use the series representation

    call gcf(gammcf,a,x,gln)
    gammq=gammcf
endif
return
END

```

The argument gln is returned by both the series and continued fraction procedures containing the value $\ln \Gamma(a)$; the reason for this is so that it is available to you if you want to modify the above two procedures to give $\gamma(a, x)$ and $\Gamma(a, x)$, in addition to $P(a, x)$ and $Q(a, x)$ (cf. equations 6.2.1 and 6.2.3).

The procedures `gser` and `gcf` which implement (6.2.5) and (6.2.7) are

```

SUBROUTINE gser(gamser,a,x,gln)
INTEGER ITMAX
REAL a,gamser,gln,x,EPS
PARAMETER (ITMAX=100,EPS=3.e-7)
C USES gammeln
      Returns the incomplete gamma function  $P(a, x)$  evaluated by its series representation as
      gamser. Also returns  $\ln \Gamma(a)$  as gln.
      INTEGER n
      REAL ap,del,sum,gammeln
      gln=gammeln(a)
      if(x.le.0.)then
          if(x.lt.0.)pause 'x < 0 in gser'
          gamser=0.
          return
      endif
      ap=a
      sum=1./a
      del=sum
      do :: n=1,ITMAX
          ap=ap+1.
          del=del*x/ap
          sum=sum+del
          if(abs(del).lt.abs(sum)*EPS)goto 1
      enddo :: 
      pause 'a too large, ITMAX too small in gser'
      gamser=sum*exp(-x+a*log(x)-gln)
      return
END

```

```

SUBROUTINE gcf(gammcf,a,x,gln)
INTEGER ITMAX
REAL a,gammcf,gln,x,EPS,FPMIN
PARAMETER (ITMAX=100,EPS=3.e-7,FPMIN=1.e-30)
C USES gammeln
      Returns the incomplete gamma function  $Q(a, x)$  evaluated by its continued fraction representation as gammcf. Also returns  $\ln \Gamma(a)$  as gln.
      Parameters: ITMAX is the maximum allowed number of iterations; EPS is the relative accuracy; FPMIN is a number near the smallest representable floating-point number.
      INTEGER i
      REAL an,b,c,d,del,h,gammeln
      gln=gammeln(a)
      b=x+1.-a
      c=1./FPMIN
      d=1./b
      h=d
      do :: i=1,ITMAX
          an=-i*(i-a)
          b=b+2.
          d=an*d+b
          if(abs(d).lt.FPMIN)d=FPMIN
          c=b+an/c
          if(abs(c).lt.FPMIN)c=FPMIN
          d=1./d
          del=d*c
          Set up for evaluating continued fraction by modified
          Lentz's method (§5.2) with  $b_0 = 0$ .
          Iterate to convergence.

```

```

h=h*del
if(abs(del-1.).lt.EPS)goto 1
enddo 11
pause 'a too large, ITMAX too small in gcf'
1 gammcf=exp(-x+a*log(x)-gln)*h      Put factors in front.
return
END

```

Error Function

The error function and complementary error function are special cases of the incomplete gamma function, and are obtained moderately efficiently by the above procedures. Their definitions are

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \quad (6.2.8)$$

and

$$\operatorname{erfc}(x) \equiv 1 - \operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} dt \quad (6.2.9)$$

The functions have the following limiting values and symmetries:

$$\operatorname{erf}(0) = 0 \quad \operatorname{erf}(\infty) = 1 \quad \operatorname{erf}(-x) = -\operatorname{erf}(x) \quad (6.2.10)$$

$$\operatorname{erfc}(0) = 1 \quad \operatorname{erfc}(\infty) = 0 \quad \operatorname{erfc}(-x) = 2 - \operatorname{erfc}(x) \quad (6.2.11)$$

They are related to the incomplete gamma functions by

$$\operatorname{erf}(x) = P\left(\frac{1}{2}, x^2\right) \quad (x \geq 0) \quad (6.2.12)$$

and

$$\operatorname{erfc}(x) = Q\left(\frac{1}{2}, x^2\right) \quad (x \geq 0) \quad (6.2.13)$$

Hence we have

```

FUNCTION erf(x)
REAL erf,x
C USES gammp
      Returns the error function erf(x).
REAL gammp
if(x.lt.0.)then
      erf=-gammp(.5,x**2)
else
      erf=gammp(.5,x**2)
endif
return
END

```

```

FUNCTION erfc(x)
REAL erfc,x
C USES gammp,gammaq
    Returns the complementary error function erfc(x).
REAL gammp,gammaq
if(x.lt.0.)then
    erfc=1.+gammp(.5,x**2)
else
    erfc=gammaq(.5,x**2)
endif
return
END

```

If you care to do so, you can easily remedy the minor inefficiency in `erf` and `erfc`, namely that $\Gamma(0.5) = \sqrt{\pi}$ is computed unnecessarily when `gammp` or `gammaq` is called. Before you do that, however, you might wish to consider the following routine, based on Chebyshev fitting to an inspired guess as to the functional form:

```

FUNCTION erfcc(x)
REAL erfcc,x
    Returns the complementary error function erfc(x) with fractional error everywhere less than
     $1.2 \times 10^{-7}$ .
REAL t,z
z=abs(x)
t=1./(1.+0.5*z)
erfcc=t*exp(-z*z-1.26551223+t*(1.00002368+t*(.37409196+
*      t*(.09678418+t*(-.18628806+t*(-.27886807+t*(-1.13520398+
*      t*(1.48851587+t*(-.82215223+t*.17087277))))))))
if (x.lt.0.) erfcc=2.-erfcc
return
END

```

There are also some functions of *two* variables that are special cases of the incomplete gamma function:

Cumulative Poisson Probability Function

$P_x(< k)$, for positive x and integer $k \geq 1$, denotes the *cumulative Poisson probability* function. It is defined as the probability that the number of Poisson random events occurring will be between 0 and $k - 1$ *inclusive*, if the expected mean number is x . It has the limiting values

$$P_x(< 1) = e^{-x} \quad P_x(< \infty) = 1 \quad (6.2.14)$$

Its relation to the incomplete gamma function is simply

$$P_x(< k) = Q(k, x) = \text{gammaq}(k, x) \quad (6.2.15)$$

Chi-Square Probability Function

$P(\chi^2|\nu)$ is defined as the probability that the observed chi-square for a correct model should be less than a value χ^2 . (We will discuss the use of this function in Chapter 15.) Its complement $Q(\chi^2|\nu)$ is the probability that the observed chi-square will exceed the value χ^2 by chance *even* for a correct model. In both cases ν is an integer, the number of degrees of freedom. The functions have the limiting values

$$P(0|\nu) = 0 \quad P(\infty|\nu) = 1 \quad (6.2.16)$$

$$Q(0|\nu) = 1 \quad Q(\infty|\nu) = 0 \quad (6.2.17)$$

and the following relation to the incomplete gamma functions,

$$P(\chi^2|\nu) = P\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) = \text{gammp}\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) \quad (6.2.18)$$

$$Q(\chi^2|\nu) = Q\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) = \text{gammq}\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) \quad (6.2.19)$$

6.3 Exponential Integrals

The standard definition of the exponential integral is

$$E_n(x) = \int_1^\infty \frac{e^{-xt}}{t^n} dt, \quad x > 0, \quad n = 0, 1, \dots \quad (6.3.1)$$

The function defined by the principal value of the integral

$$\text{Ei}(x) = - \int_{-\infty}^x \frac{e^{-t}}{t} dt = \int_{-\infty}^x \frac{e^t}{t} dt, \quad x > 0 \quad (6.3.2)$$

is also called an exponential integral. Note that $\text{Ei}(-x)$ is related to $-E_1(x)$ by analytic continuation.

The function $E_n(x)$ is a special case of the incomplete gamma function

$$E_n(x) = x^{n-1} \Gamma(1-n, x) \quad (6.3.3)$$

Chi-Square Probability Function

$P(\chi^2|\nu)$ is defined as the probability that the observed chi-square for a correct model should be less than a value χ^2 . (We will discuss the use of this function in Chapter 15.) Its complement $Q(\chi^2|\nu)$ is the probability that the observed chi-square will exceed the value χ^2 by chance *even* for a correct model. In both cases ν is an integer, the number of degrees of freedom. The functions have the limiting values

$$P(0|\nu) = 0 \quad P(\infty|\nu) = 1 \quad (6.2.16)$$

$$Q(0|\nu) = 1 \quad Q(\infty|\nu) = 0 \quad (6.2.17)$$

and the following relation to the incomplete gamma functions,

$$P(\chi^2|\nu) = P\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) = \text{gammp}\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) \quad (6.2.18)$$

$$Q(\chi^2|\nu) = Q\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) = \text{gammq}\left(\frac{\nu}{2}, \frac{\chi^2}{2}\right) \quad (6.2.19)$$

6.3 Exponential Integrals

The standard definition of the exponential integral is

$$E_n(x) = \int_1^\infty \frac{e^{-xt}}{t^n} dt, \quad x > 0, \quad n = 0, 1, \dots \quad (6.3.1)$$

The function defined by the principal value of the integral

$$\text{Ei}(x) = - \int_{-\infty}^x \frac{e^{-t}}{t} dt = \int_{-\infty}^x \frac{e^t}{t} dt, \quad x > 0 \quad (6.3.2)$$

is also called an exponential integral. Note that $\text{Ei}(-x)$ is related to $-E_1(x)$ by analytic continuation.

The function $E_n(x)$ is a special case of the incomplete gamma function

$$E_n(x) = x^{n-1} \Gamma(1-n, x) \quad (6.3.3)$$

We can therefore use a similar strategy for evaluating it. The continued fraction — just equation (6.2.6) rewritten — converges for all $x > 0$:

$$E_n(x) = e^{-x} \left(\frac{1}{x +} \frac{n}{1 +} \frac{1}{x +} \frac{n+1}{1 +} \frac{2}{x +} \dots \right) \quad (6.3.4)$$

We use it in its more rapidly converging even form,

$$E_n(x) = e^{-x} \left(\frac{1}{x+n-} \frac{1 \cdot n}{x+n+2-} \frac{2(n+1)}{x+n+4-} \dots \right) \quad (6.3.5)$$

The continued fraction only really converges fast enough to be useful for $x \gtrsim 1$. For $0 < x \lesssim 1$, we can use the series representation

$$E_n(x) = \frac{(-x)^{n-1}}{(n-1)!} [-\ln x + \psi(n)] - \sum_{\substack{m=0 \\ m \neq n-1}}^{\infty} \frac{(-x)^m}{(m-n+1)m!} \quad (6.3.6)$$

The quantity $\psi(n)$ here is the digamma function, given for integer arguments by

$$\psi(1) = -\gamma, \quad \psi(n) = -\gamma + \sum_{m=1}^{n-1} \frac{1}{m} \quad (6.3.7)$$

where $\gamma = 0.5772156649\dots$ is Euler's constant. We evaluate the expression (6.3.6) in order of ascending powers of x :

$$\begin{aligned} E_n(x) = & - \left[\frac{1}{(1-n)} - \frac{x}{(2-n) \cdot 1} + \frac{x^2}{(3-n)(1 \cdot 2)} - \dots + \frac{(-x)^{n-2}}{(-1)(n-2)!} \right] \\ & + \frac{(-x)^{n-1}}{(n-1)!} [-\ln x + \psi(n)] - \left[\frac{(-x)^n}{1 \cdot n!} + \frac{(-x)^{n+1}}{2 \cdot (n+1)!} + \dots \right] \end{aligned} \quad (6.3.8)$$

The first square bracket is omitted when $n = 1$. This method of evaluation has the advantage that for large n the series converges before reaching the term containing $\psi(n)$. Accordingly, one needs an algorithm for evaluating $\psi(n)$ only for small n , $n \lesssim 20 - 40$. We use equation (6.3.7), although a table look-up would improve efficiency slightly.

Amos [1] presents a careful discussion of the truncation error in evaluating equation (6.3.8), and gives a fairly elaborate termination criterion. We have found that simply stopping when the last term added is smaller than the required tolerance works about as well.

Two special cases have to be handled separately:

$$\begin{aligned} E_0(x) &= \frac{e^{-x}}{x} \\ E_n(0) &= \frac{1}{n-1}, \quad n > 1 \end{aligned} \quad (6.3.9)$$

The routine `expint` allows fast evaluation of $E_n(x)$ to any accuracy EPS within the reach of your machine's word length for floating-point numbers. The only modification required for increased accuracy is to supply Euler's constant with enough significant digits. Wrench [2] can provide you with the first 328 digits if necessary!

```

FUNCTION expint(n,x)
INTEGER n,MAXIT
REAL expint,x,EPS,FPMIN,EULER
PARAMETER (MAXIT=100,EPS=1.e-7,FPMIN=1.e-30,EULER=.5772156649)
Evaluates the exponential integral  $E_n(x)$ .
Parameters: MAXIT is the maximum allowed number of iterations; EPS is the desired relative error, not smaller than the machine precision; FPMIN is a number near the smallest representable floating-point number; EULER is Euler's constant  $\gamma$ .

```

A good algorithm for evaluating Ei is to use the power series for small x and the asymptotic series for large x . The power series is

$$Ei(x) = \gamma + \ln x + \frac{x}{1 \cdot 1!} + \frac{x^2}{2 \cdot 2!} + \dots \quad (6.3.10)$$

where γ is Euler's constant. The asymptotic expansion is

$$Ei(x) \sim \frac{e^x}{x} \left(1 + \frac{1!}{x} + \frac{2!}{x^2} + \dots \right) \quad (6.3.11)$$

The lower limit for the use of the asymptotic expansion is approximately $|\ln \text{EPS}|$, where EPS is the required relative error.

```

FUNCTION ei(x)
INTEGER MAXIT
REAL ei,x,EPS,EULER,FPMIN
PARAMETER (EPS=6.e-8,EULER=.57721566,MAXIT=100,FPMIN=1.e-30)
Computes the exponential integral Ei(x) for x > 0.
Parameters: EPS is the relative error, or absolute error near the zero of Ei at x = 0.3725;
EULER is Euler's constant  $\gamma$ ; MAXIT is the maximum number of iterations allowed; FPMIN
is a number near the smallest representable floating-point number.
INTEGER k
REAL fact,prev,sum,term
if(x.le.0.) pause 'bad argument in ei'
if(x.lt.FPMIN)then
  ei=log(x)+EULER
  Special case: avoid failure of convergence test be-
  cause of underflow.
else if(x.le.-log(EPS))then
  sum=0.
  fact=1.
  do 11 k=1,MAXIT
    fact=fact*x/k
    term=fact/k
    sum=sum+term
    if(term.lt.EPS*sum)goto 1
  enddo 11
  pause 'series failed in ei'
  ei=sum+log(x)+EULER
1  else
  sum=0.
  term=1.
  do 12 k=1,MAXIT
    prev=term
    term=term*k/x
    if(term.lt.EPS)goto 2
    if(term.lt.prev)then
      sum=sum+term
    else
      sum=sum-prev
    endif
  enddo 12
  ei=exp(x)*(1.+sum)/x
endif

```

Use asymptotic series.
Start with second term.

Since final sum is greater than one, term itself approximates the relative error.
Still converging: add new term.

Diverging: subtract previous term and exit.

```

return
END

```

6.4 Incomplete Beta Function, Student's Distribution, F-Distribution, Cumulative Binomial Distribution

The incomplete beta function is defined by

$$I_x(a, b) \equiv \frac{B_x(a, b)}{B(a, b)} \equiv \frac{1}{B(a, b)} \int_0^x t^{a-1} (1-t)^{b-1} dt \quad (a, b > 0) \quad (6.4.1)$$

It has the limiting values

$$I_0(a, b) = 0 \quad I_1(a, b) = 1 \quad (6.4.2)$$

and the symmetry relation

$$I_x(a, b) = 1 - I_{1-x}(b, a) \quad (6.4.3)$$

If a and b are both rather greater than one, then $I_x(a, b)$ rises from “near-zero” to “near-unity” quite sharply at about $x = a/(a+b)$. Figure 6.4.1 plots the function for several pairs (a, b) .

The incomplete beta function has a series expansion

$$I_x(a, b) = \frac{x^a (1-x)^b}{a B(a, b)} \left[1 + \sum_{n=0}^{\infty} \frac{B(a+1, n+1)}{B(a+b, n+1)} x^{n+1} \right], \quad (6.4.4)$$

but this does not prove to be very useful in its numerical evaluation. (Note, however, that the beta functions in the coefficients can be evaluated for each value of n with just the previous value and a few multiplies, using equations 6.1.9 and 6.1.3.)

The continued fraction representation proves to be much more useful,

$$I_x(a, b) = \frac{x^a (1-x)^b}{a B(a, b)} \left[\frac{1}{1} \frac{d_1}{1} \frac{d_2}{1} \dots \right] \quad (6.4.5)$$

6.4 Incomplete Beta Function, Student's Distribution, F-Distribution, Cumulative Binomial Distribution

The incomplete beta function is defined by

$$I_x(a, b) \equiv \frac{B_x(a, b)}{B(a, b)} \equiv \frac{1}{B(a, b)} \int_0^x t^{a-1} (1-t)^{b-1} dt \quad (a, b > 0) \quad (6.4.1)$$

It has the limiting values

$$I_0(a, b) = 0 \quad I_1(a, b) = 1 \quad (6.4.2)$$

and the symmetry relation

$$I_x(a, b) = 1 - I_{1-x}(b, a) \quad (6.4.3)$$

If a and b are both rather greater than one, then $I_x(a, b)$ rises from “near-zero” to “near-unity” quite sharply at about $x = a/(a+b)$. Figure 6.4.1 plots the function for several pairs (a, b) .

The incomplete beta function has a series expansion

$$I_x(a, b) = \frac{x^a (1-x)^b}{a B(a, b)} \left[1 + \sum_{n=0}^{\infty} \frac{B(a+1, n+1)}{B(a+b, n+1)} x^{n+1} \right], \quad (6.4.4)$$

but this does not prove to be very useful in its numerical evaluation. (Note, however, that the beta functions in the coefficients can be evaluated for each value of n with just the previous value and a few multiplies, using equations 6.1.9 and 6.1.3.)

The continued fraction representation proves to be much more useful,

$$I_x(a, b) = \frac{x^a (1-x)^b}{a B(a, b)} \left[\frac{1}{1} \frac{d_1}{1} \frac{d_2}{1} \dots \right] \quad (6.4.5)$$

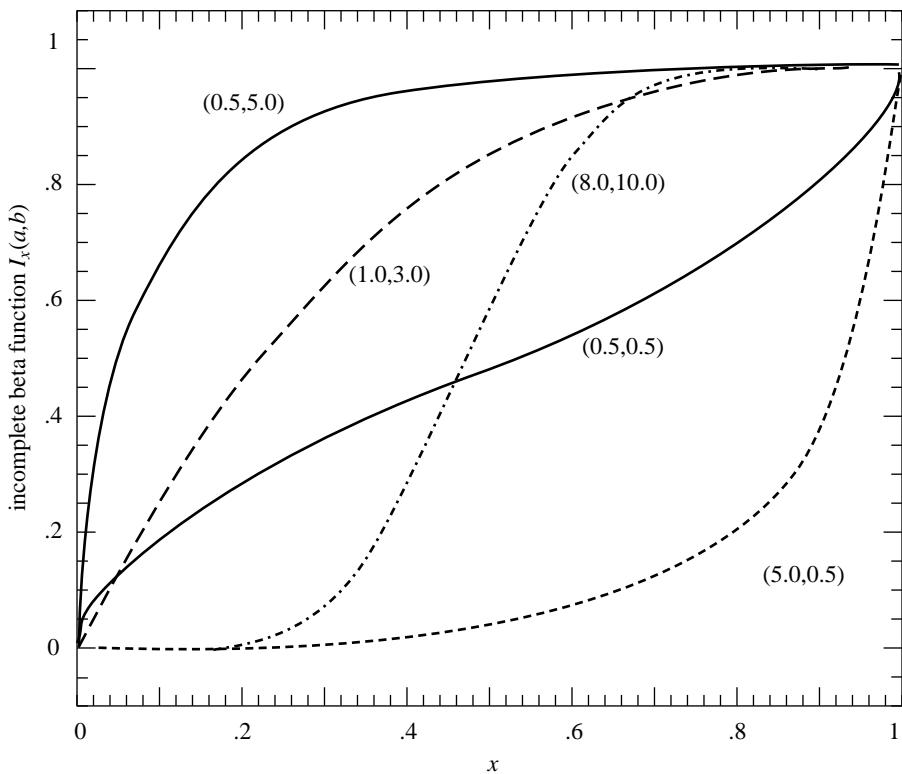

Figure 6.4.1. The incomplete beta function $I_x(a, b)$ for five different pairs of (a, b) . Notice that the pairs $(0.5, 5.0)$ and $(5.0, 0.5)$ are symmetrically related as indicated in equation (6.4.3).

where

$$\begin{aligned} d_{2m+1} &= -\frac{(a+m)(a+b+m)x}{(a+2m)(a+2m+1)} \\ d_{2m} &= \frac{m(b-m)x}{(a+2m-1)(a+2m)} \end{aligned} \quad (6.4.6)$$

This continued fraction converges rapidly for $x < (a+1)/(a+b+2)$, taking in the worst case $O(\sqrt{\max(a,b)})$ iterations. But for $x > (a+1)/(a+b+2)$ we can just use the symmetry relation (6.4.3) to obtain an equivalent computation where the continued fraction will also converge rapidly. Hence we have

```

return
END
```

These q's will be used in factors that occur in the coefficients (6.4.6).

First step of Lentz's method.

One step (the even one) of the recurrence.

Next step of the recurrence (the odd one).

Student's Distribution Probability Function

Student's distribution, denoted $A(t|\nu)$, is useful in several statistical contexts, notably in the test of whether two observed distributions have the same mean. $A(t|\nu)$ is the probability, for ν degrees of freedom, that a certain statistic t (measuring the observed difference of means) would be smaller than the observed value if the means were in fact the same. (See Chapter 14 for further details.) Two means are

significantly different if, e.g., $A(t|\nu) > 0.99$. In other words, $1 - A(t|\nu)$ is the significance level at which the hypothesis that the means are equal is disproved.

The mathematical definition of the function is

$$A(t|\nu) = \frac{1}{\nu^{1/2} B(\frac{1}{2}, \frac{\nu}{2})} \int_{-t}^t \left(1 + \frac{x^2}{\nu}\right)^{-\frac{\nu+1}{2}} dx \quad (6.4.7)$$

Limiting values are

$$A(0|\nu) = 0 \quad A(\infty|\nu) = 1 \quad (6.4.8)$$

$A(t|\nu)$ is related to the incomplete beta function $I_x(a, b)$ by

$$A(t|\nu) = 1 - I_{\frac{\nu}{\nu+t^2}} \left(\frac{\nu}{2}, \frac{1}{2} \right) \quad (6.4.9)$$

So, you can use (6.4.9) and the above routine `betai` to evaluate the function.

F-Distribution Probability Function

This function occurs in the statistical test of whether two observed samples have the same variance. A certain statistic F , essentially the ratio of the observed dispersion of the first sample to that of the second one, is calculated. (For further details, see Chapter 14.) The probability that F would be as *large* as it is if the first sample's underlying distribution actually has *smaller* variance than the second's is denoted $Q(F|\nu_1, \nu_2)$, where ν_1 and ν_2 are the number of degrees of freedom in the first and second samples, respectively. In other words, $Q(F|\nu_1, \nu_2)$ is the significance level at which the hypothesis "1 has smaller variance than 2" can be rejected. A small numerical value implies a very significant rejection, in turn implying high confidence in the hypothesis "1 has variance greater or equal to 2."

$Q(F|\nu_1, \nu_2)$ has the limiting values

$$Q(0|\nu_1, \nu_2) = 1 \quad Q(\infty|\nu_1, \nu_2) = 0 \quad (6.4.10)$$

Its relation to the incomplete beta function $I_x(a, b)$ as evaluated by `betai` above is

$$Q(F|\nu_1, \nu_2) = I_{\frac{\nu_2}{\nu_2+\nu_1 F}} \left(\frac{\nu_2}{2}, \frac{\nu_1}{2} \right) \quad (6.4.11)$$

Cumulative Binomial Probability Distribution

Suppose an event occurs with probability p per trial. Then the probability P of its occurring k or more times in n trials is termed a *cumulative binomial probability*, and is related to the incomplete beta function $I_x(a, b)$ as follows:

$$P \equiv \sum_{j=k}^n \binom{n}{j} p^j (1-p)^{n-j} = I_p(k, n-k+1) \quad (6.4.12)$$

For n larger than a dozen or so, `betai` is a much better way to evaluate the sum in (6.4.12) than would be the straightforward sum with concurrent computation of the binomial coefficients. (For n smaller than a dozen, either method is acceptable.)

6.5 Bessel Functions of Integer Order

This section and the next one present practical algorithms for computing various kinds of Bessel functions of integer order. In §6.7 we deal with fractional order. In fact, the more complicated routines for fractional order work fine for integer order too. For integer order, however, the routines in this section (and §6.6) are simpler and faster. Their only drawback is that they are limited by the precision of the underlying rational approximations. For full double precision, it is best to work with the routines for fractional order in §6.7.

For any real ν , the Bessel function $J_\nu(x)$ can be defined by the series representation

$$J_\nu(x) = \left(\frac{1}{2}x\right)^\nu \sum_{k=0}^{\infty} \frac{(-\frac{1}{4}x^2)^k}{k!\Gamma(\nu+k+1)} \quad (6.5.1)$$

The series converges for all x , but it is not computationally very useful for $x \gg 1$.

For ν not an integer the Bessel function $Y_\nu(x)$ is given by

$$Y_\nu(x) = \frac{J_\nu(x)\cos(\nu\pi) - J_{-\nu}(x)}{\sin(\nu\pi)} \quad (6.5.2)$$

The right-hand side goes to the correct limiting value $Y_n(x)$ as ν goes to some integer n , but this is also not computationally useful.

For arguments $x < \nu$, both Bessel functions look qualitatively like simple power laws, with the asymptotic forms for $0 < x \ll \nu$

$$\begin{aligned} J_\nu(x) &\sim \frac{1}{\Gamma(\nu+1)} \left(\frac{1}{2}x\right)^\nu & \nu \geq 0 \\ Y_0(x) &\sim \frac{2}{\pi} \ln(x) \\ Y_\nu(x) &\sim -\frac{\Gamma(\nu)}{\pi} \left(\frac{1}{2}x\right)^{-\nu} & \nu > 0 \end{aligned} \quad (6.5.3)$$

For n larger than a dozen or so, `betai` is a much better way to evaluate the sum in (6.4.12) than would be the straightforward sum with concurrent computation of the binomial coefficients. (For n smaller than a dozen, either method is acceptable.)

6.5 Bessel Functions of Integer Order

This section and the next one present practical algorithms for computing various kinds of Bessel functions of integer order. In §6.7 we deal with fractional order. In fact, the more complicated routines for fractional order work fine for integer order too. For integer order, however, the routines in this section (and §6.6) are simpler and faster. Their only drawback is that they are limited by the precision of the underlying rational approximations. For full double precision, it is best to work with the routines for fractional order in §6.7.

For any real ν , the Bessel function $J_\nu(x)$ can be defined by the series representation

$$J_\nu(x) = \left(\frac{1}{2}x\right)^\nu \sum_{k=0}^{\infty} \frac{(-\frac{1}{4}x^2)^k}{k!\Gamma(\nu+k+1)} \quad (6.5.1)$$

The series converges for all x , but it is not computationally very useful for $x \gg 1$.

For ν not an integer the Bessel function $Y_\nu(x)$ is given by

$$Y_\nu(x) = \frac{J_\nu(x)\cos(\nu\pi) - J_{-\nu}(x)}{\sin(\nu\pi)} \quad (6.5.2)$$

The right-hand side goes to the correct limiting value $Y_n(x)$ as ν goes to some integer n , but this is also not computationally useful.

For arguments $x < \nu$, both Bessel functions look qualitatively like simple power laws, with the asymptotic forms for $0 < x \ll \nu$

$$\begin{aligned} J_\nu(x) &\sim \frac{1}{\Gamma(\nu+1)} \left(\frac{1}{2}x\right)^\nu & \nu \geq 0 \\ Y_0(x) &\sim \frac{2}{\pi} \ln(x) \\ Y_\nu(x) &\sim -\frac{\Gamma(\nu)}{\pi} \left(\frac{1}{2}x\right)^{-\nu} & \nu > 0 \end{aligned} \quad (6.5.3)$$

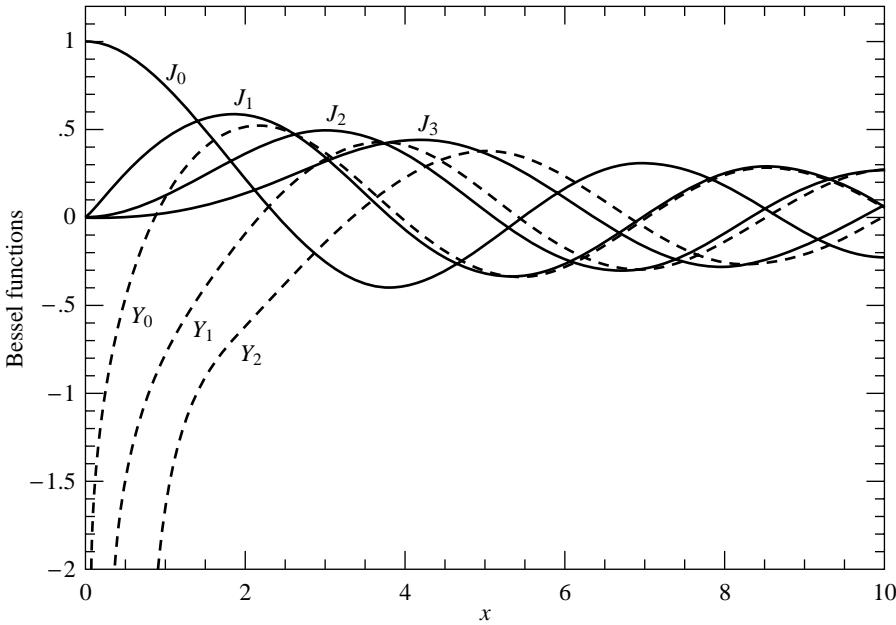

Figure 6.5.1. Bessel functions $J_0(x)$ through $J_3(x)$ and $Y_0(x)$ through $Y_2(x)$.

For $x > \nu$, both Bessel functions look qualitatively like sine or cosine waves whose amplitude decays as $x^{-1/2}$. The asymptotic forms for $x \gg \nu$ are

$$\begin{aligned} J_\nu(x) &\sim \sqrt{\frac{2}{\pi x}} \cos\left(x - \frac{1}{2}\nu\pi - \frac{1}{4}\pi\right) \\ Y_\nu(x) &\sim \sqrt{\frac{2}{\pi x}} \sin\left(x - \frac{1}{2}\nu\pi - \frac{1}{4}\pi\right) \end{aligned} \quad (6.5.4)$$

In the transition region where $x \sim \nu$, the typical amplitudes of the Bessel functions are on the order

$$\begin{aligned} J_\nu(\nu) &\sim \frac{2^{1/3}}{3^{2/3}\Gamma(\frac{2}{3})} \frac{1}{\nu^{1/3}} \sim \frac{0.4473}{\nu^{1/3}} \\ Y_\nu(\nu) &\sim -\frac{2^{1/3}}{3^{1/6}\Gamma(\frac{2}{3})} \frac{1}{\nu^{1/3}} \sim -\frac{0.7748}{\nu^{1/3}} \end{aligned} \quad (6.5.5)$$

which holds asymptotically for large ν . Figure 6.5.1 plots the first few Bessel functions of each kind.

The Bessel functions satisfy the recurrence relations

$$J_{n+1}(x) = \frac{2n}{x} J_n(x) - J_{n-1}(x) \quad (6.5.6)$$

and

$$Y_{n+1}(x) = \frac{2n}{x} Y_n(x) - Y_{n-1}(x) \quad (6.5.7)$$

As already mentioned in §5.5, only the second of these (6.5.7) is stable in the direction of increasing n for $x < n$. The reason that (6.5.6) is unstable in the

direction of increasing n is simply that it is *the same recurrence* as (6.5.7): A small amount of “polluting” Y_n introduced by roundoff error will quickly come to swamp the desired J_n , according to equation (6.5.3).

A practical strategy for computing the Bessel functions of integer order divides into two tasks: first, how to compute J_0 , J_1 , Y_0 , and Y_1 , and second, how to use the recurrence relations stably to find other J 's and Y 's. We treat the first task first:

For x between zero and some arbitrary value (we will use the value 8), approximate $J_0(x)$ and $J_1(x)$ by rational functions in x . Likewise approximate by rational functions the “regular part” of $Y_0(x)$ and $Y_1(x)$, defined as

$$Y_0(x) - \frac{2}{\pi} J_0(x) \ln(x) \quad \text{and} \quad Y_1(x) - \frac{2}{\pi} \left[J_1(x) \ln(x) - \frac{1}{x} \right] \quad (6.5.8)$$

For $8 < x < \infty$, use the approximating forms ($n = 0, 1$)

$$J_n(x) = \sqrt{\frac{2}{\pi x}} \left[P_n\left(\frac{8}{x}\right) \cos(X_n) - Q_n\left(\frac{8}{x}\right) \sin(X_n) \right] \quad (6.5.9)$$

$$Y_n(x) = \sqrt{\frac{2}{\pi x}} \left[P_n\left(\frac{8}{x}\right) \sin(X_n) + Q_n\left(\frac{8}{x}\right) \cos(X_n) \right] \quad (6.5.10)$$

where

$$X_n \equiv x - \frac{2n+1}{4}\pi \quad (6.5.11)$$

and where P_0, P_1, Q_0 , and Q_1 are each polynomials in their arguments, for $0 < 8/x < 1$. The P 's are even polynomials, the Q 's odd.

Coefficients of the various rational functions and polynomials are given by Hart [1], for various levels of desired accuracy. A straightforward implementation is

endif
return
END

```

We now turn to the second task, namely how to use the recurrence formulas (6.5.6) and (6.5.7) to get the Bessel functions $J_n(x)$ and $Y_n(x)$ for $n \geq 2$. The latter of these is straightforward, since its upward recurrence is always stable:

```

FUNCTION bessy(n,x)
INTEGER n
REAL bessy,x
C USES bessy0,bessy1
    Returns the Bessel function  $Y_n(x)$  for positive  $x$  and  $n \geq 2$ .
INTEGER j
REAL by,bym,byp,tox,bessy0,bessy1
if(n.lt.2)pause 'bad argument n in bessy'
tox=2./x
by=bessy1(x)                                Starting values for the recurrence.
bym=bessy0(x)
do ii j=1,n-1                                Recurrence (6.5.7).
    byp=j*tcox*by-bym
    bym=by
    by=byp
enddo ii
bessy=by
return
END

```

The cost of this algorithm is the call to `bessy1` and `bessy0` (which generate a call to each of `bessj1` and `bessj0`), plus $O(n)$ operations in the recurrence.

As for $J_n(x)$, things are a bit more complicated. We can start the recurrence upward on n from J_0 and J_1 , but it will remain stable only while n does not exceed x . This is, however, just fine for calls with large x and small n , a case which occurs frequently in practice.

The harder case to provide for is that with $x < n$. The best thing to do here is to use Miller's algorithm (see discussion preceding equation 5.5.16), applying the recurrence *downward* from some arbitrary starting value and making use of the upward-unstable nature of the recurrence to put us *onto* the correct solution. When we finally arrive at J_0 or J_1 we are able to normalize the solution with the sum (5.5.16) accumulated along the way.

The only subtlety is in deciding at how large an n we need start the downward recurrence so as to obtain a desired accuracy by the time we reach the n that we really want. If you play with the asymptotic forms (6.5.3) and (6.5.5), you should be able to convince yourself that the answer is to start larger than the desired n by an additive amount of order $[\text{constant} \times n]^{1/2}$, where the square root of the constant is, very roughly, the number of significant figures of accuracy.

The above considerations lead to the following function.

```

FUNCTION bessj(n,x)
INTEGER n,IACC
REAL bessj,x,BIGN0,BIGN1
PARAMETER (IACC=40,BIGN0=1.e10,BIGN1=1.e-10)
C USES bessj0,bessj1
      Returns the Bessel function  $J_n(x)$  for any real  $x$  and  $n \geq 2$ .

6.6 Modified Bessel Functions of Integer Order

The modified Bessel functions $I_n(x)$ and $K_n(x)$ are equivalent to the usual Bessel functions J_n and Y_n evaluated for purely imaginary arguments. In detail, the relationship is

$$\begin{aligned} I_n(x) &= (-i)^n J_n(ix) \\ K_n(x) &= \frac{\pi}{2} i^{n+1} [J_n(ix) + i Y_n(ix)] \end{aligned} \quad (6.6.1)$$

The particular choice of prefactor and of the linear combination of J_n and Y_n to form K_n are simply choices that make the functions real-valued for real arguments x .

For small arguments $x \ll n$, both $I_n(x)$ and $K_n(x)$ become, asymptotically, simple powers of their argument

$$I_n(x) \approx \frac{1}{n!} \left(\frac{x}{2}\right)^n \quad n \geq 0$$

$$\begin{aligned} K_0(x) &\approx -\ln(x) \\ K_n(x) &\approx \frac{(n-1)!}{2} \left(\frac{x}{2}\right)^{-n} \quad n > 0 \end{aligned} \quad (6.6.2)$$

These expressions are virtually identical to those for $J_n(x)$ and $Y_n(x)$ in this region, except for the factor of $-2/\pi$ difference between $Y_n(x)$ and $K_n(x)$. In the region

6.6 Modified Bessel Functions of Integer Order

The modified Bessel functions $I_n(x)$ and $K_n(x)$ are equivalent to the usual Bessel functions J_n and Y_n evaluated for purely imaginary arguments. In detail, the relationship is

$$\begin{aligned} I_n(x) &= (-i)^n J_n(ix) \\ K_n(x) &= \frac{\pi}{2} i^{n+1} [J_n(ix) + i Y_n(ix)] \end{aligned} \quad (6.6.1)$$

The particular choice of prefactor and of the linear combination of J_n and Y_n to form K_n are simply choices that make the functions real-valued for real arguments x .

For small arguments $x \ll n$, both $I_n(x)$ and $K_n(x)$ become, asymptotically, simple powers of their argument

$$I_n(x) \approx \frac{1}{n!} \left(\frac{x}{2}\right)^n \quad n \geq 0$$

$$\begin{aligned} K_0(x) &\approx -\ln(x) \\ K_n(x) &\approx \frac{(n-1)!}{2} \left(\frac{x}{2}\right)^{-n} \quad n > 0 \end{aligned} \quad (6.6.2)$$

These expressions are virtually identical to those for $J_n(x)$ and $Y_n(x)$ in this region, except for the factor of $-2/\pi$ difference between $Y_n(x)$ and $K_n(x)$. In the region

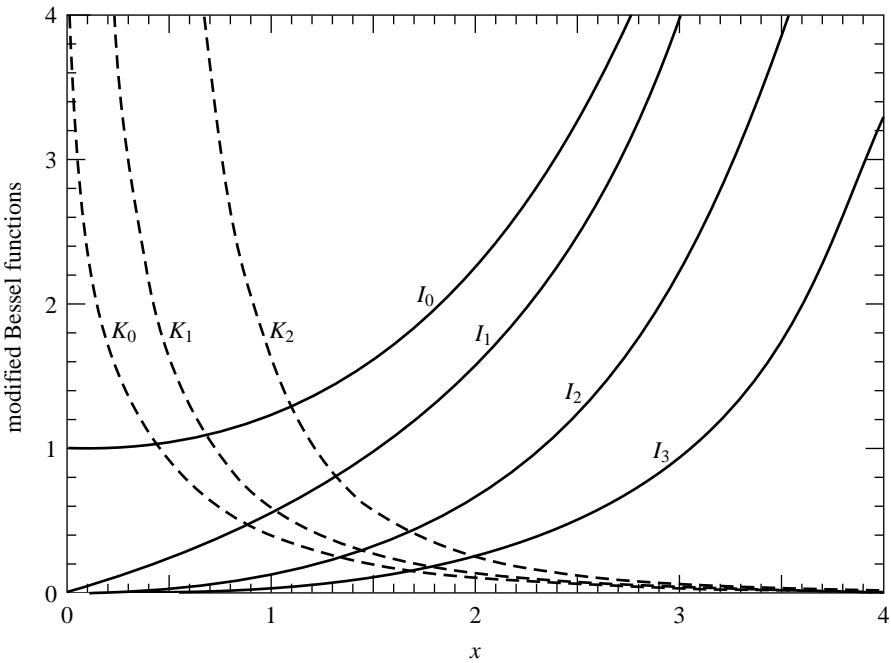

Figure 6.6.1. Modified Bessel functions $I_0(x)$ through $I_3(x)$, $K_0(x)$ through $K_2(x)$.

$x \gg n$, however, the modified functions have quite different behavior than the Bessel functions,

$$\begin{aligned} I_n(x) &\approx \frac{1}{\sqrt{2\pi x}} \exp(x) \\ K_n(x) &\approx \frac{\pi}{\sqrt{2\pi x}} \exp(-x) \end{aligned} \quad (6.6.3)$$

The modified functions evidently have exponential rather than sinusoidal behavior for large arguments (see Figure 6.6.1). The smoothness of the modified Bessel functions, once the exponential factor is removed, makes a simple polynomial approximation of a few terms quite suitable for the functions I_0 , I_1 , K_0 , and K_1 . The following routines, based on polynomial coefficients given by Abramowitz and Stegun [1], evaluate these four functions, and will provide the basis for upward recursion for $n > 1$ when $x > n$.

```

The recurrence relation for $I_n(x)$ and $K_n(x)$ is the same as that for $J_n(x)$ and $Y_n(x)$ provided that ix is substituted for x . This has the effect of changing a sign in the relation,

$$\begin{aligned} I_{n+1}(x) &= -\left(\frac{2n}{x}\right) I_n(x) + I_{n-1}(x) \\ K_{n+1}(x) &= +\left(\frac{2n}{x}\right) K_n(x) + K_{n-1}(x) \end{aligned} \quad (6.6.4)$$

These relations are always *unstable* for upward recurrence. For K_n , itself growing, this presents no problem. For I_n , however, the strategy of downward recursion is therefore required once again, and the starting point for the recursion may be chosen in the same manner as for the routine `bessj`. The only fundamental difference is that the normalization formula for $I_n(x)$ has an alternating minus sign in successive terms, which again arises from the substitution of ix for x in the formula used previously for J_n

$$1 = I_0(x) - 2I_2(x) + 2I_4(x) - 2I_6(x) + \dots \quad (6.6.5)$$

In fact, we prefer simply to normalize with a call to `bessi0`.

With this simple modification, the recursion routines `bessj` and `bessy` become the new routines `bessi` and `bessk`:

```

FUNCTION bessk(n,x)
INTEGER n

6.7 Bessel Functions of Fractional Order, Airy Functions, Spherical Bessel Functions

Many algorithms have been proposed for computing Bessel functions of fractional order numerically. Most of them are, in fact, not very good in practice. The routines given here are rather complicated, but they can be recommended wholeheartedly.

Ordinary Bessel Functions

The basic idea is *Steed's method*, which was originally developed [1] for Coulomb wave functions. The method calculates J_ν , J'_ν , Y_ν , and Y'_ν simultaneously, and so involves four relations among these functions. Three of the relations come from two continued fractions, one of which is complex. The fourth is provided by the Wronskian relation

$$W \equiv J_\nu Y'_\nu - Y_\nu J'_\nu = \frac{2}{\pi x} \quad (6.7.1)$$

The first continued fraction, CF1, is defined by

$$\begin{aligned} f_\nu &\equiv \frac{J'_\nu}{J_\nu} = \frac{\nu}{x} - \frac{J_{\nu+1}}{J_\nu} \\ &= \frac{\nu}{x} - \frac{1}{2(\nu+1)/x -} \frac{1}{2(\nu+2)/x -} \dots \end{aligned} \quad (6.7.2)$$

You can easily derive it from the three-term recurrence relation for Bessel functions: Start with equation (6.5.6) and use equation (5.5.18). Forward evaluation of the continued fraction by one of the methods of §5.2 is essentially equivalent to backward recurrence of the recurrence relation. The rate of convergence of CF1 is determined by the position of the *turning point* $x_{tp} = \sqrt{\nu(\nu+1)} \approx \nu$, beyond which the Bessel functions become oscillatory. If $x \lesssim x_{tp}$, convergence is very rapid. If $x \gtrsim x_{tp}$, then each iteration of the continued fraction effectively increases ν by one until $x \lesssim x_{tp}$; thereafter rapid convergence sets in. Thus the number of iterations of CF1 is of order x for large x . In the routine `bessjy` we set the maximum allowed number of iterations to 10,000. For larger x , you can use the usual asymptotic expressions for Bessel functions.

One can show that the sign of J_ν is the same as the sign of the denominator of CF1 once it has converged.

The complex continued fraction CF2 is defined by

$$p + iq \equiv \frac{J'_\nu + iY'_\nu}{J_\nu + iY_\nu} = -\frac{1}{2x} + i + \frac{i}{x} \frac{(1/2)^2 - \nu^2}{2(x+i) +} \frac{(3/2)^2 - \nu^2}{2(x+2i) +} \dots \quad (6.7.3)$$

(We sketch the derivation of CF2 in the analogous case of modified Bessel functions in the next subsection.) This continued fraction converges rapidly for $x \gtrsim x_{tp}$, while convergence fails as $x \rightarrow 0$. We have to adopt a special method for small x , which we describe below. For x not too small, we can ensure that $x \gtrsim x_{tp}$ by a stable recurrence of J_ν and J'_ν downwards to a value $\nu = \mu \lesssim x$, thus yielding the ratio f_μ at this lower value of ν . This is the stable direction for the recurrence relation. The initial values for the recurrence are

$$J_\nu = \text{arbitrary}, \quad J'_\nu = f_\nu J_\nu, \quad (6.7.4)$$

with the sign of the arbitrary initial value of J_ν chosen to be the sign of the denominator of CF1. Choosing the initial value of J_ν very small minimizes the possibility of overflow during the recurrence. The recurrence relations are

$$\begin{aligned} J_{\nu-1} &= \frac{\nu}{x} J_\nu + J'_\nu \\ J'_{\nu-1} &= \frac{\nu-1}{x} J_{\nu-1} - J_\nu \end{aligned} \quad (6.7.5)$$

Once CF2 has been evaluated at $\nu = \mu$, then with the Wronskian (6.7.1) we have enough relations to solve for all four quantities. The formulas are simplified by introducing the quantity

$$\gamma \equiv \frac{p - f_\mu}{q} \quad (6.7.6)$$

Then

$$J_\mu = \pm \left(\frac{W}{q + \gamma(p - f_\mu)} \right)^{1/2} \quad (6.7.7)$$

$$J'_\mu = f_\mu J_\mu \quad (6.7.8)$$

$$Y_\mu = \gamma J_\mu \quad (6.7.9)$$

$$Y'_\mu = Y_\mu \left(p + \frac{q}{\gamma} \right) \quad (6.7.10)$$

The sign of J_μ in (6.7.7) is chosen to be the same as the sign of the initial J_ν in (6.7.4).

Once all four functions have been determined at the value $\nu = \mu$, we can find them at the original value of ν . For J_ν and J'_ν , simply scale the values in (6.7.4) by the ratio of (6.7.7) to the value found after applying the recurrence (6.7.5). The quantities Y_ν and Y'_ν can be found by starting with the values in (6.7.9) and (6.7.10) and using the stable upwards recurrence

$$Y_{\nu+1} = \frac{2\nu}{x} Y_\nu - Y_{\nu-1} \quad (6.7.11)$$

together with the relation

$$Y'_\nu = \frac{\nu}{x} Y_\nu - Y_{\nu+1} \quad (6.7.12)$$

Now turn to the case of small x , when CF2 is not suitable. Temme [2] has given a good method of evaluating Y_ν and $Y_{\nu+1}$, and hence Y'_ν from (6.7.12), by series expansions that accurately handle the singularity as $x \rightarrow 0$. The expansions work only for $|\nu| \leq 1/2$, and so now the recurrence (6.7.5) is used to evaluate f_ν at a value $\nu = \mu$ in this interval. Then one calculates J_μ from

$$J_\mu = \frac{W}{Y'_\mu - Y_\mu f_\mu} \quad (6.7.13)$$

and J'_μ from (6.7.8). The values at the original value of ν are determined by scaling as before, and the Y 's are recurred up as before.

Temme's series are

$$Y_\nu = - \sum_{k=0}^{\infty} c_k g_k \quad Y_{\nu+1} = - \frac{2}{x} \sum_{k=0}^{\infty} c_k h_k \quad (6.7.14)$$

Here

$$c_k = \frac{(-x^2/4)^k}{k!} \quad (6.7.15)$$

while the coefficients g_k and h_k are defined in terms of quantities p_k , q_k , and f_k that can be found by recursion:

$$\begin{aligned} g_k &= f_k + \frac{2}{\nu} \sin^2 \left(\frac{\nu\pi}{2} \right) q_k \\ h_k &= -kg_k + p_k \\ p_k &= \frac{p_{k-1}}{k - \nu} \\ q_k &= \frac{q_{k-1}}{k + \nu} \\ f_k &= \frac{k f_{k-1} + p_{k-1} + q_{k-1}}{k^2 - \nu^2} \end{aligned} \quad (6.7.16)$$

The initial values for the recurrences are

$$\begin{aligned} p_0 &= \frac{1}{\pi} \left(\frac{x}{2} \right)^{-\nu} \Gamma(1 + \nu) \\ q_0 &= \frac{1}{\pi} \left(\frac{x}{2} \right)^\nu \Gamma(1 - \nu) \\ f_0 &= \frac{2}{\pi} \frac{\nu\pi}{\sin \nu\pi} \left[\cosh \sigma \Gamma_1(\nu) + \frac{\sinh \sigma}{\sigma} \ln \left(\frac{2}{x} \right) \Gamma_2(\nu) \right] \end{aligned} \quad (6.7.17)$$

with

$$\begin{aligned} \sigma &= \nu \ln \left(\frac{2}{x} \right) \\ \Gamma_1(\nu) &= \frac{1}{2\nu} \left[\frac{1}{\Gamma(1 - \nu)} - \frac{1}{\Gamma(1 + \nu)} \right] \\ \Gamma_2(\nu) &= \frac{1}{2} \left[\frac{1}{\Gamma(1 - \nu)} + \frac{1}{\Gamma(1 + \nu)} \right] \end{aligned} \quad (6.7.18)$$

The whole point of writing the formulas in this way is that the potential problems as $\nu \rightarrow 0$ can be controlled by evaluating $\nu\pi/\sin \nu\pi$, $\sinh \sigma/\sigma$, and Γ_1 carefully. In particular, Temme gives Chebyshev expansions for $\Gamma_1(\nu)$ and $\Gamma_2(\nu)$. We have rearranged his expansion for Γ_1 to be explicitly an even series in ν so that we can use our routine `chebvv` as explained in §5.8.

The routine assumes $\nu \geq 0$. For negative ν you can use the reflection formulas

$$\begin{aligned} J_{-\nu} &= \cos \nu\pi J_\nu - \sin \nu\pi Y_\nu \\ Y_{-\nu} &= \sin \nu\pi J_\nu + \cos \nu\pi Y_\nu \end{aligned} \quad (6.7.19)$$

The routine also assumes $x > 0$. For $x < 0$ the functions are in general complex, but expressible in terms of functions with $x > 0$. For $x = 0$, Y_ν is singular.

Internal arithmetic in the routine is carried out in double precision. To maintain portability, complex arithmetic has been recoded with real variables.

Modified Bessel Functions

Steed's method does not work for modified Bessel functions because in this case CF2 is purely imaginary and we have only three relations among the four functions. Temme[3] has given a normalization condition that provides the fourth relation.

The Wronskian relation is

$$W \equiv I_\nu K'_\nu - K_\nu I'_\nu = -\frac{1}{x} \quad (6.7.20)$$

The continued fraction CF1 becomes

$$f_\nu \equiv \frac{I'_\nu}{I_\nu} = \frac{\nu}{x} + \frac{1}{2(\nu+1)/x +} \frac{1}{2(\nu+2)/x +} \dots \quad (6.7.21)$$

To get CF2 and the normalization condition in a convenient form, consider the sequence of confluent hypergeometric functions

$$z_n(x) = U(\nu + 1/2 + n, 2\nu + 1, 2x) \quad (6.7.22)$$

for fixed ν . Then

$$K_\nu(x) = \pi^{1/2} (2x)^\nu e^{-x} z_0(x) \quad (6.7.23)$$

$$\frac{K_{\nu+1}(x)}{K_\nu(x)} = \frac{1}{x} \left[\nu + \frac{1}{2} + x + \left(\nu^2 - \frac{1}{4} \right) \frac{z_1}{z_0} \right] \quad (6.7.24)$$

Equation (6.7.23) is the standard expression for K_ν in terms of a confluent hypergeometric function, while equation (6.7.24) follows from relations between contiguous confluent hypergeometric functions (equations 13.4.16 and 13.4.18 in Abramowitz and Stegun). Now the functions z_n satisfy the three-term recurrence relation (equation 13.4.15 in Abramowitz and Stegun)

$$z_{n-1}(x) = b_n z_n(x) + a_{n+1} z_{n+1} \quad (6.7.25)$$

with

$$b_n = 2(n+x) \quad (6.7.26)$$

$$a_{n+1} = -[(n+1/2)^2 - \nu^2]$$

Following the steps leading to equation (5.5.18), we get the continued fraction CF2

$$\frac{z_1}{z_0} = \frac{1}{b_1 + \frac{a_2}{b_2 + \dots}} \quad (6.7.27)$$

from which (6.7.24) gives $K_{\nu+1}/K_\nu$ and thus K'_ν/K_ν .

Temme's normalization condition is that

$$\sum_{n=0}^{\infty} C_n z_n = \left(\frac{1}{2x}\right)^{\nu+1/2} \quad (6.7.28)$$

where

$$C_n = \frac{(-1)^n}{n!} \frac{\Gamma(\nu + 1/2 + n)}{\Gamma(\nu + 1/2 - n)} \quad (6.7.29)$$

Note that the C_n 's can be determined by recursion:

$$C_0 = 1, \quad C_{n+1} = -\frac{a_{n+1}}{n+1} C_n \quad (6.7.30)$$

We use the condition (6.7.28) by finding

$$S = \sum_{n=1}^{\infty} C_n \frac{z_n}{z_0} \quad (6.7.31)$$

Then

$$z_0 = \left(\frac{1}{2x}\right)^{\nu+1/2} \frac{1}{1+S} \quad (6.7.32)$$

and (6.7.23) gives K_ν .

Thompson and Barnett [4] have given a clever method of doing the sum (6.7.31) simultaneously with the forward evaluation of the continued fraction CF2. Suppose the continued fraction is being evaluated as

$$\frac{z_1}{z_0} = \sum_{n=0}^{\infty} \Delta h_n \quad (6.7.33)$$

where the increments Δh_n are being found by, e.g., Steed's algorithm or the modified Lentz's algorithm of §5.2. Then the approximation to S keeping the first N terms can be found as

$$S_N = \sum_{n=1}^N Q_n \Delta h_n \quad (6.7.34)$$

Here

$$Q_n = \sum_{k=1}^n C_k q_k \quad (6.7.35)$$

and q_k is found by recursion from

$$q_{k+1} = (q_{k-1} - b_k q_k)/a_{k+1} \quad (6.7.36)$$

starting with $q_0 = 0$, $q_1 = 1$. For the case at hand, approximately three times as many terms are needed to get S to converge as are needed simply for CF2 to converge.

To find K_ν and $K_{\nu+1}$ for small x we use series analogous to (6.7.14):

$$K_\nu = \sum_{k=0}^{\infty} c_k f_k \quad K_{\nu+1} = \frac{2}{x} \sum_{k=0}^{\infty} c_k h_k \quad (6.7.37)$$

Here

$$\begin{aligned} c_k &= \frac{(x^2/4)^k}{k!} \\ h_k &= -kf_k + p_k \\ p_k &= \frac{p_{k-1}}{k-\nu} \\ q_k &= \frac{q_{k-1}}{k+\nu} \\ f_k &= \frac{kf_{k-1} + p_{k-1} + q_{k-1}}{k^2 - \nu^2} \end{aligned} \quad (6.7.38)$$

The initial values for the recurrences are

$$\begin{aligned} p_0 &= \frac{1}{2} \left(\frac{x}{2} \right)^{-\nu} \Gamma(1+\nu) \\ q_0 &= \frac{1}{2} \left(\frac{x}{2} \right)^\nu \Gamma(1-\nu) \\ f_0 &= \frac{\nu\pi}{\sin\nu\pi} \left[\cosh\sigma\Gamma_1(\nu) + \frac{\sinh\sigma}{\sigma} \ln\left(\frac{2}{x}\right) \Gamma_2(\nu) \right] \end{aligned} \quad (6.7.39)$$

Both the series for small x , and CF2 and the normalization relation (6.7.28) require $|\nu| \leq 1/2$. In both cases, therefore, we recurse I_ν down to a value $\nu = \mu$ in this interval, find K_μ there, and recurse K_ν back up to the original value of ν .

The routine assumes $\nu \geq 0$. For negative ν use the reflection formulas

$$\begin{aligned} I_{-\nu} &= I_\nu + \frac{2}{\pi} \sin(\nu\pi) K_\nu \\ K_{-\nu} &= K_\nu \end{aligned} \quad (6.7.40)$$

Note that for large x , $I_\nu \sim e^x$, $K_\nu \sim e^{-x}$, and so these functions will overflow or underflow. It is often desirable to be able to compute the scaled quantities $e^{-x} I_\nu$ and $e^x K_\nu$. Simply omitting the factor e^{-x} in equation (6.7.23) will ensure that all four quantities will have the appropriate scaling. If you also want to scale the four quantities for small x when the series in equation (6.7.37) are used, you must multiply each series by e^x .

Evaluate CF2 by Steed's algorithm (§5.2),
which is OK because there can be no
zero denominators.

Initializations for recurrence (6.7.35).

First term in equation (6.7.34).

Need only test convergence of sum since
CF2 itself converges more quickly.

Omit the factor $\exp(-x)$ to scale all the
returned functions by $\exp(x)$ for $x \geq XMIN$.

Get I_μ from Wronskian.
Scale original I_ν and I'_ν .

Upward recurrence of K_ν .

Airy Functions

For positive x , the Airy functions are defined by

$$\text{Ai}(x) = \frac{1}{\pi} \sqrt{\frac{x}{3}} K_{1/3}(z) \quad (6.7.41)$$

$$\text{Bi}(x) = \sqrt{\frac{x}{3}}[I_{1/3}(z) + I_{-1/3}(z)] \quad (6.7.42)$$

where

$$z = \frac{2}{3}x^{3/2} \quad (6.7.43)$$

By using the reflection formula (6.7.40), we can convert (6.7.42) into the computationally more useful form

$$\text{Bi}(x) = \sqrt{x} \left[\frac{2}{\sqrt{3}}I_{1/3}(z) + \frac{1}{\pi}K_{1/3}(z) \right] \quad (6.7.44)$$

so that Ai and Bi can be evaluated with a single call to `bessik`.

The derivatives should not be evaluated by simply differentiating the above expressions because of possible subtraction errors near $x = 0$. Instead, use the equivalent expressions

$$\begin{aligned} \text{Ai}'(x) &= -\frac{x}{\pi\sqrt{3}}K_{2/3}(z) \\ \text{Bi}'(x) &= x \left[\frac{2}{\sqrt{3}}I_{2/3}(z) + \frac{1}{\pi}K_{2/3}(z) \right] \end{aligned} \quad (6.7.45)$$

The corresponding formulas for negative arguments are

$$\begin{aligned} \text{Ai}(-x) &= \frac{\sqrt{x}}{2} \left[J_{1/3}(z) - \frac{1}{\sqrt{3}}Y_{1/3}(z) \right] \\ \text{Bi}(-x) &= -\frac{\sqrt{x}}{2} \left[\frac{1}{\sqrt{3}}J_{1/3}(z) + Y_{1/3}(z) \right] \\ \text{Ai}'(-x) &= \frac{x}{2} \left[J_{2/3}(z) + \frac{1}{\sqrt{3}}Y_{2/3}(z) \right] \\ \text{Bi}'(-x) &= \frac{x}{2} \left[\frac{1}{\sqrt{3}}J_{2/3}(z) - Y_{2/3}(z) \right] \end{aligned} \quad (6.7.46)$$

```

Spherical Bessel Functions

For integer n , spherical Bessel functions are defined by

$$\begin{aligned} j_n(x) &= \sqrt{\frac{\pi}{2x}} J_{n+(1/2)}(x) \\ y_n(x) &= \sqrt{\frac{\pi}{2x}} Y_{n+(1/2)}(x) \end{aligned} \quad (6.7.47)$$

They can be evaluated by a call to `bessjy`, and the derivatives can safely be found from the derivatives of equation (6.7.47).

Note that in the continued fraction CF2 in (6.7.3) just the first term survives for $\nu = 1/2$. Thus one can make a very simple algorithm for spherical Bessel functions along the lines of `bessjy` by always recursing j_n down to $n = 0$, setting p and q from the first term in CF2, and then recursing y_n up. No special series is required near $x = 0$. However, `bessjy` is already so efficient that we have not bothered to provide an independent routine for spherical Bessels.

6.8 Spherical Harmonics

Spherical harmonics occur in a large variety of physical problems, for example, whenever a wave equation, or Laplace's equation, is solved by separation of variables in spherical coordinates. The spherical harmonic $Y_{lm}(\theta, \phi)$, $-l \leq m \leq l$, is a function of the two coordinates θ, ϕ on the surface of a sphere.

The spherical harmonics are orthogonal for different l and m , and they are normalized so that their integrated square over the sphere is unity:

$$\int_0^{2\pi} d\phi \int_{-1}^1 d(\cos \theta) Y_{l'm'}^*(\theta, \phi) Y_{lm}(\theta, \phi) = \delta_{l'l} \delta_{m'm} \quad (6.8.1)$$

Here asterisk denotes complex conjugation.

Mathematically, the spherical harmonics are related to *associated Legendre polynomials* by the equation

$$Y_{lm}(\theta, \phi) = \sqrt{\frac{2l+1}{4\pi} \frac{(l-m)!}{(l+m)!}} P_l^m(\cos \theta) e^{im\phi} \quad (6.8.2)$$

By using the relation

$$Y_{l,-m}(\theta, \phi) = (-1)^m Y_{lm}^*(\theta, \phi) \quad (6.8.3)$$

we can always relate a spherical harmonic to an associated Legendre polynomial with $m \geq 0$. With $x \equiv \cos \theta$, these are defined in terms of the ordinary Legendre polynomials (cf. §4.5 and §5.5) by

$$P_l^m(x) = (-1)^m (1-x^2)^{m/2} \frac{d^m}{dx^m} P_l(x) \quad (6.8.4)$$

The first few associated Legendre polynomials, and their corresponding normalized spherical harmonics, are

$P_0^0(x) = 1$	$Y_{00} = \sqrt{\frac{1}{4\pi}}$
$P_1^1(x) = -(1-x^2)^{1/2}$	$Y_{11} = -\sqrt{\frac{3}{8\pi}} \sin \theta e^{i\phi}$
$P_1^0(x) = x$	$Y_{10} = \sqrt{\frac{3}{4\pi}} \cos \theta$
$P_2^2(x) = 3(1-x^2)$	$Y_{22} = \frac{1}{4} \sqrt{\frac{15}{2\pi}} \sin^2 \theta e^{2i\phi}$
$P_2^1(x) = -3(1-x^2)^{1/2}x$	$Y_{21} = -\sqrt{\frac{15}{8\pi}} \sin \theta \cos \theta e^{i\phi}$
$P_2^0(x) = \frac{1}{2}(3x^2 - 1)$	$Y_{20} = \sqrt{\frac{5}{4\pi}} (\frac{3}{2} \cos^2 \theta - \frac{1}{2})$

(6.8.5)

There are many bad ways to evaluate associated Legendre polynomials numerically. For example, there are explicit expressions, such as

$$\begin{aligned} P_l^m(x) &= \frac{(-1)^m (l+m)!}{2^m m! (l-m)!} (1-x^2)^{m/2} \left[1 - \frac{(l-m)(m+l+1)}{1!(m+1)} \left(\frac{1-x}{2} \right) \right. \\ &\quad \left. + \frac{(l-m)(l-m-1)(m+l+1)(m+l+2)}{2!(m+1)(m+2)} \left(\frac{1-x}{2} \right)^2 - \dots \right] \end{aligned} \quad (6.8.6)$$

where the polynomial continues up through the term in $(1 - x)^{l-m}$. (See [1] for this and related formulas.) This is not a satisfactory method because evaluation of the polynomial involves delicate cancellations between successive terms, which alternate in sign. For large l , the individual terms in the polynomial become very much larger than their sum, and all accuracy is lost.

In practice, (6.8.6) can be used only in single precision (32-bit) for l up to 6 or 8, and in double precision (64-bit) for l up to 15 or 18, depending on the precision required for the answer. A more robust computational procedure is therefore desirable, as follows:

The associated Legendre functions satisfy numerous recurrence relations, tabulated in [1-2]. These are recurrences on l alone, on m alone, and on both l and m simultaneously. Most of the recurrences involving m are unstable, and so dangerous for numerical work. The following recurrence on l is, however, stable (compare 5.5.1):

$$(l - m)P_l^m = x(2l - 1)P_{l-1}^m - (l + m - 1)P_{l-2}^m \quad (6.8.7)$$

It is useful because there is a closed-form expression for the starting value,

$$P_m^m = (-1)^m (2m - 1)!! (1 - x^2)^{m/2} \quad (6.8.8)$$

(The notation $n!!$ denotes the product of all *odd* integers less than or equal to n .) Using (6.8.7) with $l = m + 1$, and setting $P_{m-1}^m = 0$, we find

$$P_{m+1}^m = x(2m + 1)P_m^m \quad (6.8.9)$$

Equations (6.8.8) and (6.8.9) provide the two starting values required for (6.8.7) for general l .

The function that implements this is

```

6.9 Fresnel Integrals, Cosine and Sine Integrals

Fresnel Integrals

The two Fresnel integrals are defined by

$$C(x) = \int_0^x \cos\left(\frac{\pi}{2}t^2\right) dt, \quad S(x) = \int_0^x \sin\left(\frac{\pi}{2}t^2\right) dt \quad (6.9.1)$$

The most convenient way of evaluating these functions to arbitrary precision is to use power series for small x and a continued fraction for large x . The series are

$$\begin{aligned} C(x) &= x - \left(\frac{\pi}{2}\right)^2 \frac{x^5}{5 \cdot 2!} + \left(\frac{\pi}{2}\right)^4 \frac{x^9}{9 \cdot 4!} - \dots \\ S(x) &= \left(\frac{\pi}{2}\right) \frac{x^3}{3 \cdot 1!} - \left(\frac{\pi}{2}\right)^3 \frac{x^7}{7 \cdot 3!} + \left(\frac{\pi}{2}\right)^5 \frac{x^{11}}{11 \cdot 5!} - \dots \end{aligned} \quad (6.9.2)$$

There is a complex continued fraction that yields both $S(x)$ and $C(x)$ simultaneously:

$$C(x) + iS(x) = \frac{1+i}{2} \operatorname{erf} z, \quad z = \frac{\sqrt{\pi}}{2}(1-i)x \quad (6.9.3)$$

where

$$\begin{aligned} e^{z^2} \operatorname{erfc} z &= \frac{1}{\sqrt{\pi}} \left(\frac{1}{z+} \frac{1/2}{z+} \frac{1}{z+} \frac{3/2}{z+} \frac{2}{z+} \dots \right) \\ &= \frac{2z}{\sqrt{\pi}} \left(\frac{1}{2z^2+1-} \frac{1 \cdot 2}{2z^2+5-} \frac{3 \cdot 4}{2z^2+9-} \dots \right) \end{aligned} \quad (6.9.4)$$

```

p11=(x*(2*ll-1)*pmmp1-(ll+m-1)*pmm)/(ll-m)
pmm=pmmp1
pmmp1=p11
enddo i2
plgndr=p11
endif
endif
return
END

```

6.9 Fresnel Integrals, Cosine and Sine Integrals

Fresnel Integrals

The two Fresnel integrals are defined by

$$C(x) = \int_0^x \cos\left(\frac{\pi}{2}t^2\right) dt, \quad S(x) = \int_0^x \sin\left(\frac{\pi}{2}t^2\right) dt \quad (6.9.1)$$

The most convenient way of evaluating these functions to arbitrary precision is to use power series for small x and a continued fraction for large x . The series are

$$\begin{aligned} C(x) &= x - \left(\frac{\pi}{2}\right)^2 \frac{x^5}{5 \cdot 2!} + \left(\frac{\pi}{2}\right)^4 \frac{x^9}{9 \cdot 4!} - \dots \\ S(x) &= \left(\frac{\pi}{2}\right) \frac{x^3}{3 \cdot 1!} - \left(\frac{\pi}{2}\right)^3 \frac{x^7}{7 \cdot 3!} + \left(\frac{\pi}{2}\right)^5 \frac{x^{11}}{11 \cdot 5!} - \dots \end{aligned} \quad (6.9.2)$$

There is a complex continued fraction that yields both $S(x)$ and $C(x)$ simultaneously:

$$C(x) + iS(x) = \frac{1+i}{2} \operatorname{erf} z, \quad z = \frac{\sqrt{\pi}}{2}(1-i)x \quad (6.9.3)$$

where

$$\begin{aligned} e^{z^2} \operatorname{erfc} z &= \frac{1}{\sqrt{\pi}} \left(\frac{1}{z+} \frac{1/2}{z+} \frac{1}{z+} \frac{3/2}{z+} \frac{2}{z+} \dots \right) \\ &= \frac{2z}{\sqrt{\pi}} \left(\frac{1}{2z^2+1-} \frac{1 \cdot 2}{2z^2+5-} \frac{3 \cdot 4}{2z^2+9-} \dots \right) \end{aligned} \quad (6.9.4)$$

In the last line we have converted the “standard” form of the continued fraction to its “even” form (see §5.2), which converges twice as fast. We must be careful not to evaluate the alternating series (6.9.2) at too large a value of x ; inspection of the terms shows that $x = 1.5$ is a good point to switch over to the continued fraction.

Note that for large x

$$C(x) \sim \frac{1}{2} + \frac{1}{\pi x} \sin \left(\frac{\pi}{2} x^2 \right), \quad S(x) \sim \frac{1}{2} - \frac{1}{\pi x} \cos \left(\frac{\pi}{2} x^2 \right) \quad (6.9.5)$$

Thus the precision of the routine `frenel` may be limited by the precision of the library routines for sine and cosine for large x .

Cosine and Sine Integrals

The cosine and sine integrals are defined by

$$\begin{aligned} \text{Ci}(x) &= \gamma + \ln x + \int_0^x \frac{\cos t - 1}{t} dt \\ \text{Si}(x) &= \int_0^x \frac{\sin t}{t} dt \end{aligned} \quad (6.9.6)$$

Here $\gamma \approx 0.5772\dots$ is Euler's constant. We only need a way to calculate the functions for $x > 0$, because

$$\text{Si}(-x) = -\text{Si}(x), \quad \text{Ci}(-x) = \text{Ci}(x) - i\pi \quad (6.9.7)$$

Once again we can evaluate these functions by a judicious combination of power series and complex continued fraction. The series are

$$\begin{aligned} \text{Si}(x) &= x - \frac{x^3}{3 \cdot 3!} + \frac{x^5}{5 \cdot 5!} - \dots \\ \text{Ci}(x) &= \gamma + \ln x + \left(-\frac{x^2}{2 \cdot 2!} + \frac{x^4}{4 \cdot 4!} - \dots \right) \end{aligned} \quad (6.9.8)$$

The continued fraction for the exponential integral $E_1(ix)$ is

$$\begin{aligned} E_1(ix) &= -\text{Ci}(x) + i[\text{Si}(x) - \pi/2] \\ &= e^{-ix} \left(\frac{1}{ix+} \frac{1}{1+} \frac{1}{ix+} \frac{2}{1+} \frac{2}{ix+} \dots \right) \\ &= e^{-ix} \left(\frac{1}{1+ix-} \frac{1^2}{3+ix-} \frac{2^2}{5+ix-} \dots \right) \end{aligned} \quad (6.9.9)$$

The “even” form of the continued fraction is given in the last line and converges twice as fast for about the same amount of computation. A good crossover point from the alternating series to the continued fraction is $x = 2$ in this case. As for the Fresnel integrals, for large x the precision may be limited by the precision of the sine and cosine routines.

6.10 Dawson's Integral

Dawson's Integral $F(x)$ is defined by

$$F(x) = e^{-x^2} \int_0^x e^{t^2} dt \quad (6.10.1)$$

The function can also be related to the complex error function by

$$F(z) = \frac{i\sqrt{\pi}}{2} e^{-z^2} [1 - \operatorname{erfc}(-iz)]. \quad (6.10.2)$$

A remarkable approximation for $F(z)$, due to Rybicki [1], is

$$F(z) = \lim_{h \rightarrow 0} \frac{1}{\sqrt{\pi}} \sum_{n \text{ odd}} \frac{e^{-(z-nh)^2}}{n} \quad (6.10.3)$$

What makes equation (6.10.3) unusual is that its accuracy increases *exponentially* as h gets small, so that quite moderate values of h (and correspondingly quite rapid convergence of the series) give very accurate approximations.

6.10 Dawson's Integral

Dawson's Integral $F(x)$ is defined by

$$F(x) = e^{-x^2} \int_0^x e^{t^2} dt \quad (6.10.1)$$

The function can also be related to the complex error function by

$$F(z) = \frac{i\sqrt{\pi}}{2} e^{-z^2} [1 - \operatorname{erfc}(-iz)]. \quad (6.10.2)$$

A remarkable approximation for $F(z)$, due to Rybicki [1], is

$$F(z) = \lim_{h \rightarrow 0} \frac{1}{\sqrt{\pi}} \sum_{n \text{ odd}} \frac{e^{-(z-nh)^2}}{n} \quad (6.10.3)$$

What makes equation (6.10.3) unusual is that its accuracy increases *exponentially* as h gets small, so that quite moderate values of h (and correspondingly quite rapid convergence of the series) give very accurate approximations.

We will discuss the theory that leads to equation (6.10.3) later, in §13.11, as an interesting application of Fourier methods. Here we simply implement a routine for real values of x based on the formula.

It is first convenient to shift the summation index to center it approximately on the maximum of the exponential term. Define n_0 to be the even integer nearest to x/h , and $x_0 \equiv n_0 h$, $x' \equiv x - x_0$, and $n' \equiv n - n_0$, so that

$$F(x) \approx \frac{1}{\sqrt{\pi}} \sum_{\substack{n'=-N \\ n' \text{ odd}}}^N \frac{e^{-(x'-n'h)^2}}{n' + n_0}, \quad (6.10.4)$$

where the approximate equality is accurate when h is sufficiently small and N is sufficiently large. The computation of this formula can be greatly speeded up if we note that

$$e^{-(x'-n'h)^2} = e^{-x'^2} e^{-(n'h)^2} \left(e^{2x'h} \right)^{n'}. \quad (6.10.5)$$

The first factor is computed once, the second is an array of constants to be stored, and the third can be computed recursively, so that only two exponentials need be evaluated. Advantage is also taken of the symmetry of the coefficients $e^{-(n'h)^2}$ by breaking the summation up into positive and negative values of n' separately.

In the following routine, the choices $h = 0.4$ and $N = 11$ are made. Because of the symmetry of the summations and the restriction to odd values of n , the limits on the do loops are 1 to 6. The accuracy of the result in this REAL version is about 2×10^{-7} . In order to maintain relative accuracy near $x = 0$, where $F(x)$ vanishes, the program branches to the evaluation of the power series [2] for $F(x)$, for $|x| < 0.2$.

6.11 Elliptic Integrals and Jacobian Elliptic Functions

Elliptic integrals occur in many applications, because any integral of the form

$$\int R(t, s) dt \quad (6.11.1)$$

where R is a rational function of t and s , and s is the square root of a cubic or quartic polynomial in t , can be evaluated in terms of elliptic integrals. Standard references [1] describe how to carry out the reduction, which was originally done by Legendre. Legendre showed that only three basic elliptic integrals are required. The simplest of these is

$$I_1 = \int_y^x \frac{dt}{\sqrt{(a_1 + b_1 t)(a_2 + b_2 t)(a_3 + b_3 t)(a_4 + b_4 t)}} \quad (6.11.2)$$

where we have written the quartic s^2 in factored form. In standard integral tables [2], one of the limits of integration is always a zero of the quartic, while the other limit lies closer than the next zero, so that there is no singularity within the interval. To evaluate I_1 , we simply break the interval $[y, x]$ into subintervals, each of which either begins or ends on a singularity. The tables, therefore, need only distinguish the eight cases in which each of the four zeros (ordered according to size) appears as the upper or lower limit of integration. In addition, when one of the b 's in (6.11.2) tends to zero, the quartic reduces to a cubic, with the largest or smallest singularity moving to $\pm\infty$; this leads to eight more cases (actually just special cases of the first eight). The sixteen cases in total are then usually tabulated in terms of Legendre's standard elliptic integral of the 1st kind, which we will define below. By a change of the variable of integration t , the zeros of the quartic are mapped to standard locations

6.11 Elliptic Integrals and Jacobian Elliptic Functions

Elliptic integrals occur in many applications, because any integral of the form

$$\int R(t, s) dt \quad (6.11.1)$$

where R is a rational function of t and s , and s is the square root of a cubic or quartic polynomial in t , can be evaluated in terms of elliptic integrals. Standard references [1] describe how to carry out the reduction, which was originally done by Legendre. Legendre showed that only three basic elliptic integrals are required. The simplest of these is

$$I_1 = \int_y^x \frac{dt}{\sqrt{(a_1 + b_1 t)(a_2 + b_2 t)(a_3 + b_3 t)(a_4 + b_4 t)}} \quad (6.11.2)$$

where we have written the quartic s^2 in factored form. In standard integral tables [2], one of the limits of integration is always a zero of the quartic, while the other limit lies closer than the next zero, so that there is no singularity within the interval. To evaluate I_1 , we simply break the interval $[y, x]$ into subintervals, each of which either begins or ends on a singularity. The tables, therefore, need only distinguish the eight cases in which each of the four zeros (ordered according to size) appears as the upper or lower limit of integration. In addition, when one of the b 's in (6.11.2) tends to zero, the quartic reduces to a cubic, with the largest or smallest singularity moving to $\pm\infty$; this leads to eight more cases (actually just special cases of the first eight). The sixteen cases in total are then usually tabulated in terms of Legendre's standard elliptic integral of the 1st kind, which we will define below. By a change of the variable of integration t , the zeros of the quartic are mapped to standard locations

on the real axis. Then only two dimensionless parameters are needed to tabulate Legendre's integral. However, the symmetry of the original integral (6.11.2) under permutation of the roots is concealed in Legendre's notation. We will get back to Legendre's notation below. But first, here is a better way:

Carlson [3] has given a new definition of a standard elliptic integral of the first kind,

$$R_F(x, y, z) = \frac{1}{2} \int_0^\infty \frac{dt}{\sqrt{(t+x)(t+y)(t+z)}} \quad (6.11.3)$$

where x , y , and z are nonnegative and at most one is zero. By standardizing the range of integration, he retains permutation symmetry for the zeros. (Weierstrass' canonical form also has this property.) Carlson first shows that when x or y is a zero of the quartic in (6.11.2), the integral I_1 can be written in terms of R_F in a form that is symmetric under permutation of the *remaining* three zeros. In the general case when neither x nor y is a zero, two such R_F functions can be combined into a single one by an *addition theorem*, leading to the fundamental formula

$$I_1 = 2R_F(U_{12}^2, U_{13}^2, U_{14}^2) \quad (6.11.4)$$

where

$$U_{ij} = (X_i X_j Y_k Y_m + Y_i Y_j X_k X_m)/(x - y) \quad (6.11.5)$$

$$X_i = (a_i + b_i x)^{1/2}, \quad Y_i = (a_i + b_i y)^{1/2} \quad (6.11.6)$$

and i, j, k, m is any permutation of 1, 2, 3, 4. A short-cut in evaluating these expressions is

$$\begin{aligned} U_{13}^2 &= U_{12}^2 - (a_1 b_4 - a_4 b_1)(a_2 b_3 - a_3 b_2) \\ U_{14}^2 &= U_{12}^2 - (a_1 b_3 - a_3 b_1)(a_2 b_4 - a_4 b_2) \end{aligned} \quad (6.11.7)$$

The U 's correspond to the three ways of pairing the four zeros, and I_1 is thus manifestly symmetric under permutation of the zeros. Equation (6.11.4) therefore reproduces all sixteen cases when one limit is a zero, and also includes the cases when neither limit is a zero.

Thus Carlson's function allows arbitrary ranges of integration and arbitrary positions of the branch points of the integrand relative to the interval of integration. To handle elliptic integrals of the second and third kind, Carlson defines the standard integral of the third kind as

$$R_J(x, y, z, p) = \frac{3}{2} \int_0^\infty \frac{dt}{(t+p)\sqrt{(t+x)(t+y)(t+z)}} \quad (6.11.8)$$

which is symmetric in x , y , and z . The degenerate case when two arguments are equal is denoted

$$R_D(x, y, z) = R_J(x, y, z, z) \quad (6.11.9)$$

and is symmetric in x and y . The function R_D replaces Legendre's integral of the second kind. The degenerate form of R_F is denoted

$$R_C(x, y) = R_F(x, y, y) \quad (6.11.10)$$

It embraces logarithmic, inverse circular, and inverse hyperbolic functions.

Carlson [4-7] gives integral tables in terms of the exponents of the linear factors of the quartic in (6.11.1). For example, the integral where the exponents are $(\frac{1}{2}, \frac{1}{2}, -\frac{1}{2}, -\frac{3}{2})$ can be expressed as a single integral in terms of R_D ; it accounts for 144 separate cases in Gradshteyn and Ryzhik [2]!

Refer to Carlson's papers [3-7] for some of the practical details in reducing elliptic integrals to his standard forms, such as handling complex conjugate zeros.

Turn now to the numerical evaluation of elliptic integrals. The traditional methods [8] are Gauss or Landen transformations. *Descending* transformations decrease the modulus k of the Legendre integrals towards zero, *increasing* transformations increase it towards unity. In these limits the functions have simple analytic expressions. While these methods converge quadratically and are quite satisfactory for integrals of the first and second kinds, they generally lead to loss of significant figures in certain regimes for integrals of the third kind. Carlson's algorithms [9,10], by contrast, provide a unified method for all three kinds with no significant cancellations.

The key ingredient in these algorithms is the *duplication theorem*:

$$\begin{aligned} R_F(x, y, z) &= 2R_F(x + \lambda, y + \lambda, z + \lambda) \\ &= R_F\left(\frac{x + \lambda}{4}, \frac{y + \lambda}{4}, \frac{z + \lambda}{4}\right) \end{aligned} \quad (6.11.11)$$

where

$$\lambda = (xy)^{1/2} + (xz)^{1/2} + (yz)^{1/2} \quad (6.11.12)$$

This theorem can be proved by a simple change of variable of integration[11]. Equation (6.11.11) is iterated until the arguments of R_F are nearly equal. For equal arguments we have

$$R_F(x, x, x) = x^{-1/2} \quad (6.11.13)$$

When the arguments are close enough, the function is evaluated from a fixed Taylor expansion about (6.11.13) through fifth-order terms. While the iterative part of the algorithm is only linearly convergent, the error ultimately decreases by a factor of $4^6 = 4096$ for each iteration. Typically only two or three iterations are required, perhaps six or seven if the initial values of the arguments have huge ratios. We list the algorithm for R_F here, and refer you to Carlson's paper [9] for the other cases.

Stage 1: For $n = 0, 1, 2, \dots$ compute

$$\begin{aligned} \mu_n &= (x_n + y_n + z_n)/3 \\ X_n &= 1 - (x_n/\mu_n), \quad Y_n = 1 - (y_n/\mu_n), \quad Z_n = 1 - (z_n/\mu_n) \\ \epsilon_n &= \max(|X_n|, |Y_n|, |Z_n|) \end{aligned}$$

If $\epsilon_n < \text{tol}$ go to Stage 2; else compute

$$\begin{aligned} \lambda_n &= (x_n y_n)^{1/2} + (x_n z_n)^{1/2} + (y_n z_n)^{1/2} \\ x_{n+1} &= (x_n + \lambda_n)/4, \quad y_{n+1} = (y_n + \lambda_n)/4, \quad z_{n+1} = (z_n + \lambda_n)/4 \end{aligned}$$

and repeat this stage.

Stage 2: Compute

$$E_2 = X_n Y_n - Z_n^2, \quad E_3 = X_n Y_n Z_n$$

$$R_F = (1 - \frac{1}{10} E_2 + \frac{1}{14} E_3 + \frac{1}{24} E_2^2 - \frac{3}{44} E_2 E_3) / (\mu_n)^{1/2}$$

In some applications the argument p in R_J or the argument y in R_C is negative, and the Cauchy principal value of the integral is required. This is easily handled by using the formulas

$$\begin{aligned} R_J(x, y, z, p) &= \\ &[(\gamma - y) R_J(x, y, z, \gamma) - 3R_F(x, y, z) + 3R_C(xz/y, p\gamma/y)] / (y - p) \end{aligned} \quad (6.11.14)$$

where

$$\gamma \equiv y + \frac{(z - y)(y - x)}{y - p} \quad (6.11.15)$$

is positive if p is negative, and

$$R_C(x, y) = \left(\frac{x}{x - y} \right)^{1/2} R_C(x - y, -y) \quad (6.11.16)$$

The Cauchy principal value of R_J has a zero at some value of $p < 0$, so (6.11.14) will give some loss of significant figures near the zero.

```

A value of 0.08 for the error tolerance parameter is adequate for single precision (7 significant digits). Since the error scales as ϵ_n^6 , we see that 0.0025 will yield double precision (16 significant digits) and require at most two or three more iterations. Since the coefficients of the sixth-order truncation error are different for the other elliptic functions, these values for the error tolerance should be changed to 0.04 and 0.0012 in the algorithm for R_C , and 0.05 and 0.0015 for R_J and R_D . As well as being an algorithm in its own right for certain combinations of elementary functions, the algorithm for R_C is used repeatedly in the computation of R_J .

The Fortran implementations test the input arguments against two machine-dependent constants, TINY and BIG, to ensure that there will be no underflow or overflow during the computation. We have chosen conservative values, corresponding to a machine minimum of 3×10^{-39} and a machine maximum of 1.7×10^{38} . You can always extend the range of admissible argument values by using the homogeneity relations (6.11.22), below.

At times you may want to express your answer in Legendre's notation. Alternatively, you may be given results in that notation and need to compute their values with the programs given above. It is a simple matter to transform back and forth. The *Legendre elliptic integral of the 1st kind* is defined as

$$F(\phi, k) \equiv \int_0^\phi \frac{d\theta}{\sqrt{1 - k^2 \sin^2 \theta}} \quad (6.11.17)$$

The *complete elliptic integral of the 1st kind* is given by

$$K(k) \equiv F(\pi/2, k) \quad (6.11.18)$$

In terms of R_F ,

$$\begin{aligned} F(\phi, k) &= \sin \phi R_F(\cos^2 \phi, 1 - k^2 \sin^2 \phi, 1) \\ K(k) &= R_F(0, 1 - k^2, 1) \end{aligned} \quad (6.11.19)$$

The *Legendre elliptic integral of the 2nd kind* and the *complete elliptic integral of the 2nd kind* are given by

$$\begin{aligned} E(\phi, k) &\equiv \int_0^\phi \sqrt{1 - k^2 \sin^2 \theta} d\theta \\ &= \sin \phi R_F(\cos^2 \phi, 1 - k^2 \sin^2 \phi, 1) \\ &\quad - \frac{1}{3} k^2 \sin^3 \phi R_D(\cos^2 \phi, 1 - k^2 \sin^2 \phi, 1) \end{aligned} \quad (6.11.20)$$

$$E(k) \equiv E(\pi/2, k) = R_F(0, 1 - k^2, 1) - \frac{1}{3} k^2 R_D(0, 1 - k^2, 1)$$

Finally, the *Legendre elliptic integral of the 3rd kind* is

$$\begin{aligned} \Pi(\phi, n, k) &\equiv \int_0^\phi \frac{d\theta}{(1 + n \sin^2 \theta) \sqrt{1 - k^2 \sin^2 \theta}} \\ &= \sin \phi R_F(\cos^2 \phi, 1 - k^2 \sin^2 \phi, 1) \\ &\quad - \frac{1}{3} n \sin^3 \phi R_J(\cos^2 \phi, 1 - k^2 \sin^2 \phi, 1, 1 + n \sin^2 \phi) \end{aligned} \quad (6.11.21)$$

(Note that this sign convention for n is opposite that of Abramowitz and Stegun [12], and that their $\sin \alpha$ is our k .)

```

    and  $R_F$ . (Note that the sign convention on  $n$  is opposite that of Abramowitz and Stegun.)
    The ranges of  $\phi$  and  $k$  are  $0 \leq \phi \leq \pi/2$ ,  $0 \leq k \sin \phi \leq 1$ .
REAL cc,enss,q,s,rf,rj
s=sin(phi)
enss=en*s*s
cc=cos(phi)**2
q=(1.-s*ak)*(1.+s*ak)
ellpi=s*(rf(cc,q,1.)-enss*rj(cc,q,1.,1.+enss)/3.)
return
END

```

Carlson's functions are homogeneous of degree $-\frac{1}{2}$ and $-\frac{3}{2}$, so

$$\begin{aligned} R_F(\lambda x, \lambda y, \lambda z) &= \lambda^{-1/2} R_F(x, y, z) \\ R_J(\lambda x, \lambda y, \lambda z, \lambda p) &= \lambda^{-3/2} R_J(x, y, z, p) \end{aligned} \quad (6.11.22)$$

Thus to express a Carlson function in Legendre's notation, permute the first three arguments into ascending order, use homogeneity to scale the third argument to be 1, and then use equations (6.11.19)–(6.11.21).

Jacobian Elliptic Functions

The Jacobian elliptic function sn is defined as follows: instead of considering the elliptic integral

$$u(y, k) \equiv u = F(\phi, k) \quad (6.11.23)$$

consider the *inverse* function

$$y = \sin \phi = \text{sn}(u, k) \quad (6.11.24)$$

Equivalently,

$$u = \int_0^{\text{sn}} \frac{dy}{\sqrt{(1-y^2)(1-k^2y^2)}} \quad (6.11.25)$$

When $k = 0$, sn is just \sin . The functions cn and dn are defined by the relations

$$\text{sn}^2 + \text{cn}^2 = 1, \quad k^2 \text{sn}^2 + \text{dn}^2 = 1 \quad (6.11.26)$$

The routine given below actually takes $m_c \equiv k_c^2 = 1 - k^2$ as an input parameter. It also computes all three functions sn , cn , and dn since computing all three is no harder than computing any one of them. For a description of the method, see [8].

6.12 Hypergeometric Functions

As was discussed in §5.14, a fast, general routine for the the complex hypergeometric function ${}_2F_1(a, b, c; z)$, is difficult or impossible. The function is defined as the analytic continuation of the hypergeometric series,

$$\begin{aligned} {}_2F_1(a, b, c; z) = & 1 + \frac{ab}{c} \frac{z}{1!} + \frac{a(a+1)b(b+1)}{c(c+1)} \frac{z^2}{2!} + \dots \\ & + \frac{a(a+1)\dots(a+j-1)b(b+1)\dots(b+j-1)}{c(c+1)\dots(c+j-1)} \frac{z^j}{j!} + \dots \end{aligned} \quad (6.12.1)$$

This series converges only within the unit circle $|z| < 1$ (see [1]), but one's interest in the function is not confined to this region.

Section 5.14 discussed the method of evaluating this function by direct path integration in the complex plane. We here merely list the routines that result.

Implementation of the function `hypgeo` is straightforward, and is described by comments in the program. The machinery associated with Chapter 16's routine for integrating differential equations, `odeint`, is only minimally intrusive, and need not even be completely understood: use of `odeint` requires a common block with one zeroed variable, one subroutine call, and a prescribed format for the derivative routine `hypdrv`.

The subroutine `hypgeo` will fail, of course, for values of z too close to the singularity at 1. (If you need to approach this singularity, or the one at ∞ , use the “linear transformation formulas” in §15.3 of [1].) Away from $z = 1$, and for moderate values of a, b, c , it is often remarkable how few steps are required to integrate the equations. A half-dozen is typical.

6.12 Hypergeometric Functions

As was discussed in §5.14, a fast, general routine for the the complex hypergeometric function ${}_2F_1(a, b, c; z)$, is difficult or impossible. The function is defined as the analytic continuation of the hypergeometric series,

$$\begin{aligned} {}_2F_1(a, b, c; z) = & 1 + \frac{ab}{c} \frac{z}{1!} + \frac{a(a+1)b(b+1)}{c(c+1)} \frac{z^2}{2!} + \dots \\ & + \frac{a(a+1)\dots(a+j-1)b(b+1)\dots(b+j-1)}{c(c+1)\dots(c+j-1)} \frac{z^j}{j!} + \dots \end{aligned} \quad (6.12.1)$$

This series converges only within the unit circle $|z| < 1$ (see [1]), but one's interest in the function is not confined to this region.

Section 5.14 discussed the method of evaluating this function by direct path integration in the complex plane. We here merely list the routines that result.

Implementation of the function `hypgeo` is straightforward, and is described by comments in the program. The machinery associated with Chapter 16's routine for integrating differential equations, `odeint`, is only minimally intrusive, and need not even be completely understood: use of `odeint` requires a common block with one zeroed variable, one subroutine call, and a prescribed format for the derivative routine `hypdrv`.

The subroutine `hypgeo` will fail, of course, for values of z too close to the singularity at 1. (If you need to approach this singularity, or the one at ∞ , use the “linear transformation formulas” in §15.3 of [1].) Away from $z = 1$, and for moderate values of a, b, c , it is often remarkable how few steps are required to integrate the equations. A half-dozen is typical.

```

FUNCTION hypgeo(a,b,c,z)
COMPLEX hypgeo,a,b,c,z
REAL EPS
PARAMETER (EPS=1.e-6)                                Accuracy parameter.
C USES bsstep,hypdrv,hypser,odeint
   Complex hypergeometric function  ${}_2F_1$  for complex  $a, b, c$ , and  $z$ , by direct integration of
   the hypergeometric equation in the complex plane. The branch cut is taken to lie along
   the real axis,  $\text{Re } z > 1$ .
INTEGER kmax,nbad,nok
EXTERNAL bsstep,hypdrv
COMPLEX z0,dz,aa,bb,cc,y(2)
COMMON /hypg/ aa,bb,cc,z0,dz
COMMON /path/ kmax                                     Used by odeint.
kmax=0

Chapter 7. Random Numbers

7.0 Introduction

It may seem perverse to use a computer, that most precise and deterministic of all machines conceived by the human mind, to produce “random” numbers. More than perverse, it may seem to be a conceptual impossibility. Any program, after all, will produce output that is entirely predictable, hence not truly “random.”

Nevertheless, practical computer “random number generators” are in common use. We will leave it to philosophers of the computer age to resolve the paradox in a deep way (see, e.g., Knuth [1] §3.5 for discussion and references). One sometimes hears computer-generated sequences termed *pseudo-random*, while the word *random* is reserved for the output of an intrinsically random physical process, like the elapsed time between clicks of a Geiger counter placed next to a sample of some radioactive element. We will not try to make such fine distinctions.

A working, though imprecise, definition of randomness in the context of computer-generated sequences, is to say that the deterministic program that produces a random sequence should be different from, and — in all measurable respects — statistically uncorrelated with, the computer program that *uses* its output. In other words, any two different random number generators ought to produce statistically the same results when coupled to your particular applications program. If they don’t, then at least one of them is not (from your point of view) a good generator.

The above definition may seem circular, comparing, as it does, one generator to another. However, there exists a body of random number generators which mutually do satisfy the definition over a very, very broad class of applications programs. And it is also found empirically that statistically identical results are obtained from random numbers produced by physical processes. So, because such generators are known to exist, we can leave to the philosophers the problem of defining them.

A pragmatic point of view, then, is that randomness is in the eye of the beholder (or programmer). What is random enough for one application may not be random enough for another. Still, one is not entirely adrift in a sea of incommensurable applications programs: There is a certain list of statistical tests, some sensible and some merely enshrined by history, which on the whole will do a very good job of ferreting out any correlations that are likely to be detected by an applications program (in this case, yours). Good random number generators ought to pass all of these tests; or at least the user had better be aware of any that they fail, so that he or she will be able to judge whether they are relevant to the case at hand.

As for references on this subject, the one to turn to first is Knuth [1]. Then try [2]. Only a few of the standard books on numerical methods [3-4] treat topics relating to random numbers.

7.1 Uniform Deviates

Uniform deviates are just random numbers that lie within a specified range (typically 0 to 1), with any one number in the range just as likely as any other. They are, in other words, what you probably think “random numbers” are. However, we want to distinguish uniform deviates from other sorts of random numbers, for example numbers drawn from a normal (Gaussian) distribution of specified mean and standard deviation. These other sorts of deviates are almost always generated by performing appropriate operations on one or more uniform deviates, as we will see in subsequent sections. So, a reliable source of random uniform deviates, the subject of this section, is an essential building block for any sort of stochastic modeling or Monte Carlo computer work.

System-Supplied Random Number Generators

Your computer very likely has lurking within it a library routine which is called a “random number generator.” That routine typically has an unforgettable name like “`ran`,” and a calling sequence like

`x=ran(iseed)` sets `x` to the next random number and updates `iseed`

You initialize `iseed` to a (usually) arbitrary value before the first call to `ran`. Each initializing value will typically return a different subsequent random sequence, or at least a different subsequence of some one enormously long sequence. The *same* initializing value of `iseed` will always return the *same* random sequence, however.

Now our first, and perhaps most important, lesson in this chapter is: Be *very*, *very* suspicious of a system-supplied `ran` that resembles the one just described. If all scientific papers whose results are in doubt because of bad `rans` were to disappear from library shelves, there would be a gap on each shelf about as big as your fist. System-supplied `rans` are almost always *linear congruential generators*, which

System-Supplied Random Number Generators

Your computer very likely has lurking within it a library routine which is called a “random number generator.” That routine typically has an unforgettable name like “`ran`,” and a calling sequence like

`x=ran(iseed)` sets `x` to the next random number and updates `iseed`

You initialize `iseed` to a (usually) arbitrary value before the first call to `ran`. Each initializing value will typically return a different subsequent random sequence, or at least a different subsequence of some one enormously long sequence. The *same* initializing value of `iseed` will always return the *same* random sequence, however.

Now our first, and perhaps most important, lesson in this chapter is: Be *very*, *very* suspicious of a system-supplied `ran` that resembles the one just described. If all scientific papers whose results are in doubt because of bad `rans` were to disappear from library shelves, there would be a gap on each shelf about as big as your fist. System-supplied `rans` are almost always *linear congruential generators*, which

generate a sequence of integers I_1, I_2, I_3, \dots , each between 0 and $m - 1$ (a large number) by the recurrence relation

$$I_{j+1} = aI_j + c \pmod{m} \quad (7.1.1)$$

Here m is called the *modulus*, and a and c are positive integers called the *multiplier* and the *increment*, respectively. The recurrence (7.1.1) will eventually repeat itself, with a period that is obviously no greater than m . If m , a , and c are properly chosen, then the period will be of maximal length, i.e., of length m . In that case, all possible integers between 0 and $m - 1$ occur at some point, so any initial “seed” choice of I_0 is as good as any other: The sequence just takes off from that point. The real number between 0 and 1 which is returned is generally I_{j+1}/m , so that it is strictly less than 1, but occasionally (once in m calls) exactly equal to zero. `iseed` is set to I_{j+1} (or some encoding of it), so that it can be used on the next call to generate I_{j+2} , and so on.

The linear congruential method has the advantage of being very fast, requiring only a few operations per call, hence its almost universal use. It has the disadvantage that it is not free of sequential correlation on successive calls. If k random numbers at a time are used to plot points in k dimensional space (with each coordinate between 0 and 1), then the points will not tend to “fill up” the k -dimensional space, but rather will lie on $(k - 1)$ -dimensional “planes.” There will be *at most* about $m^{1/k}$ such planes. If the constants m , a , and c are not very carefully chosen, there will be *many fewer than that*. The number m is usually close to the machine’s largest representable integer, e.g., $\sim 2^{32}$. So, for example, the number of planes on which triples of points lie in three-dimensional space is usually no greater than about the cube root of 2^{32} , about 1600. You might well be focusing attention on a physical process that occurs in a small fraction of the total volume, so that the discreteness of the planes can be very pronounced.

Even worse, you might be using a `ran` whose choices of m , a , and c have been botched. One infamous such routine, RANDU, with $a = 65539$ and $m = 2^{31}$, was widespread on IBM mainframe computers for many years, and widely copied onto other systems [1]. One of us recalls producing a “random” plot with only 11 planes, and being told by his computer center’s programming consultant that he had misused the random number generator: “We guarantee that each number is random individually, but we don’t guarantee that more than one of them is random.” Figure that out.

Correlation in k -space is not the only weakness of linear congruential generators. Such generators often have their low-order (least significant) bits much less random than their high-order bits. If you want to generate a random integer between 1 and 10, you should always do it using high-order bits, as in

```
j=1+int(10.*ran(iseed))
```

and never by anything resembling

```
j=1+mod(int(1000000.*ran(iseed)),10)
```

(which uses lower-order bits). Similarly you should never try to take apart a “ran” number into several supposedly random pieces. Instead use separate calls for every piece.

Portable Random Number Generators

Park and Miller [1] have surveyed a large number of random number generators that have been used over the last 30 years or more. Along with a good theoretical review, they present an anecdotal sampling of a number of inadequate generators that have come into widespread use. The historical record is nothing if not appalling.

There is good evidence, both theoretical and empirical, that the simple multiplicative congruential algorithm

$$I_{j+1} = aI_j \pmod{m} \quad (7.1.2)$$

can be as good as any of the more general linear congruential generators that have $c \neq 0$ (equation 7.1.1) — if the multiplier a and modulus m are chosen exquisitely carefully. Park and Miller propose a “Minimal Standard” generator based on the choices

$$a = 7^5 = 16807 \quad m = 2^{31} - 1 = 2147483647 \quad (7.1.3)$$

First proposed by Lewis, Goodman, and Miller in 1969, this generator has in subsequent years passed all new theoretical tests, and (perhaps more importantly) has accumulated a large amount of successful use. Park and Miller do not claim that the generator is “perfect” (we will see below that it is not), but only that it is a good minimal standard against which other generators should be judged.

It is not possible to implement equations (7.1.2) and (7.1.3) directly in a high-level language, since the product of a and $m - 1$ exceeds the maximum value for a 32-bit integer. Assembly language implementation using a 64-bit product register is straightforward, but not portable from machine to machine. A trick due to Schrage [2,3] for multiplying two 32-bit integers modulo a 32-bit constant, without using any intermediates larger than 32 bits (including a sign bit) is therefore extremely interesting: It allows the Minimal Standard generator to be implemented in essentially any programming language on essentially any machine.

Schrage’s algorithm is based on an *approximate factorization* of m ,

$$m = aq + r, \quad \text{i.e.,} \quad q = [m/a], \quad r = m \bmod a \quad (7.1.4)$$

with square brackets denoting integer part. If r is small, specifically $r < q$, and $0 < z < m - 1$, it can be shown that both $a(z \bmod q)$ and $r[z/q]$ lie in the range $0, \dots, m - 1$, and that

$$az \bmod m = \begin{cases} a(z \bmod q) - r[z/q] & \text{if it is } \geq 0, \\ a(z \bmod q) - r[z/q] + m & \text{otherwise} \end{cases} \quad (7.1.5)$$

The application of Schrage’s algorithm to the constants (7.1.3) uses the values $q = 127773$ and $r = 2836$.

Here is an implementation of the Minimal Standard generator:

```

FUNCTION ran0(idum)
INTEGER idum,IA,IM,IQ,IR,MASK
REAL ran0,AM
PARAMETER (IA=16807,IM=2147483647,AM=1./IM,
           IQ=127773,IR=2836,MASK=123459876)
*   "Minimal" random number generator of Park and Miller. Returns a uniform random deviate
   between 0.0 and 1.0. Set or reset idum to any integer value (except the unlikely value MASK)
   to initialize the sequence; idum must not be altered between calls for successive deviates
   in a sequence.
INTEGER k
idum=ieor(idum,MASK)          XORing with MASK allows use of zero and other simple
k=idum/IQ                      bit patterns for idum.
idum=IA*(idum-k*IQ)-IR*k      Compute idum=mod(IA*idum,IM) without overflows by
if (idum.lt.0) idum=idum+IM    Schrage's method.
ran0=AM*idum                     Convert idum to a floating result.
idum=ieor(idum,MASK)           Unmask before return.
return
END

```

The period of `ran0` is $2^{31} - 2 \approx 2.1 \times 10^9$. A peculiarity of generators of the form (7.1.2) is that the value 0 must never be allowed as the initial seed — it perpetuates itself — and it never occurs for any nonzero initial seed. Experience has shown that users always manage to call random number generators with the seed `idum=0`. That is why `ran0` performs its exclusive-or with an arbitrary constant both on entry and exit. If you are the first user in history to be proof against human error, you can remove the two lines with the `ieor` function.

Park and Miller discuss two other multipliers a that can be used with the same $m = 2^{31} - 1$. These are $a = 48271$ (with $q = 44488$ and $r = 3399$) and $a = 69621$ (with $q = 30845$ and $r = 23902$). These can be substituted in the routine `ran0` if desired; they may be slightly superior to Lewis *et al.*'s longer-tested values. No values other than these should be used.

The routine `ran0` is a Minimal Standard, satisfactory for the majority of applications, but we do not recommend it as the final word on random number generators. Our reason is precisely the simplicity of the Minimal Standard. It is not hard to think of situations where successive random numbers might be used in a way that accidentally conflicts with the generation algorithm. For example, since successive numbers differ by a multiple of only 1.6×10^{-4} out of a modulus of more than 2×10^9 , very small random numbers will tend to be followed by smaller than average values. One time in 10^6 , for example, there will be a value $< 10^{-6}$ returned (as there should be), but this will *always* be followed by a value less than about 0.0168. One can easily think of applications involving rare events where this property would lead to wrong results.

There are other, more subtle, serial correlations present in `ran0`. For example, if successive points (I_i, I_{i+1}) are binned into a two-dimensional plane for $i = 1, 2, \dots, N$, then the resulting distribution fails the χ^2 test when N is greater than a few $\times 10^7$, much less than the period $m - 2$. Since low-order serial correlations have historically been such a bugaboo, and since there is a very simple way to remove them, we think that it is prudent to do so.

The following routine, `ran1`, uses the Minimal Standard for its random value, but it shuffles the output to remove low-order serial correlations. A random deviate derived from the j th value in the sequence, I_j , is output not on the j th call, but rather on a randomized later call, $j + 32$ on average. The shuffling algorithm is due to Bays and Durham as described in Knuth [4], and is illustrated in Figure 7.1.1.

```

FUNCTION ran1(idum)
INTEGER idum,IA,IM,IQ,IR,NTAB,NDIV
REAL ran1,AM,EPS,RNMX
PARAMETER (IA=16807,IM=2147483647,AM=1./IM,IQ=127773,IR=2836,
           NTAB=32,NDIV=1+(IM-1)/NTAB,EPS=1.2e-7,RNMX=1.-EPS)
*   "Minimal" random number generator of Park and Miller with Bays-Durham shuffle and
  "Minimal" random number generator of Park and Miller with Bays-Durham shuffle and
  added safeguards. Returns a uniform random deviate between 0.0 and 1.0 (exclusive of
  the endpoint values). Call with idum a negative integer to initialize; thereafter, do not
  alter idum between successive deviates in a sequence. RNMX should approximate the largest
  floating value that is less than 1.
INTEGER j,k,iv(NTAB),iy
SAVE iv,iy
DATA iv /NTAB*0/, iy /0/
if (idum.le.0.or.iv.eq.0) then Initialize.
  idum=max(-idum,1)                                Be sure to prevent idum = 0.
  do 11 j=NTAB+8,1,-1                            Load the shuffle table (after 8 warm-ups).
    k=idum/IQ
    idum=IA*(idum-k*IQ)-IR*k
    if (idum.lt.0) idum=idum+IM
    if (j.le.NTAB) iv(j)=idum
  enddo 11
  iy=iv(1)
endif
k=idum/IQ                                         Start here when not initializing.
idum=IA*(idum-k*IQ)-IR*k                         Compute idum=mod(IA*idum,IM) without overflows by
if (idum.lt.0) idum=idum+IM                      Schrage's method.
j=1+iy/NDIV                                         Will be in the range 1:NTAB.
iy=iv(j)                                            Output previously stored value and refill the shuffle ta-
iv(j)=idum                                         ble.
ran1=min(AM*iy,RNMX)                             Because users don't expect endpoint values.
return
END

```

The routine `ran1` passes those statistical tests that `ran0` is known to fail. In fact, we do not know of any statistical test that `ran1` fails to pass, except when the number of calls starts to become on the order of the period m , say $> 10^8 \approx m/20$.

For situations when even longer random sequences are needed, L'Ecuyer [6] has given a good way of combining two different sequences with different periods so as to obtain a new sequence whose period is the least common multiple of the two periods. The basic idea is simply to add the two sequences, modulo the modulus of *either* of them (call it m). A trick to avoid an intermediate value that overflows the integer wordsize is to subtract rather than add, and then add back the constant $m - 1$ if the result is ≤ 0 , so as to wrap around into the desired interval $0, \dots, m - 1$.

Notice that it is not necessary that this wrapped subtraction be able to reach all values $0, \dots, m - 1$ from *every* value of the first sequence. Consider the absurd extreme case where the value subtracted was only between 1 and 10: The resulting sequence would still be no less random than the first sequence by itself. As a practical matter it is only necessary that the second sequence have a range covering *substantially* all of the range of the first. L'Ecuyer recommends the use of the two generators $m_1 = 2147483563$ (with $a_1 = 40014$, $q_1 = 53668$, $r_1 = 12211$) and $m_2 = 2147483399$ (with $a_2 = 40692$, $q_2 = 52774$, $r_2 = 3791$). Both moduli are slightly less than 2^{31} . The periods $m_1 - 1 = 2 \times 3 \times 7 \times 631 \times 81031$ and $m_2 - 1 = 2 \times 19 \times 31 \times 1019 \times 1789$ share only the factor 2, so the period of the combined generator is $\approx 2.3 \times 10^{18}$. For present computers, period exhaustion is a practical impossibility.

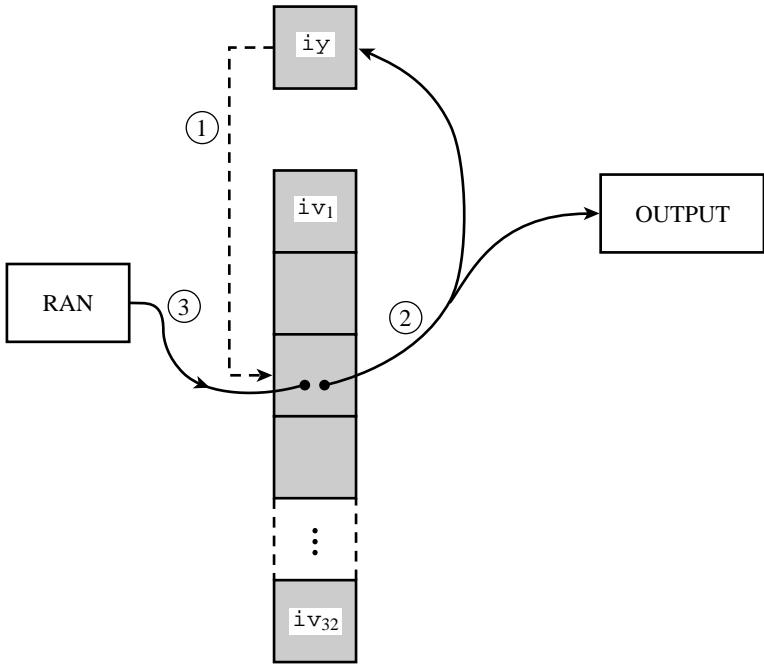

Figure 7.1.1. Shuffling procedure used in `ran1` to break up sequential correlations in the Minimal Standard generator. Circled numbers indicate the sequence of events: On each call, the random number in `iy` is used to choose a random element in the array `iv`. That element becomes the output random number, and also is the next `iy`. Its spot in `iv` is refilled from the Minimal Standard routine.

Combining the two generators breaks up serial correlations to a considerable extent. We nevertheless recommend the additional shuffle that is implemented in the following routine, `ran2`. We think that, within the limits of its floating-point precision, `ran2` provides perfect random numbers; a practical definition of “perfect” is that we will pay \$1000 to the first reader who convinces us otherwise (by finding a statistical test that `ran2` fails in a nontrivial way, excluding the ordinary limitations of a machine’s floating-point representation).

```

FUNCTION ran2(idum)
INTEGER idum,IM1,IM2,IMM1,IA1,IA2,IQ1,IQ2,IR1,IR2,NTAB,NDIV
REAL ran2,AM,EPS,RNMX
PARAMETER (IM1=2147483563,IM2=2147483399,AM=1./IM1,IMM1=IM1-1,
           IA1=40014,IA2=40692,IQ1=53668,IQ2=52774,IR1=12211,
           IR2=3791,NTAB=32,NDIV=1+IMM1/NTAB,EPS=1.2e-7,RNMX=1.-EPS)
* Long period ( $> 2 \times 10^{18}$ ) random number generator of L’Ecuyer with Bays-Durham shuffle
* and added safeguards. Returns a uniform random deviate between 0.0 and 1.0 (exclusive
* of the endpoint values). Call with idum a negative integer to initialize; thereafter, do not
* alter idum between successive deviates in a sequence. RNMX should approximate the largest
* floating value that is less than 1.
INTEGER idum2,j,k,iv(NTAB),iy
SAVE iv,iy,idum2
DATA idum2/123456789/, iv/NTAB*0/, iy/0/
if (idum.le.0) then
    idum=max(-idum,1)                                Initialize.
    idum2=idum                                         Be sure to prevent idum = 0.
    do ii j=NTAB+8,1,-1
        k=idum/IQ1                                     Load the shuffle table (after 8 warm-ups).
    enddo
end

```

```

        idum=IA1*(idum-k*IQ1)-k*IR1
        if (idum.lt.0) idum=idum+IM1

    enddo !!
    iy=iv(1)
endif
k=idum/IQ1
idum=IA1*(idum-k*IQ1)-k*IR1
if (idum.lt.0) idum=idum+IM1
k=idum2/IQ2
idum2=IA2*(idum2-k*IQ2)-k*IR2
if (idum2.lt.0) idum2=idum2+IM2
j=1+iy/NDIV
iy=iv(j)-idum2
iv(j)=idum
if(iy.lt.1)iy=iy+IMM1
ran2=min(AM*iy,RNMX)
return
END

```

Start here when not initializing.
Compute $\text{idum} = \text{mod}(\text{IA1} * \text{idum}, \text{IM1})$ without overflows by Schrage's method.

Compute $\text{idum2} = \text{mod}(\text{IA2} * \text{idum2}, \text{IM2})$ likewise.

Will be in the range 1:NTAB.
Here idum is shuffled, idum and idum2 are combined to generate output.

Because users don't expect endpoint values.

L'Ecuyer [6] lists additional short generators that can be combined into longer ones, including generators that can be implemented in 16-bit integer arithmetic.

Finally, we give you Knuth's suggestion [4] for a portable routine, which we have translated to the present conventions as `ran3`. This is not based on the linear congruential method at all, but rather on a *subtractive method* (see also [5]). One might hope that its weaknesses, if any, are therefore of a highly different character from the weaknesses, if any, of `ran1` above. If you ever suspect trouble with one routine, it is a good idea to try the other in the same application. `ran3` has one nice feature: if your machine is poor on integer arithmetic (i.e., is limited to 16-bit integers), substitution of the three "commented" lines for the ones directly preceding them will render the routine entirely floating-point.

```

FUNCTION ran3(idum)
    Returns a uniform random deviate between 0.0 and 1.0. Set idum to any negative value
    to initialize or reinitialize the sequence.
INTEGER idum
INTEGER MBIG,MSEED,MZ

if(mj.lt.MZ)mj=mj+MBIG
ma(inext)=mj
ran3=mj*FAC
return
END

```

We randomize them by “warming up the generator.”

Prepare indices for our first generated number.
The constant 31 is special; see Knuth.

Here is where we start, except on initialization. Increment
inext, wrapping around 56 to 1.
Ditto for inextp.

Now generate a new random number subtractively.
Be sure that it is in range.
Store it,
and output the derived uniform deviate.

Quick and Dirty Generators

One sometimes would like a “quick and dirty” generator to embed in a program, perhaps taking only one or two lines of code, just to *somewhat* randomize things. One might wish to process data from an experiment not always in exactly the same order, for example, so that the first output is more “typical” than might otherwise be the case.

For this kind of application, all we really need is a list of “good” choices for m , a , and c in equation (7.1.1). If we don’t need a period longer than 10^4 to 10^6 , say, we can keep the value of $(m - 1)a + c$ small enough to avoid overflows that would otherwise mandate the extra complexity of Schrage’s method (above). We can thus easily embed in our programs

```
jran=mod(jran*ia+ic,im)
ran=float(jran)/float(im)
```

whenever we want a quick and dirty uniform deviate, or

```
jran=mod(jran*ia+ic,im)
j=jlo+((jhi-jlo+1)*jran)/im
```

whenever we want an integer between j_{lo} and j_{hi} , inclusive. (In both cases j_{ran} was once initialized to any seed value between 0 and $\text{im}-1$.)

Be sure to remember, however, that when im is small, the k th root of it, which is the number of planes in k -space, is even smaller! So a quick and dirty generator should never be used to select points in k -space with $k > 1$.

With these caveats, some “good” choices for the constants are given in the accompanying table. These constants (i) give a period of maximal length im , and, more important, (ii) pass Knuth’s “spectral test” for dimensions 2, 3, 4, 5, and 6. The increment ic is a prime, close to the value $(\frac{1}{2} - \frac{1}{6}\sqrt{3})\text{im}$; actually almost any value of ic that is relatively prime to im will do just as well, but there is some “lore” favoring this choice (see [4], p. 84).

An Even Quicker and Dirtier Generator

Many FORTRAN compilers can be abused in such a way that they will multiply two 32-bit integers *ignoring any resulting overflow*. In such cases, on many machines, the value returned is predictably the low-order 32 bits of the true 64-bit product. (C compilers, incidentally, can do this without the requirement of abuse — it is guaranteed behavior for so-called `unsigned long int` integers. On VMS VAXes, the necessary FORTRAN command is `FORTRAN/CHECK=NOOVERFLOW`.) If we now choose $m = 2^{32}$, the “mod” in equation (7.1.1) is free, and we have simply

$$I_{j+1} = aI_j + c \quad (7.1.6)$$

Knuth suggests $a = 1664525$ as a suitable multiplier for this value of m . H.W. Lewis has conducted extensive tests of this value of a with $c = 1013904223$, which is a prime close to $(\sqrt{5} - 2)m$. The resulting in-line generator (we will call it `ranqd1`) is simply

```
idum=1664525*idum+1013904223
```

This is about as good as any 32-bit linear congruential generator, entirely adequate for many uses. And, with only a single multiply and add, it is *very* fast.

To check whether your compiler and machine have the desired overflow properties, see if you can generate the following sequence of 32-bit values (given here in hex): 00000000, 3C6EF35F, 47502932, D1CCF6E9, AAF95334, 6252E503, 9F2EC686, 57FE6C2D, A3D95FA8, 81FDBEE7, 94F0AF1A, CBF633B1.

If you need floating-point values instead of 32-bit integers, and want to avoid a divide by floating-point 2^{32} , a dirty trick is to mask in an exponent that makes the value lie between 1 and 2, then subtract 1.0. The resulting in-line generator (call it `ranqd2`) will look something like

```

INTEGER idum, itemp, jflone, jflmsk
REAL ftemp
EQUIVALENCE (itemp,ftemp)
DATA jflone /Z'3F800000'/, jflmsk /Z'007FFFFF'/
...
idum=1664525*idum+1013904223
itemp=ior(jflone,iand(jflmsk,idum))
ran=ftemp-1.0

```

The hex constants 3F800000 and 007FFFFF are the appropriate ones for computers using the IEEE representation for 32-bit floating-point numbers (e.g., IBM PCs and most UNIX workstations). For DEC VAXes, the correct hex constants are, respectively, 00004080 and FFFF007F. Notice that the IEEE mask results in the floating-point number being constructed out of the 23 low-order bits of the integer, which is not ideal. Also notice that your compiler may require a different notation for hex constants, e.g., x'3f800000', '3F800000'X, or even 16#3F800000. (Your authors have tried very hard to make *almost all* of the material in this book machine and compiler independent — indeed, even programming language independent. This subsection is a rare aberration. Forgive us. Once in a great while the temptation to be *really dirty* is just irresistible.)

Relative Timings and Recommendations

Timings are inevitably machine dependent. Nevertheless the following table is indicative of the *relative* timings, for typical machines, of the various uniform generators discussed in this section, plus ran4 from §7.5. Smaller values in the table indicate faster generators. The generators ranqd1 and ranqd2 refer to the “quick and dirty” generators immediately above.

Generator	Relative Execution Time
ran0	$\equiv 1.0$
ran1	≈ 1.3
ran2	≈ 2.0
ran3	≈ 0.6
ranqd1	≈ 0.10
ranqd2	≈ 0.25
ran4	≈ 4.0

On balance, we recommend ran1 for general use. It is portable, based on Park and Miller’s Minimal Standard generator with an additional shuffle, and has no known (to us) flaws other than period exhaustion.

If you are generating more than 100,000,000 random numbers in a single calculation (that is, more than about 5% of ran1’s period), we recommend the use of ran2, with its much longer period.

Knuth’s subtractive routine ran3 seems to be the timing winner among portable routines. Unfortunately the subtractive method is not so well studied, and not a standard. We like to keep ran3 in reserve for a “second opinion,” substituting it when we suspect another generator of introducing unwanted correlations into a calculation.

The routine ran4 generates *extremely* good random deviates, and has some other nice properties, but it is slow. See §7.5 for discussion.

Finally, the quick and dirty in-line generators `ranqd1` and `ranqd2` are very fast, but they are machine dependent, nonportable, and at best only as good as a 32-bit linear congruential generator ever is — in our view not good enough in many situations. We would use these only in very special cases, where speed is critical.

7.2 Transformation Method: Exponential and Normal Deviates

In the previous section, we learned how to generate random deviates with a uniform probability distribution, so that the probability of generating a number between x and $x + dx$, denoted $p(x)dx$, is given by

$$p(x)dx = \begin{cases} dx & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases} \quad (7.2.1)$$

The probability distribution $p(x)$ is of course normalized, so that

$$\int_{-\infty}^{\infty} p(x)dx = 1 \quad (7.2.2)$$

Now suppose that we generate a uniform deviate x and then take some prescribed function of it, $y(x)$. The probability distribution of y , denoted $p(y)dy$, is determined by the fundamental transformation law of probabilities, which is simply

$$|p(y)dy| = |p(x)dx| \quad (7.2.3)$$

or

$$p(y) = p(x) \left| \frac{dx}{dy} \right| \quad (7.2.4)$$

Finally, the quick and dirty in-line generators `ranqd1` and `ranqd2` are very fast, but they are machine dependent, nonportable, and at best only as good as a 32-bit linear congruential generator ever is — in our view not good enough in many situations. We would use these only in very special cases, where speed is critical.

7.2 Transformation Method: Exponential and Normal Deviates

In the previous section, we learned how to generate random deviates with a uniform probability distribution, so that the probability of generating a number between x and $x + dx$, denoted $p(x)dx$, is given by

$$p(x)dx = \begin{cases} dx & 0 < x < 1 \\ 0 & \text{otherwise} \end{cases} \quad (7.2.1)$$

The probability distribution $p(x)$ is of course normalized, so that

$$\int_{-\infty}^{\infty} p(x)dx = 1 \quad (7.2.2)$$

Now suppose that we generate a uniform deviate x and then take some prescribed function of it, $y(x)$. The probability distribution of y , denoted $p(y)dy$, is determined by the fundamental transformation law of probabilities, which is simply

$$|p(y)dy| = |p(x)dx| \quad (7.2.3)$$

or

$$p(y) = p(x) \left| \frac{dx}{dy} \right| \quad (7.2.4)$$

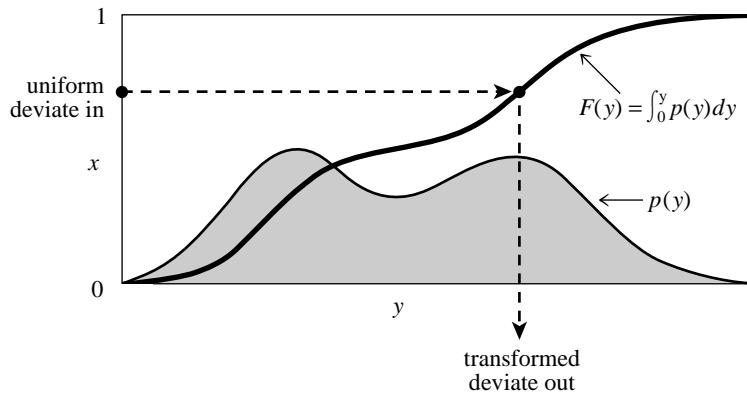

Figure 7.2.1. Transformation method for generating a random deviate y from a known probability distribution $p(y)$. The indefinite integral of $p(y)$ must be known and invertible. A uniform deviate x is chosen between 0 and 1. Its corresponding y on the definite-integral curve is the desired deviate.

Exponential Deviates

As an example, suppose that $y(x) \equiv -\ln(x)$, and that $p(x)$ is as given by equation (7.2.1) for a uniform deviate. Then

$$p(y)dy = \left| \frac{dx}{dy} \right| dy = e^{-y} dy \quad (7.2.5)$$

which is distributed exponentially. This exponential distribution occurs frequently in real problems, usually as the distribution of waiting times between independent Poisson-random events, for example the radioactive decay of nuclei. You can also easily see (from 7.2.4) that the quantity y/λ has the probability distribution $\lambda e^{-\lambda y}$.

So we have

```

FUNCTION expdev(idum)
INTEGER idum
REAL expdev
C USES ran1
      Returns an exponentially distributed, positive, random deviate of unit mean, using
      ran1(idum) as the source of uniform deviates.
REAL dum,ran1
1  dum=ran1(idum)
if(dum.eq.0.)goto 1
expdev=-log(dum)
return
END

```

Let's see what is involved in using the above *transformation method* to generate some arbitrary desired distribution of y 's, say one with $p(y) = f(y)$ for some positive function f whose integral is 1. (See Figure 7.2.1.) According to (7.2.4), we need to solve the differential equation

$$\frac{dx}{dy} = f(y) \quad (7.2.6)$$

But the solution of this is just $x = F(y)$, where $F(y)$ is the indefinite integral of $f(y)$. The desired transformation which takes a uniform deviate into one distributed as $f(y)$ is therefore

$$y(x) = F^{-1}(x) \quad (7.2.7)$$

where F^{-1} is the inverse function to F . Whether (7.2.7) is feasible to implement depends on whether the *inverse function of the integral of $f(y)$* is itself feasible to compute, either analytically or numerically. Sometimes it is, and sometimes it isn't.

Incidentally, (7.2.7) has an immediate geometric interpretation: Since $F(y)$ is the area under the probability curve to the left of y , (7.2.7) is just the prescription: choose a uniform random x , then find the value y that has that fraction x of probability area to its left, and return the value y .

Normal (Gaussian) Deviates

Transformation methods generalize to more than one dimension. If x_1, x_2, \dots are random deviates with a *joint* probability distribution $p(x_1, x_2, \dots)$ $dx_1 dx_2 \dots$, and if y_1, y_2, \dots are each functions of all the x 's (same number of y 's as x 's), then the joint probability distribution of the y 's is

$$p(y_1, y_2, \dots) dy_1 dy_2 \dots = p(x_1, x_2, \dots) \left| \frac{\partial(x_1, x_2, \dots)}{\partial(y_1, y_2, \dots)} \right| dy_1 dy_2 \dots \quad (7.2.8)$$

where $|\partial(\)/\partial(\)|$ is the Jacobian determinant of the x 's with respect to the y 's (or reciprocal of the Jacobian determinant of the y 's with respect to the x 's).

An important example of the use of (7.2.8) is the *Box-Muller* method for generating random deviates with a normal (Gaussian) distribution,

$$p(y) dy = \frac{1}{\sqrt{2\pi}} e^{-y^2/2} dy \quad (7.2.9)$$

Consider the transformation between two uniform deviates on $(0,1)$, x_1, x_2 , and two quantities y_1, y_2 ,

$$\begin{aligned} y_1 &= \sqrt{-2 \ln x_1} \cos 2\pi x_2 \\ y_2 &= \sqrt{-2 \ln x_1} \sin 2\pi x_2 \end{aligned} \quad (7.2.10)$$

Equivalently we can write

$$\begin{aligned} x_1 &= \exp \left[-\frac{1}{2}(y_1^2 + y_2^2) \right] \\ x_2 &= \frac{1}{2\pi} \arctan \frac{y_2}{y_1} \end{aligned} \quad (7.2.11)$$

Now the Jacobian determinant can readily be calculated (try it!):

$$\frac{\partial(x_1, x_2)}{\partial(y_1, y_2)} = \begin{vmatrix} \frac{\partial x_1}{\partial y_1} & \frac{\partial x_1}{\partial y_2} \\ \frac{\partial x_2}{\partial y_1} & \frac{\partial x_2}{\partial y_2} \end{vmatrix} = - \left[\frac{1}{\sqrt{2\pi}} e^{-y_1^2/2} \right] \left[\frac{1}{\sqrt{2\pi}} e^{-y_2^2/2} \right] \quad (7.2.12)$$

Since this is the product of a function of y_2 alone and a function of y_1 alone, we see that each y is independently distributed according to the normal distribution (7.2.9).

One further trick is useful in applying (7.2.10). Suppose that, instead of picking uniform deviates x_1 and x_2 in the unit square, we instead pick v_1 and v_2 as the ordinate and abscissa of a random point inside the unit circle around the origin. Then the sum of their squares, $R^2 \equiv v_1^2 + v_2^2$ is a uniform deviate, which can be used for x_1 , while the angle that (v_1, v_2) defines with respect to the v_1 axis can serve as the random angle $2\pi x_2$. What's the advantage? It's that the cosine and sine in (7.2.10) can now be written as $v_1/\sqrt{R^2}$ and $v_2/\sqrt{R^2}$, obviating the trigonometric function calls!

We thus have

```

FUNCTION gasdev(idum)
INTEGER idum
REAL gasdev
C USES ran1
      Returns a normally distributed deviate with zero mean and unit variance, using ran1(idum)
      as the source of uniform deviates.
INTEGER iset
REAL fac,gset,rsq,v1,v2,ran1
SAVE iset,gset
DATA iset/0/
if (idum.lt.0) iset=0
if (iset.eq.0) then
 1   v1=2.*ran1(idum)-1.
  v2=2.*ran1(idum)-1.
  rsq=v1**2+v2**2
  if(rsq.ge.1.or.rsq.eq.0.)goto 1
  fac=sqrt(-2.*log(rsq)/rsq)
  gset=v1*fac
  gasdev=v2*fac
  iset=1
else
  gasdev=gset
  iset=0
endif
return
END

```

Reinitialize.
We don't have an extra deviate handy, so pick two uniform numbers in the square extending from -1 to +1 in each direction, see if they are in the unit circle, and if they are not, try again.
Now make the Box-Muller transformation to get two normal deviates. Return one and save the other for next time.
Set flag.
We have an extra deviate handy, so return it, and unset the flag.

See Devroye [1] and Bratley [2] for many additional algorithms.

7.3 Rejection Method: Gamma, Poisson, Binomial Deviates

The *rejection method* is a powerful, general technique for generating random deviates whose distribution function $p(x)dx$ (probability of a value occurring between x and $x + dx$) is known and computable. The rejection method does *not* require that the cumulative distribution function [indefinite integral of $p(x)$] be readily computable, much less the inverse of that function — which was required for the transformation method in the previous section.

The rejection method is based on a simple geometrical argument:

Draw a graph of the probability distribution $p(x)$ that you wish to generate, so that the area under the curve in any range of x corresponds to the desired probability of generating an x in that range. If we had some way of choosing a random point *in two dimensions*, with uniform probability in the *area* under your curve, then the x value of that random point would have the desired distribution.

Now, on the same graph, draw any other curve $f(x)$ which has finite (not infinite) area and lies everywhere *above* your original probability distribution. (This is always possible, because your original curve encloses only unit area, by definition of probability.) We will call this $f(x)$ the *comparison function*. Imagine now that you have some way of choosing a random point in two dimensions that is uniform in the area under the comparison function. Whenever that point lies outside the area under the original probability distribution, we will *reject* it and choose another random point. Whenever it lies inside the area under the original probability distribution, we will *accept* it. It should be obvious that the accepted points are uniform in the accepted area, so that their x values have the desired distribution. It should also be obvious that the fraction of points rejected just depends on the ratio of the area of the comparison function to the area of the probability distribution function, not on the details of shape of either function. For example, a comparison function whose area is less than 2 will reject fewer than half the points, even if it approximates the probability function very badly at some values of x , e.g., remains finite in some region where $p(x)$ is zero.

It remains only to suggest how to choose a uniform random point in two dimensions under the comparison function $f(x)$. A variant of the transformation method (§7.2) does nicely: Be sure to have chosen a comparison function whose indefinite integral is known analytically, and is also analytically invertible to give x as a function of “area under the comparison function to the left of x .” Now pick a uniform deviate between 0 and A , where A is the total area under $f(x)$, and use it to get a corresponding x . Then pick a uniform deviate between 0 and $f(x)$ as the y value for the two-dimensional point. You should be able to convince yourself that the point (x, y) is uniformly distributed in the area under the comparison function $f(x)$.

An equivalent procedure is to pick the second uniform deviate between zero and one, and accept or reject according to whether it is respectively less than or greater than the ratio $p(x)/f(x)$.

So, to summarize, the rejection method for some given $p(x)$ requires that one find, once and for all, some reasonably good comparison function $f(x)$. Thereafter, each deviate generated requires two uniform random deviates, one evaluation of f (to get the coordinate y), and one evaluation of p (to decide whether to accept or reject

7.3 Rejection Method: Gamma, Poisson, Binomial Deviates

The *rejection method* is a powerful, general technique for generating random deviates whose distribution function $p(x)dx$ (probability of a value occurring between x and $x + dx$) is known and computable. The rejection method does *not* require that the cumulative distribution function [indefinite integral of $p(x)$] be readily computable, much less the inverse of that function — which was required for the transformation method in the previous section.

The rejection method is based on a simple geometrical argument:

Draw a graph of the probability distribution $p(x)$ that you wish to generate, so that the area under the curve in any range of x corresponds to the desired probability of generating an x in that range. If we had some way of choosing a random point *in two dimensions*, with uniform probability in the *area* under your curve, then the x value of that random point would have the desired distribution.

Now, on the same graph, draw any other curve $f(x)$ which has finite (not infinite) area and lies everywhere *above* your original probability distribution. (This is always possible, because your original curve encloses only unit area, by definition of probability.) We will call this $f(x)$ the *comparison function*. Imagine now that you have some way of choosing a random point in two dimensions that is uniform in the area under the comparison function. Whenever that point lies outside the area under the original probability distribution, we will *reject* it and choose another random point. Whenever it lies inside the area under the original probability distribution, we will *accept* it. It should be obvious that the accepted points are uniform in the accepted area, so that their x values have the desired distribution. It should also be obvious that the fraction of points rejected just depends on the ratio of the area of the comparison function to the area of the probability distribution function, not on the details of shape of either function. For example, a comparison function whose area is less than 2 will reject fewer than half the points, even if it approximates the probability function very badly at some values of x , e.g., remains finite in some region where $p(x)$ is zero.

It remains only to suggest how to choose a uniform random point in two dimensions under the comparison function $f(x)$. A variant of the transformation method (§7.2) does nicely: Be sure to have chosen a comparison function whose indefinite integral is known analytically, and is also analytically invertible to give x as a function of “area under the comparison function to the left of x .” Now pick a uniform deviate between 0 and A , where A is the total area under $f(x)$, and use it to get a corresponding x . Then pick a uniform deviate between 0 and $f(x)$ as the y value for the two-dimensional point. You should be able to convince yourself that the point (x, y) is uniformly distributed in the area under the comparison function $f(x)$.

An equivalent procedure is to pick the second uniform deviate between zero and one, and accept or reject according to whether it is respectively less than or greater than the ratio $p(x)/f(x)$.

So, to summarize, the rejection method for some given $p(x)$ requires that one find, once and for all, some reasonably good comparison function $f(x)$. Thereafter, each deviate generated requires two uniform random deviates, one evaluation of f (to get the coordinate y), and one evaluation of p (to decide whether to accept or reject

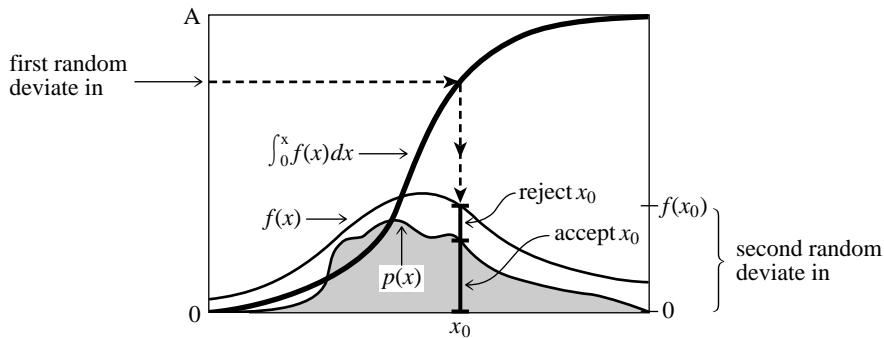

Figure 7.3.1. Rejection method for generating a random deviate x from a known probability distribution $p(x)$ that is everywhere less than some other function $f(x)$. The transformation method is first used to generate a random deviate x of the distribution f (compare Figure 7.2.1). A second uniform deviate is used to decide whether to accept or reject that x . If it is rejected, a new deviate of f is found; and so on. The ratio of accepted to rejected points is the ratio of the area under p to the area between p and f .

the point x, y). Figure 7.3.1 illustrates the procedure. Then, of course, this procedure must be repeated, on the average, A times before the final deviate is obtained.

Gamma Distribution

The gamma distribution of integer order $a > 0$ is the waiting time to the a th event in a Poisson random process of unit mean. For example, when $a = 1$, it is just the exponential distribution of §7.2, the waiting time to the first event.

A gamma deviate has probability $p_a(x)dx$ of occurring with a value between x and $x + dx$, where

$$p_a(x)dx = \frac{x^{a-1}e^{-x}}{\Gamma(a)}dx \quad x > 0 \quad (7.3.1)$$

To generate deviates of (7.3.1) for small values of a , it is best to add up a exponentially distributed waiting times, i.e., logarithms of uniform deviates. Since the sum of logarithms is the logarithm of the product, one really has only to generate the product of a uniform deviates, then take the log.

For larger values of a , the distribution (7.3.1) has a typically “bell-shaped” form, with a peak at $x = a$ and a half-width of about \sqrt{a} .

We will be interested in several probability distributions with this same qualitative form. A useful comparison function in such cases is derived from the *Lorentzian distribution*

$$p(y)dy = \frac{1}{\pi} \left(\frac{1}{1+y^2} \right) dy \quad (7.3.2)$$

whose inverse indefinite integral is just the tangent function. It follows that the x -coordinate of an area-uniform random point under the comparison function

$$f(x) = \frac{c_0}{1+(x-x_0)^2/a_0^2} \quad (7.3.3)$$

for any constants a_0, c_0 , and x_0 , can be generated by the prescription

$$x = a_0 \tan(\pi U) + x_0 \quad (7.3.4)$$

where U is a uniform deviate between 0 and 1. Thus, for some specific “bell-shaped” $p(x)$ probability distribution, we need only find constants a_0, c_0, x_0 , with the product $a_0 c_0$ (which determines the area) as small as possible, such that (7.3.3) is everywhere greater than $p(x)$.

Ahrens has done this for the gamma distribution, yielding the following algorithm (as described in Knuth [1]):

```

FUNCTION gamdev(ia,idum)
INTEGER ia,idum
REAL gamdev
C USES ran1
      Returns a deviate distributed as a gamma distribution of integer order ia, i.e., a waiting
      time to the iath event in a Poisson process of unit mean, using ran1(idum) as the source
      of uniform deviates.
INTEGER j
REAL am,e,s,v1,v2,x,y,ran1
if(ia.lt.1)pause 'bad argument in gamdev'
if(ia.lt.6)then           Use direct method, adding waiting times.
  x=1.
  do 11 j=1,ia
    x=x*ran1(idum)
  enddo 11
  x=-log(x)
else           Use rejection method.
  v1=ran1(idum)      These four lines generate the tangent of a random angle, i.e.,
  v2=2.*ran1(idum)-1.      are equivalent to y = tan(3.14159265 * ran1(idum)).
  if(v1**2+v2**2.gt.1.)goto 1
    y=v2/v1
    am=ia-1
    s=sqrt(2.*am+1.)
    x=s*y+am          We decide whether to reject x:
    if(x.le.0.)goto 1      Reject in region of zero probability.
    e=(1.+y**2)*exp(am*log(x/am)-s*y)      Ratio of prob. fn. to comparison fn.
    if(ran1(idum).gt.e)goto 1      Reject on basis of a second uniform de-
  endif               vice.
gamdev=x
return
END

```

Poisson Deviates

The Poisson distribution is conceptually related to the gamma distribution. It gives the probability of a certain integer number m of unit rate Poisson random events occurring in a given interval of time x , while the gamma distribution was the probability of waiting time between x and $x + dx$ to the m th event. Note that m takes on only integer values ≥ 0 , so that the Poisson distribution, viewed as a continuous distribution function $p_x(m)dm$, is zero everywhere except where m is an integer ≥ 0 . At such places, it is infinite, such that the integrated probability over a region containing the integer is some finite number. The total probability at an integer j is

$$\text{Prob}(j) = \int_{j-\epsilon}^{j+\epsilon} p_x(m)dm = \frac{x^j e^{-x}}{j!} \quad (7.3.5)$$

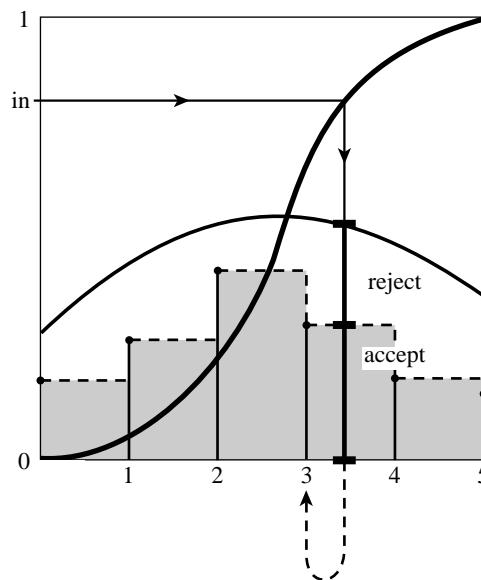

Figure 7.3.2. Rejection method as applied to an integer-valued distribution. The method is performed on the step function shown as a dashed line, yielding a real-valued deviate. This deviate is rounded down to the next lower integer, which is output.

At first sight this might seem an unlikely candidate distribution for the rejection method, since no continuous comparison function can be larger than the infinitely tall, but infinitely narrow, *Dirac delta functions* in $p_x(m)$. However, there is a trick that we can do: Spread the finite area in the spike at j uniformly into the interval between j and $j + 1$. This defines a continuous distribution $q_x(m)dm$ given by

$$q_x(m)dm = \frac{x^{[m]} e^{-x}}{[m]!} dm \quad (7.3.6)$$

where $[m]$ represents the largest integer less than m . If we now use the rejection method to generate a (noninteger) deviate from (7.3.6), and then take the integer part of that deviate, it will be as if drawn from the desired distribution (7.3.5). (See Figure 7.3.2.) This trick is general for any integer-valued probability distribution.

For x large enough, the distribution (7.3.6) is qualitatively bell-shaped (albeit with a bell made out of small, square steps), and we can use the same kind of Lorentzian comparison function as was already used above. For small x , we can generate independent exponential deviates (waiting times between events); when the sum of these first exceeds x , then the number of events that would have occurred in waiting time x becomes known and is one less than the number of terms in the sum.

These ideas produce the following routine:

```

FUNCTION poidev(xm,idum)
INTEGER idum
REAL poidev,xm,PI
PARAMETER (PI=3.141592654)
C USES gammln,ran1
      Returns as a floating-point number an integer value that is a random deviate drawn from a
      Poisson distribution of mean xm, using ran1(idum) as a source of uniform random deviates.

```

```

REAL alxm,em,g,oldm,sq,t,y,gammln,ran1
SAVE alxm,g,oldm,sq
DATA oldm /-1./
if (xm.lt.12.)then
    if (xm.ne.oldm) then
        oldm=xm
        g=exp(-xm)
    endif
    em=-1
    t=1.
2   em=em+1.
    t=t*ran1(idum)
    if (t.gt.g) goto 2
else
    if (xm.ne.oldm) then
        oldm=xm
        sq=sqrt(2.*xm)
        alxm=log(xm)
        g=xm*alxm-gammln(xm+1.) The function gammln is the natural log of the gamma
        function, as given in §6.1.
    endif
1   y=tan(PI*ran1(idum))      y is a deviate from a Lorentzian comparison function.
    em=sq*y+xm
    if (em.lt.0.) goto 1      Reject if in regime of zero probability.
    em=int(em)               The trick for integer-valued distributions.
    t=0.9*(1.+y**2)*exp(em*alxm-gammln(em+1.)-g)      The ratio of the desired distribu-
    if (ran1(idum).gt.t) goto 1      tion to the comparison function; we accept or re-
    endif                         ject by comparing it to another uniform deviate.
    poidev=em
return
END

```

Binomial Deviates

If an event occurs with probability q , and we make n trials, then the number of times m that it occurs has the binomial distribution,

$$\int_{j-\epsilon}^{j+\epsilon} p_{n,q}(m) dm = \binom{n}{j} q^j (1-q)^{n-j} \quad (7.3.7)$$

The binomial distribution is integer valued, with m taking on possible values from 0 to n . It depends on two parameters, n and q , so is correspondingly a bit harder to implement than our previous examples. Nevertheless, the techniques already illustrated are sufficiently powerful to do the job:

```

FUNCTION bnldev(pp,n,idum)
INTEGER idum,n
REAL bnldev,pp,PI
C USES gammln,ran1
PARAMETER (PI=3.141592654)
    Returns as a floating-point number an integer value that is a random deviate drawn from
    a binomial distribution of n trials each of probability pp, using ran1(idum) as a source
    of uniform random deviates.
INTEGER j,nold
REAL am,em,en,g,oldg,p,pc,pclog,plog,pold,sq,t,y,gammln,ran1

```

```

SAVE nold,pold,pc,plog,pclog,en,oldg
DATA nold /-1/, pold /-1./ Arguments from previous calls.
if(pp.le.0.5)then          The binomial distribution is invariant under changing pp to
    p=pp                      1.-pp, if we also change the answer to n minus itself;
else                         we'll remember to do this below.
    p=1.-pp
endif
am=n*p                      This is the mean of the deviate to be produced.
if (n.lt.25)then             Use the direct method while n is not too large. This can
    bnldev=0.                  require up to 25 calls to ran1.
    do 11 j=1,n
        if(ran1(idum).lt.p)bnldev=bnldev+1.
    enddo 11
else if (am.lt.1.) then      If fewer than one event is expected out of 25 or more tri-
    g=exp(-am)                als, then the distribution is quite accurately Poisson. Use
    t=1.                         direct Poisson method.
    do 12 j=0,n
        t=t*ran1(idum)
        if (t.lt.g) goto 1
    enddo 12
    j=n
    bnldev=j
1 else                         Use the rejection method.
    if (n.ne.nold) then       If n has changed, then compute useful quantities.
        en=n
        oldg=gammeln(en+1.)
        nold=n
    endif
    if (p.ne.pold) then      If p has changed, then compute useful quantities.
        pc=1.-p
        plog=log(p)
        pclog=log(pc)
        pold=p
    endif
    sq=sqrt(2.*am*pc)        The following code should by now seem familiar: rejection
    y=tan(PI*ran1(idum))    method with a Lorentzian comparison function.
    em=sq*y+am
    if (em.lt.0..or.em.ge.en+1.) goto 2      Reject.
    em=int(em)                Trick for integer-valued distribution.
    t=1.2*sq*(1.+y**2)*exp(oldg-gammeln(em+1.))
    -gammeln(em-em+1.)*em*plog+(en-em)*pclog
    if (ran1(idum).gt.t) goto 2      Reject. This happens about 1.5 times per deviate, on
    bnldev=em                  average.
endif
if (p.ne.pp) bnldev=n-bnldev      Remember to undo the symmetry transformation.
return
END

```

7.4 Generation of Random Bits

This topic is not very useful for programming in high-level languages, but it can be quite useful when you have access to the machine-language level of a machine or when you are in a position to build special-purpose hardware out of readily available chips.

The problem is how to generate single random bits, with 0 and 1 equally probable. Of course you can just generate uniform random deviates between zero and one and use their high-order bit (i.e., test if they are greater than or less than 0.5). However this takes a lot of arithmetic; there are special-purpose applications, such as real-time signal processing, where you want to generate bits very much faster than that.

One method for generating random bits, with two variant implementations, is based on “primitive polynomials modulo 2.” The theory of these polynomials is beyond our scope (although §7.7 and §20.3 will give you small tastes of it). Here, suffice it to say that there are special polynomials among those whose coefficients are zero or one. An example is

$$x^{18} + x^5 + x^2 + x^1 + x^0 \quad (7.4.1)$$

which we can abbreviate by just writing the nonzero powers of x , e.g.,

$$(18, 5, 2, 1, 0)$$

Every primitive polynomial modulo 2 of order n ($=18$ above) defines a recurrence relation for obtaining a new random bit from the n preceding ones. The recurrence relation is guaranteed to produce a sequence of maximal length, i.e., cycle through all possible sequences of n bits (except all zeros) before it repeats. Therefore one can seed the sequence with any initial bit pattern (except all zeros), and get $2^n - 1$ random bits before the sequence repeats.

Let the bits be numbered from 1 (most recently generated) through n (generated n steps ago), and denoted a_1, a_2, \dots, a_n . We want to give a formula for a new bit a_0 . After generating a_0 we will shift all the bits by one, so that the old a_n is finally lost, and the new a_0 becomes a_1 . We then apply the formula again, and so on.

“Method I” is the easiest to implement in hardware, requiring only a single shift register n bits long and a few XOR (“exclusive or” or bit addition mod 2) gates. For the primitive polynomial given above, the recurrence formula is

$$a_0 = a_{18} \text{ XOR } a_5 \text{ XOR } a_2 \text{ XOR } a_1 \quad (7.4.2)$$

The terms that are XOR’d together can be thought of as “taps” on the shift register, XOR’d into the register’s input. More generally, there is precisely one term for each nonzero coefficient in the primitive polynomial except the constant (zero bit) term. So the first term will always be a_n for a primitive polynomial of degree n , while the last term might or might not be a_1 , depending on whether the primitive polynomial has a term in x^1 .

It is rather cumbersome to illustrate the method in FORTRAN. Assume that `iand` is a bitwise AND function, `not` is bitwise complement, `ishft(,1)` is leftshift by one bit, `ior` is bitwise OR. (These are available in many FORTRAN implementations.) Then we have the following routine.

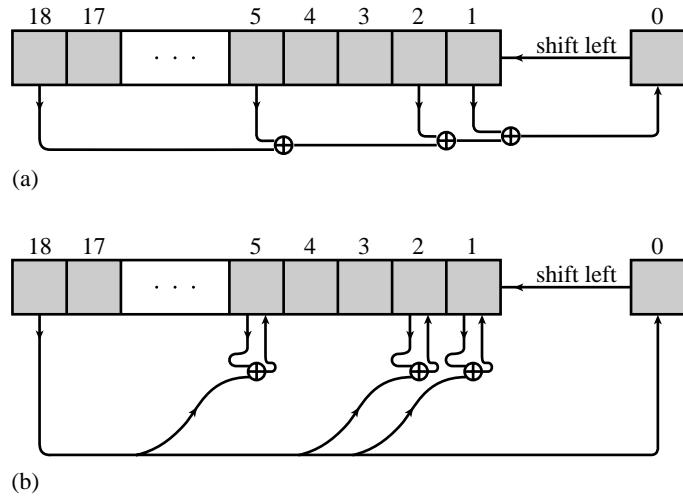

Figure 7.4.1. Two related methods for obtaining random bits from a shift register and a primitive polynomial modulo 2. (a) The contents of selected taps are combined by exclusive-or (addition modulo 2), and the result is shifted in from the right. This method is easiest to implement in hardware. (b) Selected bits are modified by exclusive-or with the leftmost bit, which is then shifted in from the right. This method is easiest to implement in software.

```

FUNCTION irbit1(iseed)
INTEGER irbit1,iseed,IB1,IB2,IB5,IB18
PARAMETER (IB1=1,IB2=2,IB5=16,IB18=131072)      Powers of 2.
    Returns as an integer a random bit, based on the 18 low-significance bits in iseed (which
    is modified for the next call).
LOGICAL newbit                                The accumulated XOR's.
newbit=iand(iseed,IB18).ne.0                  Get bit 18.
if(iand(iseed,IB5).ne.0)newbit=.not.newbit    XOR with bit 5.
if(iand(iseed,IB2).ne.0)newbit=.not.newbit    XOR with bit 2.
if(iand(iseed,IB1).ne.0)newbit=.not.newbit    XOR with bit 1.
irbit1=0
iseed=iand(ishft(iseed,1),not(IB1))        Leftshift the seed and put a zero in its bit 1.
if(newbit)then                                But if the XOR calculation gave a 1,
    irbit1=1                                  then put that in bit 1 instead.
    iseed=ior(iseed,IB1)
endif
return
END

```

“Method II” is less suited to direct hardware implementation (though still possible), but is more suited to machine-language implementation. It modifies more than one bit among the saved n bits as each new bit is generated (Figure 7.4.1). It generates the maximal length sequence, but not in the same order as Method I. The prescription for the primitive polynomial (7.4.1) is:

$$\begin{aligned}
 a_0 &= a_{18} \\
 a_5 &= a_5 \text{ XOR } a_0 \\
 a_2 &= a_2 \text{ XOR } a_0 \\
 a_1 &= a_1 \text{ XOR } a_0

(49, 6, 5, 4, 0)	(99, 7, 5, 4, 0)
(50, 4, 3, 2, 0)	(100, 8, 7, 2, 0)

In general there will be an exclusive-or for each nonzero term in the primitive polynomial except 0 and n . The nice feature about Method II is that all the exclusive-or's can usually be done as a single masked word XOR (here assumed to be the FORTRAN function ieor):

```

FUNCTION irbit2(iseed)
INTEGER irbit2,iseed,IB1,IB2,IB5,IB18,MASK
PARAMETER (IB1=1,IB2=2,IB5=16,IB18=131072,MASK=IB1+IB2+IB5)
    Returns as an integer a random bit, based on the 18 low-significance bits in iseed (which
    is modified for the next call).
if(iand(iseed,IB18).ne.0)then  Change all masked bits, shift, and put 1 into bit 1.
    iseed=ior(ishft(ieor(iseed,MASK),1),IB1)
    irbit2=1
else                           Shift and put 0 into bit 1.
    iseed=iand(ishft(iseed,1),not(IB1))
    irbit2=0
endif
return
END

```

A word of caution is: Don't use sequential bits from these routines as the bits of a large, supposedly random, integer, or as the bits in the mantissa of a supposedly random floating-point number. They are not very random for that purpose; see Knuth [1]. Examples of acceptable uses of these random bits are: (i) multiplying a signal randomly by ± 1 at a rapid "chip rate," so as to spread its spectrum uniformly (but recoverably) across some desired bandpass, or (ii) Monte Carlo exploration of a binary tree, where decisions as to whether to branch left or right are to be made randomly.

Now we do not want you to go through life thinking that there is something special about the primitive polynomial of degree 18 used in the above examples. (We chose 18 because 2^{18} is small enough for you to verify our claims directly by numerical experiment.) The accompanying table [2] lists one primitive polynomial for each degree up to 100. (In fact there exist many such for each degree. For example, see §7.7 for a complete table up to degree 10.)

7.5 Random Sequences Based on Data Encryption

In *Numerical Recipes'* first edition, we described how to use the Data Encryption Standard (DES) [1-3] for the generation of random numbers. Unfortunately, when implemented in software in a high-level language like FORTRAN, DES is very slow, so excruciatingly slow, in fact, that our previous implementation can be viewed as more mischievous than useful. Here we give a much faster and simpler algorithm which, though it may not be secure in the cryptographic sense, generates about equally good random numbers.

DES, like its progenitor cryptographic system LUCIFER, is a so-called "block product cipher" [4]. It acts on 64 bits of input by iteratively applying (16 times, in fact) a kind of highly

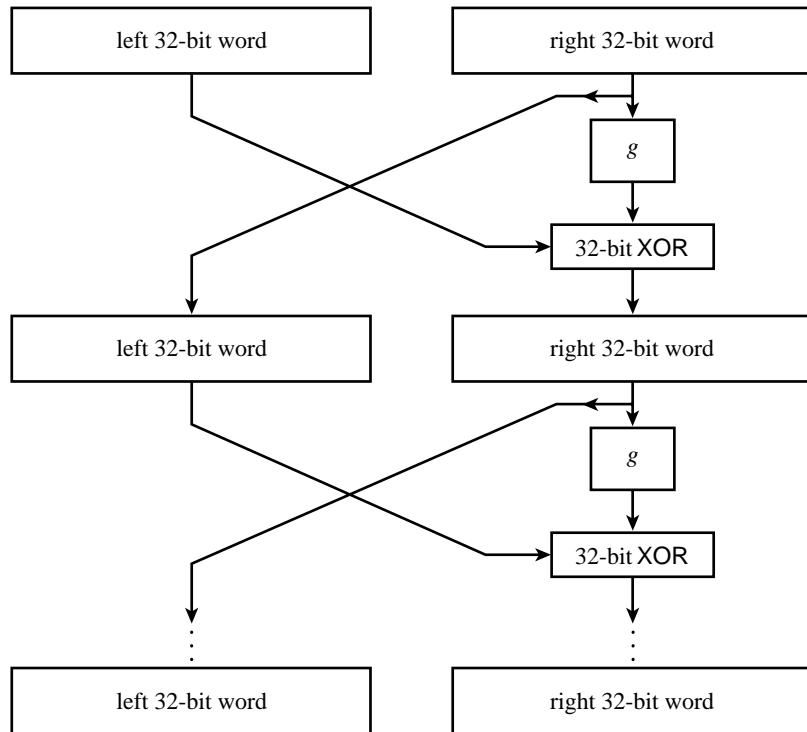

Figure 7.5.1. The Data Encryption Standard (DES) iterates a nonlinear function g on two 32-bit words, in the manner shown here (after Meyer and Matyas [4]).

nonlinear bit-mixing function. Figure 7.5.1 shows the flow of information in DES during this mixing. The function g , which takes 32-bits into 32-bits, is called the “cipher function.” Meyer and Matyas [4] discuss the importance of the cipher function being nonlinear, as well as other design criteria.

DES constructs its cipher function g from an intricate set of bit permutations and table lookups acting on short sequences of consecutive bits. Apparently, this function was chosen to be particularly strong cryptographically (or conceivably as some critics contend, to have an exquisitely subtle cryptographic flaw!). For our purposes, a different function g that can be rapidly computed in a high-level computer language is preferable. Such a function may weaken the algorithm cryptographically. Our purposes are not, however, cryptographic: We want to find the fastest g , and smallest number of iterations of the mixing procedure in Figure 7.5.1, such that our output random sequence passes the standard tests that are customarily applied to random number generators. The resulting algorithm will not be DES, but rather a kind of “pseudo-DES,” better suited to the purpose at hand.

Following the criterion, mentioned above, that g should be nonlinear, we must give the integer multiply operation a prominent place in g . Because 64-bit registers are not generally accessible in high-level languages, we must confine ourselves to multiplying 16-bit operands into a 32-bit result. So, the general idea of g , almost forced, is to calculate the three distinct 32-bit products of the high and low 16-bit input half-words, and then to combine these, and perhaps additional fixed constants, by fast operations (e.g., add or exclusive-or) into a single 32-bit result.

There are only a limited number of ways of effecting this general scheme, allowing systematic exploration of the alternatives. Experimentation, and tests of the randomness of the output, lead to the sequence of operations shown in Figure 7.5.2. The few new elements in the figure need explanation: The values C_1 and C_2 are fixed constants, chosen randomly with the constraint that they have exactly 16 1-bits and 16 0-bits; combining these constants

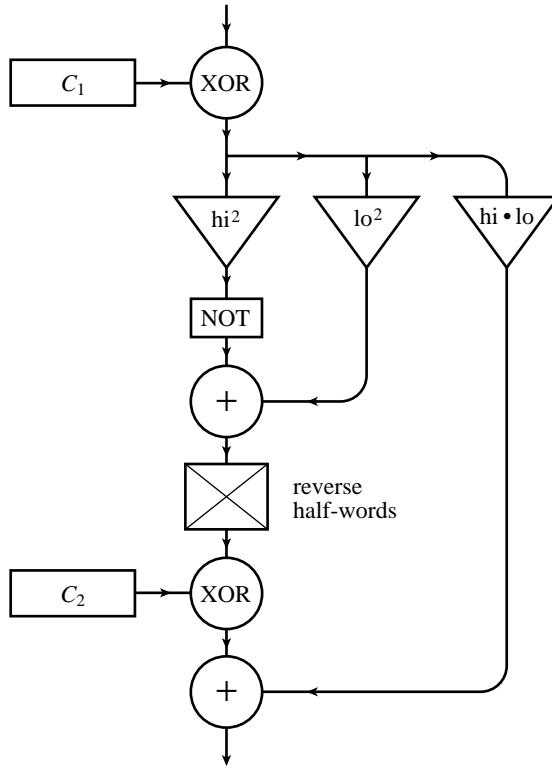

Figure 7.5.2. The nonlinear function g used by the routine `psdes`.

via exclusive-or ensures that the overall g has no bias towards 0 or 1 bits.

The “reverse half-words” operation in Figure 7.5.2 turns out to be essential; otherwise, the very lowest and very highest bits are not properly mixed by the three multiplications. The nonobvious choices in g are therefore: where along the vertical “pipeline” to do the reverse; in what order to combine the three products and C_2 ; and with which operation (add or exclusive-or) should each combining be done? We tested these choices exhaustively before settling on the algorithm shown in the figure.

It remains to determine the smallest number of iterations N_{it} that we can get away with. The minimum meaningful N_{it} is evidently two, since a single iteration simply moves one 32-bit word without altering it. One can use the constants C_1 and C_2 to help determine an appropriate N_{it} : When $N_{it} = 2$ and $C_1 = C_2 = 0$ (an intentionally very poor choice), the generator fails several tests of randomness by easily measurable, though not overwhelming, amounts. When $N_{it} = 4$, on the other hand, or with $N_{it} = 2$ but with the constants C_1, C_2 nonsparse, we have been unable to find *any* statistical deviation from randomness in sequences of up to 10^9 floating numbers r_i derived from this scheme. The combined strength of $N_{it} = 4$ and nonsparse C_1, C_2 should therefore give sequences that are random to tests even far beyond those that we have actually tried. These are our recommended conservative parameter values, notwithstanding the fact that $N_{it} = 2$ (which is, of course, twice as fast) has no nonrandomness discernible (by us).

We turn now to implementation. The nonlinear function shown in Figure 7.5.2 is not implementable in strictly portable FORTRAN, for at least three reasons: (1) The addition of two 32-bit integers may overflow, and the multiplication of two 16-bit integers may not produce the correct 32-bit product because of sign-bit conventions. We intend that the overflow be ignored, and that the 16-bit integers be multiplied as if they are positive. It is possible to force this behavior on most machines. (2) We assume 32-bit integers; however, there

is no reason to believe that *longer* integers would be in any way inferior (with suitable extensions of the constants C_1, C_2). (3) Your compiler may require a different notation for hex constants (see below).

We have been able to run the following routine, `psdes`, successfully on machines ranging from PCs to VAXes and both “big-endian” and “little-endian” UNIX workstations. (Big- and little-endian refer to the order in which the bytes are stored in a word.) A strictly portable implementation is possible in C. If all else fails, you can make a FORTRAN-callable version of the C routine, found in *Numerical Recipes in C*.

```
SUBROUTINE psdes(lword,irword)
INTEGER irword,lword,NITER
PARAMETER (NITER=4)
  "Pseudo-DES" hashing of the 64-bit word (lword,irword). Both 32-bit arguments are
  returned hashed on all bits. NOTE: This routine assumes that arbitrary 32-bit integers can
  be added without overflow. To accomplish this, you may need to compile with a special
  directive (e.g., /check=nooverflow for VMS). In other languages, such as C, one can
  instead type the integers as "unsigned."
  INTEGER i,ia,ib,iswap,itmph,itmpl,c1(4),c2(4)
  SAVE c1,c2
  DATA c1 /Z'BA96887',Z'1E17D32C',Z'03BCDC3C',
*           Z'0F33D1B2', c2 /Z'4B0F3B58',Z'E874F0C3',
*           Z'6955C5A6', Z'55A7CA46'/                                Your compiler may use a differ-
*                                         ent notation for hex constants!
*                                         do ii i=1,NITER          Perform niter iterations of DES logic, using a simpler (non-
                                         iswap=irword          cryptographic) nonlinear function instead of DES's.
                                         ia=ieor(irword,c1(i))  The bit-rich constants c1 and (below) c2 guarantee lots of
                                         itmpl=iand(ia,65535)    nonlinear mixing.
                                         itmph=ishft(ia,-16),65535
                                         ib=itmpl**2+not(itmph**2)
                                         ia=ior(ishft(ib,16),iand(ishft(ib,-16),65535))
                                         irword=ieor(lword,ieor(c2(i),ia)+itmpl*itmph)
                                         lword=iswap
  enddo ii
  return
END
```

The routine `ran4`, listed below, uses `psdes` to generate uniform random deviates. We adopt the convention that a negative value of the argument `idum` sets the left 32-bit word, while a positive value i sets the right 32-bit word, returns the i th random deviate, and increments `idum` to $i + 1$. This is no more than a convenient way of defining many different sequences (negative values of `idum`), but still with random access to each sequence (positive values of `idum`). For getting a floating-point number from the 32-bit integer, we like to do it by the masking trick described at the end of §7.1, above. The hex constants 3F800000 and 007FFFFF are the appropriate ones for computers using the IEEE representation for 32-bit floating-point numbers (e.g., IBM PCs and most UNIX workstations). For DEC VAXes, the correct hex constants are, respectively, 00004080 and FFFF007F. Note that your compiler may require a different notation for hex constants, e.g., x'3f800000', '3F800000'X, or even 16#3F800000. For greater portability, you can instead construct a floating number by making the (signed) 32-bit integer nonnegative (typically, you add exactly 2^{31} if it is negative) and then multiplying it by a floating constant (typically 2^{-31}).

An interesting, and sometimes useful, feature of the routine `ran4`, below, is that it allows random access to the n th random value in a sequence, without the necessity of first generating values $1 \dots n - 1$. This property is shared by any random number generator based on *hashing* (the technique of mapping data keys, which may be highly clustered in value, approximately uniformly into a storage address space) [5,6]. One might have a simulation problem in which some certain rare situation becomes recognizable by its consequences only considerably after it has occurred. One may wish to restart the simulation back at that occurrence, using identical random values but, say, varying some other control parameters. The relevant question might then be something like “what random numbers were used in cycle number 337098901?” It might already be cycle number 395100273 before the question comes up. Random generators based on recursion, rather than hashing, cannot easily answer such a question.

Values for Verifying the Implementation of psdes						
idum	before psdes call		after psdes call (hex)		ran4(idum)	
	lword	irword	lword	irword	VAX	PC
-1	1	1	604D1DCE	509C0C23	0.275898	0.219120
99	1	99	D97F8571	A66CB41A	0.208204	0.849246
-99	99	1	7822309D	64300984	0.034307	0.375290
99	99	99	D7F376F0	59BA89EB	0.838676	0.457334

Successive calls to ran4 with arguments -1, 99, -99, and 99 should produce exactly the lword and irword values shown. Masking conversion to a returned floating random value is allowed to be machine dependent; values for VAX and PC are shown.

```

FUNCTION ran4(idum)
INTEGER idum
REAL ran4
C USES psdes
    Returns a uniform random deviate in the range 0.0 to 1.0, generated by pseudo-DES (DES-like) hashing of the 64-bit word (idums, idum), where idums was set by a previous call with negative idum. Also increments idum. Routine can be used to generate a random sequence by successive calls, leaving idum unaltered between calls; or it can randomly access the nth deviate in a sequence by calling with idum = n. Different sequences are initialized by calls with differing negative values of idum.
INTEGER idums,irword,itemp,jflmsk,jflone,lword
REAL ftemp
EQUIVALENCE (itemp,ftemp)
SAVE idums,jflone,jflmsk
DATA idums /0/, jflone /Z'3F800000'/, jflmsk /Z'007FFFFF'/
    The hexadecimal constants jflone and jflmsk are used to produce a floating number between 1. and 2. by bitwise masking. They are machine-dependent. See text.
if(idum.lt.0)then
    idums=-idum
    idum=1
endif
irword=idum
lword=idums
call psdes(lword,irword)
itemp=ior(jflone,iand(jflmsk,irword))
ran4=ftemp-1.0
idum=idum+1
return
END

```

The accompanying table gives data for verifying that ran4 and psdes work correctly on your machine. We do not advise the use of ran4 unless you are able to reproduce the hex values shown. Typically, ran4 is about 4 times slower than ran0 (§7.1), or about 3 times slower than ran1.

7.6 Simple Monte Carlo Integration

Inspirations for numerical methods can spring from unlikely sources. “Splines” first were flexible strips of wood used by draftsmen. “Simulated annealing” (we shall see in §10.9) is rooted in a thermodynamic analogy. And who does not feel at least a faint echo of glamor in the name “Monte Carlo method”?

Suppose that we pick N random points, uniformly distributed in a multidimensional volume V . Call them x_1, \dots, x_N . Then the basic theorem of Monte Carlo integration estimates the integral of a function f over the multidimensional volume,

$$\int f \, dV \approx V \langle f \rangle \pm V \sqrt{\frac{\langle f^2 \rangle - \langle f \rangle^2}{N}} \quad (7.6.1)$$

Here the angle brackets denote taking the arithmetic mean over the N sample points,

$$\langle f \rangle \equiv \frac{1}{N} \sum_{i=1}^N f(x_i) \quad \langle f^2 \rangle \equiv \frac{1}{N} \sum_{i=1}^N f^2(x_i) \quad (7.6.2)$$

The “plus-or-minus” term in (7.6.1) is a one standard deviation error estimate for the integral, not a rigorous bound; further, there is no guarantee that the error is distributed as a Gaussian, so the error term should be taken only as a rough indication of probable error.

Suppose that you want to integrate a function g over a region W that is not easy to sample randomly. For example, W might have a very complicated shape. No problem. Just find a region V that *includes* W and that *can* easily be sampled (Figure 7.6.1), and then define f to be equal to g for points in W and equal to zero for points outside of W (but still inside the sampled V). You want to try to make V enclose W as closely as possible, because the zero values of f will increase the error estimate term of (7.6.1). And well they should: points chosen outside of W have no information content, so the effective value of N , the number of points, is reduced. The error estimate in (7.6.1) takes this into account.

General purpose routines for Monte Carlo integration are quite complicated (see §7.8), but a worked example will show the underlying simplicity of the method. Suppose that we want to find the weight and the position of the center of mass of an

7.6 Simple Monte Carlo Integration

Inspirations for numerical methods can spring from unlikely sources. “Splines” first were flexible strips of wood used by draftsmen. “Simulated annealing” (we shall see in §10.9) is rooted in a thermodynamic analogy. And who does not feel at least a faint echo of glamor in the name “Monte Carlo method”?

Suppose that we pick N random points, uniformly distributed in a multidimensional volume V . Call them x_1, \dots, x_N . Then the basic theorem of Monte Carlo integration estimates the integral of a function f over the multidimensional volume,

$$\int f \, dV \approx V \langle f \rangle \pm V \sqrt{\frac{\langle f^2 \rangle - \langle f \rangle^2}{N}} \quad (7.6.1)$$

Here the angle brackets denote taking the arithmetic mean over the N sample points,

$$\langle f \rangle \equiv \frac{1}{N} \sum_{i=1}^N f(x_i) \quad \langle f^2 \rangle \equiv \frac{1}{N} \sum_{i=1}^N f^2(x_i) \quad (7.6.2)$$

The “plus-or-minus” term in (7.6.1) is a one standard deviation error estimate for the integral, not a rigorous bound; further, there is no guarantee that the error is distributed as a Gaussian, so the error term should be taken only as a rough indication of probable error.

Suppose that you want to integrate a function g over a region W that is not easy to sample randomly. For example, W might have a very complicated shape. No problem. Just find a region V that *includes* W and that *can* easily be sampled (Figure 7.6.1), and then define f to be equal to g for points in W and equal to zero for points outside of W (but still inside the sampled V). You want to try to make V enclose W as closely as possible, because the zero values of f will increase the error estimate term of (7.6.1). And well they should: points chosen outside of W have no information content, so the effective value of N , the number of points, is reduced. The error estimate in (7.6.1) takes this into account.

General purpose routines for Monte Carlo integration are quite complicated (see §7.8), but a worked example will show the underlying simplicity of the method. Suppose that we want to find the weight and the position of the center of mass of an

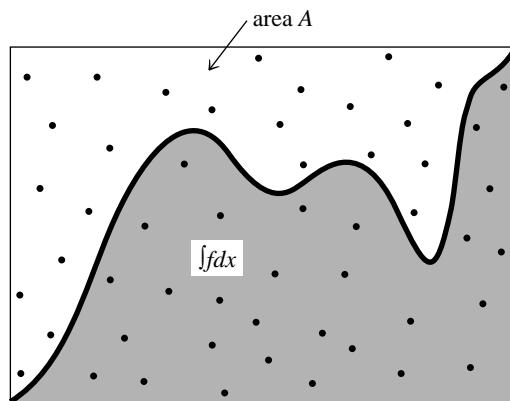

Figure 7.6.1. Monte Carlo integration. Random points are chosen within the area A . The integral of the function f is estimated as the area of A multiplied by the fraction of random points that fall below the curve f . Refinements on this procedure can improve the accuracy of the method; see text.

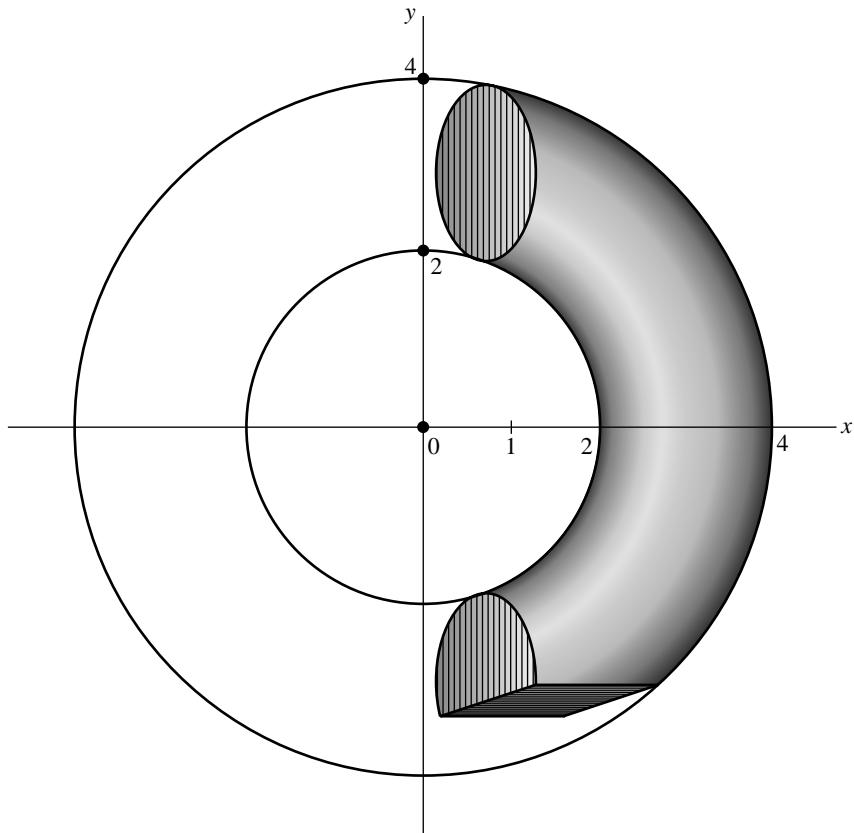

Figure 7.6.2. Example of Monte Carlo integration (see text). The region of interest is a piece of a torus, bounded by the intersection of two planes. The limits of integration of the region cannot easily be written in analytically closed form, so Monte Carlo is a useful technique.

object of complicated shape, namely the intersection of a torus with the edge of a large box. In particular let the object be defined by the three simultaneous conditions

$$z^2 + \left(\sqrt{x^2 + y^2} - 3 \right)^2 \leq 1 \quad (7.6.3)$$

(torus centered on the origin with major radius = 4, minor radius = 2)

$$x \geq 1 \quad y \geq -3 \quad (7.6.4)$$

(two faces of the box, see Figure 7.6.2). Suppose for the moment that the object has a constant density ρ .

We want to estimate the following integrals over the interior of the complicated object:

$$\int \rho \, dx \, dy \, dz \quad \int x\rho \, dx \, dy \, dz \quad \int y\rho \, dx \, dy \, dz \quad \int z\rho \, dx \, dy \, dz \quad (7.6.5)$$

The coordinates of the center of mass will be the ratio of the latter three integrals (linear moments) to the first one (the weight).

In the following fragment, the region V , enclosing the piece-of-torus W , is the rectangular box extending from 1 to 4 in x , -3 to 4 in y , and -1 to 1 in z .

dz=vol*sqrt((varz/n-(swz/n)**2)/n)
and their corresponding error estimates.

```

A change of variable can often be extremely worthwhile in Monte Carlo integration. Suppose, for example, that we want to evaluate the same integrals, but for a piece-of-torus whose density is a strong function of z , in fact varying according to

$$\rho(x, y, z) = e^{5z} \quad (7.6.6)$$

One way to do this is to put the statement

```
den=exp(5.*z)
```

inside the `if . . . then` block, just before `den` is first used. This will work, but it is a poor way to proceed. Since (7.6.6) falls so rapidly to zero as z decreases (down to its lower limit -1), most sampled points contribute almost nothing to the sum of the weight or moments. These points are effectively wasted, almost as badly as those that fall outside of the region W . A change of variable, exactly as in the transformation methods of §7.2, solves this problem. Let

$$ds = e^{5z} dz \quad \text{so that} \quad s = \frac{1}{5}e^{5z}, \quad z = \frac{1}{5} \ln(5s) \quad (7.6.7)$$

Then $\rho dz = ds$, and the limits $-1 < z < 1$ become $.00135 < s < 29.682$. The program fragment now looks like this

```
n=                                         Set to the number of sample points desired.

```

If you think for a minute, you will realize that equation (7.6.7) was useful only because the part of the integrand that we wanted to eliminate (e^{5z}) was both integrable analytically, and had an integral that could be analytically inverted. (Compare §7.2.) In general these properties will not hold. Question: What then? Answer: Pull out of the integrand the “best” factor that *can* be integrated and inverted. The criterion for “best” is to try to reduce the remaining integrand to a function that is as close as possible to constant.

The limiting case is instructive: If you manage to make the integrand f *exactly* constant, and if the region V , of known volume, *exactly* encloses the desired region W , then the average of f that you compute will be exactly its constant value, and the error estimate in equation (7.6.1) will exactly vanish. You will, in fact, have done the integral exactly, and the Monte Carlo numerical evaluations are superfluous. So, backing off from the extreme limiting case, *to the extent* that you are able to make f approximately constant by change of variable, and *to the extent* that you can sample a region only slightly larger than W , you will increase the accuracy of the Monte Carlo integral. This technique is generically called *reduction of variance* in the literature.

The fundamental disadvantage of simple Monte Carlo integration is that its accuracy increases only as the square root of N , the number of sampled points. If your accuracy requirements are modest, or if your computer budget is large, then the technique is highly recommended as one of great generality. In the next two sections we will see that there are techniques available for “breaking the square root of N barrier” and achieving, at least in some cases, higher accuracy with fewer function evaluations.

7.7 Quasi- (that is, Sub-) Random Sequences

We have just seen that choosing N points uniformly randomly in an n -dimensional space leads to an error term in Monte Carlo integration that decreases as $1/\sqrt{N}$. In essence, each new point sampled adds linearly to an accumulated sum that will become the function average, and also linearly to an accumulated sum of squares that will become the variance (equation 7.6.2). The estimated error comes from the square root of this variance, hence the power $N^{-1/2}$.

Just because this square root convergence is familiar does not, however, mean that it is inevitable. A simple counterexample is to choose sample points that lie on a Cartesian grid, and to sample each grid point exactly once (in whatever order). The Monte Carlo method thus becomes a deterministic quadrature scheme — albeit a simple one — whose fractional error decreases at least as fast as N^{-1} (even faster if the function goes to zero smoothly at the boundaries of the sampled region, or is periodic in the region).

If you think for a minute, you will realize that equation (7.6.7) was useful only because the part of the integrand that we wanted to eliminate (e^{5z}) was both integrable analytically, and had an integral that could be analytically inverted. 7.7 Quasi- (that is, Sub-) Random Sequences

We have just seen that choosing N points uniformly randomly in an n -dimensional space leads to an error term in Monte Carlo integration that decreases as $1/\sqrt{N}$. In essence, each new point sampled adds linearly to an accumulated sum that will become the function average, and also linearly to an accumulated sum of squares that will become the variance (equation 7.6.2). The estimated error comes from the square root of this variance, hence the power $N^{-1/2}$.

Just because this square root convergence is familiar does not, however, mean that it is inevitable. A simple counterexample is to choose sample points that lie on a Cartesian grid, and to sample each grid point exactly once (in whatever order). The Monte Carlo method thus becomes a deterministic quadrature scheme — albeit a simple one — whose fractional error decreases at least as fast as N^{-1} (even faster if the function goes to zero smoothly at the boundaries of the sampled region, or is periodic in the region).

The trouble with a grid is that one has to decide *in advance* how fine it should be. One is then committed to completing all of its sample points. With a grid, it is not convenient to “sample *until*” some convergence or termination criterion is met. One might ask if there is not some intermediate scheme, some way to pick sample points “at random,” yet spread out in some self-avoiding way, avoiding the chance clustering that occurs with uniformly random points.

A similar question arises for tasks other than Monte Carlo integration. We might want to search an n -dimensional space for a point where some (locally computable) condition holds. Of course, for the task to be computationally meaningful, there had better be continuity, so that the desired condition will hold in some finite n -dimensional neighborhood. We may not know *a priori* how large that neighborhood is, however. We want to “sample *until*” the desired point is found, moving smoothly to finer scales with increasing samples. Is there any way to do this that is better than uncorrelated, random samples?

The answer to the above question is “yes.” Sequences of n -tuples that fill n -space more uniformly than uncorrelated random points are called *quasi-random sequences*. That term is somewhat of a misnomer, since there is nothing “random” about quasi-random sequences: They are cleverly crafted to be, in fact, *sub-random*. The sample points in a quasi-random sequence are, in a precise sense, “maximally avoiding” of each other.

A conceptually simple example is *Halton’s sequence* [1]. In one dimension, the j th number H_j in the sequence is obtained by the following steps: (i) Write j as a number in base b , where b is some prime. (For example $j = 17$ in base $b = 3$ is 122.) (ii) Reverse the digits and put a radix point (i.e., a decimal point base b) in front of the sequence. (In the example, we get 0.221 base 3.) The result is H_j . To get a sequence of n -tuples in n -space, you make each component a Halton sequence with a different prime base b . Typically, the first n primes are used.

It is not hard to see how Halton’s sequence works: Every time the number of digits in j increases by one place, j ’s digit-reversed fraction becomes a factor of b finer-meshed. Thus the process is one of filling in all the points on a sequence of finer and finer Cartesian grids — and in a kind of maximally spread-out order on each grid (since, e.g., the most rapidly changing digit in j controls the *most significant digit* of the fraction).

Other ways of generating quasi-random sequences have been suggested by Faure, Sobol’, Niederreiter, and others. Bratley and Fox [2] provide a good review and references, and discuss a particularly efficient variant of the Sobol’ [3] sequence suggested by Antonov and Saleev [4]. It is this Antonov-Saleev variant whose implementation we now discuss.

The Sobol’ sequence generates numbers between zero and one directly as binary fractions of length w bits, from a set of w special binary fractions, V_i , $i = 1, 2, \dots, w$, called *direction numbers*. In Sobol’s original method, the j th number X_j is generated by XORing (bitwise exclusive or) together the set of V_i ’s satisfying the criterion on i , “the i th bit of j is nonzero.” As j increments, in other words, different ones of the V_i ’s flash in and out of X_j on different time scales. V_1 alternates between being present and absent most quickly, while V_k goes from present to absent (or vice versa) only every 2^{k-1} steps.

Antonov and Saleev’s contribution was to show that instead of using the bits of the integer j to select direction numbers, one could just as well use the bits of the *Gray code* of j , $G(j)$. (For a quick review of Gray codes, look at §20.2.)

Now $G(j)$ and $G(j + 1)$ differ in exactly one bit position, namely in the position of the

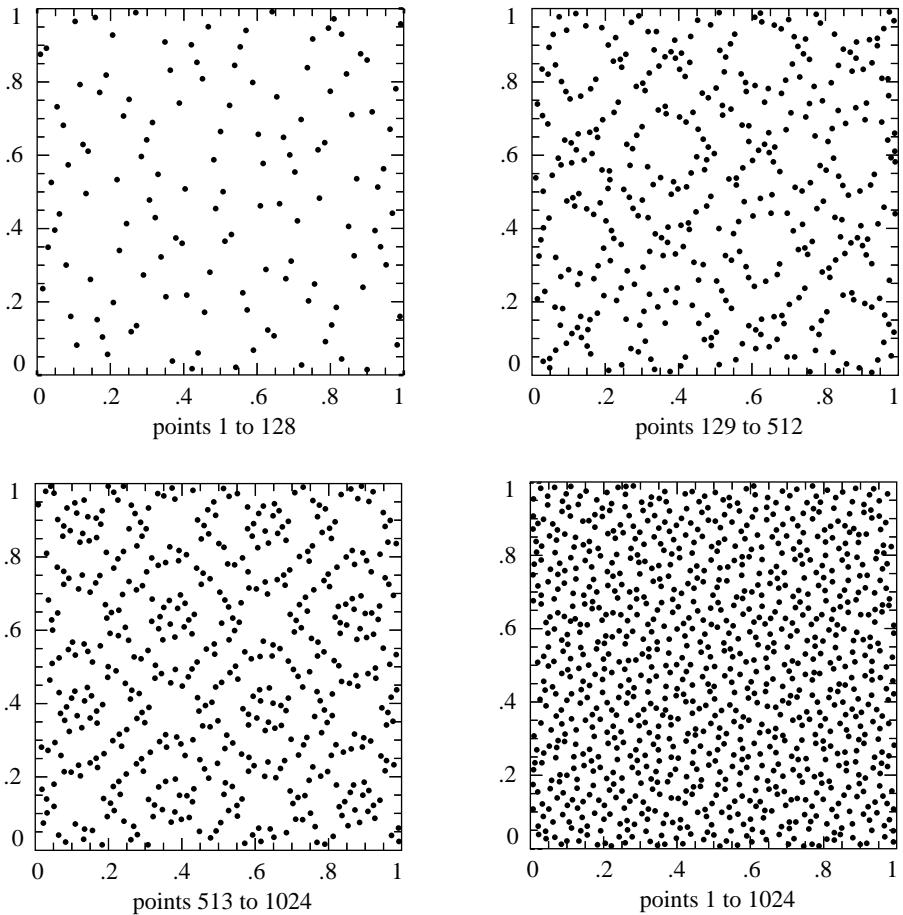

Figure 7.7.1. First 1024 points of a two-dimensional Sobol' sequence. The sequence is generated number-theoretically, rather than randomly, so successive points at any stage “know” how to fill in the gaps in the previously generated distribution.

rightmost zero bit in the binary representation of j (adding a leading zero to j if necessary). A consequence is that the $j + 1$ st Sobol'-Antonov-Saleev number can be obtained from the j th by XORing it with a single V_i , namely with i the position of the rightmost zero bit in j . This makes the calculation of the sequence very efficient, as we shall see.

Figure 7.7.1 plots the first 1024 points generated by a two-dimensional Sobol' sequence. One sees that successive points do “know” about the gaps left previously, and keep filling them in, hierarchically.

We have deferred to this point a discussion of how the direction numbers V_i are generated. Some nontrivial mathematics is involved in that, so we will content ourselves with a cookbook summary only: Each different Sobol' sequence (or component of an n -dimensional sequence) is based on a different primitive polynomial over the integers modulo 2, that is, a polynomial whose coefficients are either 0 or 1, and which generates a maximal length shift register sequence. (Primitive polynomials modulo 2 were used in §7.4, and are further discussed in §20.3.) Suppose P is such a polynomial, of degree q ,

$$P = x^q + a_1 x^{q-1} + a_2 x^{q-2} + \cdots + a_{q-1} x + 1 \quad (7.7.1)$$

Degree	Primitive Polynomials Modulo 2*

10	4, 13, 19, 22, 50, 55, 64, 69, 98, 107, 115, 121, 127, 134, 140, 145, 152, 158, 161, 171, 181, 194, 199, 203, 208, 227, 242, 251, 253, 265, 266, 274, 283, 289, 295, 301, 316, 319, 324, 346, 352, 361, 367, 382, 395, 398, 400, 412, 419, 422, 426, 428, 433, 446, 454, 457, 472, 493, 505, 508
*Expressed as a decimal integer representing the interior bits (that is, omitting the high-order bit and the unit bit).	

Define a sequence of integers M_i by the q -term recurrence relation,

$$M_i = 2a_1 M_{i-1} \oplus 2^2 a_2 M_{i-2} \oplus \cdots \oplus 2^{q-1} a_{q-1} M_{i-q+1} \oplus (2^q M_{i-q} \oplus M_{i-q}) \quad (7.7.2)$$

Here bitwise XOR is denoted by \oplus . The starting values for this recurrence are that M_1, \dots, M_q can be arbitrary odd integers less than $2, \dots, 2^q$, respectively. Then, the direction numbers V_i are given by

$$V_i = M_i / 2^i \quad i = 1, \dots, w \quad (7.7.3)$$

The accompanying table lists all primitive polynomials modulo 2 with degree $q \leq 10$. Since the coefficients are either 0 or 1, and since the coefficients of x^q and of 1 are predictably 1, it is convenient to denote a polynomial by its middle coefficients taken as the bits of a binary number (higher powers of x being more significant bits). The table uses this convention.

Turn now to the implementation of the Sobol' sequence. Successive calls to the function `sobseq` (after a preliminary initializing call) return successive points in an n -dimensional Sobol' sequence based on the first n primitive polynomials in the table. As given, the routine is initialized for maximum n of 6 dimensions, and for a word length w of 30 bits. These parameters can be altered by changing `MAXBIT` ($\equiv w$) and `MAXDIM`, and by adding more initializing data to the arrays `ip` (the primitive polynomials from the table), `mdeg` (their degrees), and `iv` (the starting values for the recurrence, equation 7.7.2). A second table, below, elucidates the initializing data in the routine.

```
SUBROUTINE sobseq(n,x)
INTEGER n,MAXBIT,MAXDIM
REAL x(*)
PARAMETER (MAXBIT=30,MAXDIM=6)
```

When n is negative, internally initializes a set of `MAXBIT` direction numbers for each of `MAXDIM` different Sobol' sequences. When n is positive (but $\leq MAXDIM$), returns as the

How good is a Sobol' sequence, anyway? For Monte Carlo integration of a smooth function in n dimensions, the answer is that the fractional error will decrease with N , the number of samples, as $(\ln N)^n/N$, i.e., almost as fast as $1/N$. As an example, let us integrate a function that is nonzero inside a torus (doughnut) in three-dimensional space. If the major radius of the torus is R_0 , the minor radial coordinate r is defined by

$$r = \left([(x^2 + y^2)^{1/2} - R_0]^2 + z^2 \right)^{1/2} \quad (7.7.4)$$

Let us try the function

$$f(x, y, z) = \begin{cases} 1 + \cos\left(\frac{\pi r^2}{a^2}\right) & r < r_0 \\ 0 & r \geq r_0 \end{cases} \quad (7.7.5)$$

which can be integrated analytically in cylindrical coordinates, giving

$$\int \int \int dx dy dz f(x, y, z) = 2\pi^2 a^2 R_0 \quad (7.7.6)$$

With parameters $R_0 = 0.6$, $r_0 = 0.3$, we did 100 successive Monte Carlo integrations of equation (7.7.4), sampling uniformly in the region $-1 < x, y, z < 1$, for the two cases of uncorrelated random points and the Sobol' sequence generated by the routine `sobseq`. Figure 7.7.2 shows the results, plotting the r.m.s. average error of the 100 integrations as a function of the number of points sampled. (For any *single* integration, the error of course wanders from positive to negative, or vice versa, so a logarithmic plot of fractional error is not very informative.) The thin, dashed curve corresponds to uncorrelated random points and shows the familiar $N^{-1/2}$ asymptotics. The thin, solid gray curve shows the result for the Sobol' sequence. The logarithmic term in the expected $(\ln N)^3/N$ is readily apparent as curvature in the curve, but the asymptotic N^{-1} is unmistakable.

To understand the importance of Figure 7.7.2, suppose that a Monte Carlo integration of f with 1% accuracy is desired. The Sobol' sequence achieves this accuracy in a few thousand samples, while pseudorandom sampling requires nearly 100,000 samples. The ratio would be even greater for higher desired accuracies.

A different, not quite so favorable, case occurs when the function being integrated has hard (discontinuous) boundaries inside the sampling region, for example the function that is one inside the torus, zero outside,

$$f(x, y, z) = \begin{cases} 1 & r < r_0 \\ 0 & r \geq r_0 \end{cases} \quad (7.7.7)$$

where r is defined in equation (7.7.4). Not by coincidence, this function has the same analytic integral as the function of equation (7.7.5), namely $2\pi^2 a^2 R_0$.

The carefully hierarchical Sobol' sequence is based on a set of Cartesian grids, but the boundary of the torus has no particular relation to those grids. The result is that it is essentially random whether sampled points in a thin layer at the surface of the torus, containing on the order of $N^{2/3}$ points, come out to be inside, or outside, the torus. The square root law, applied to this thin layer, gives $N^{1/3}$ fluctuations in the sum, or $N^{-2/3}$ fractional error in the Monte Carlo integral. One sees this behavior verified in Figure 7.7.2 by the thicker gray curve. The thicker dashed curve in Figure 7.7.2 is the result of integrating the function of equation (7.7.7) using independent random points. While the advantage of the Sobol' sequence is not quite so dramatic as in the case of a smooth function, it can nonetheless be a significant factor (~ 5) even at modest accuracies like 1%, and greater at higher accuracies.

Note that we have not provided the routine `sobseq` with a means of starting the sequence at a point other than the beginning, but this feature would be easy to add. Once the initialization of the direction numbers `iv` has been done, the j th point can be obtained directly by XORing together those direction numbers corresponding to nonzero bits in the Gray code of j , as described above.

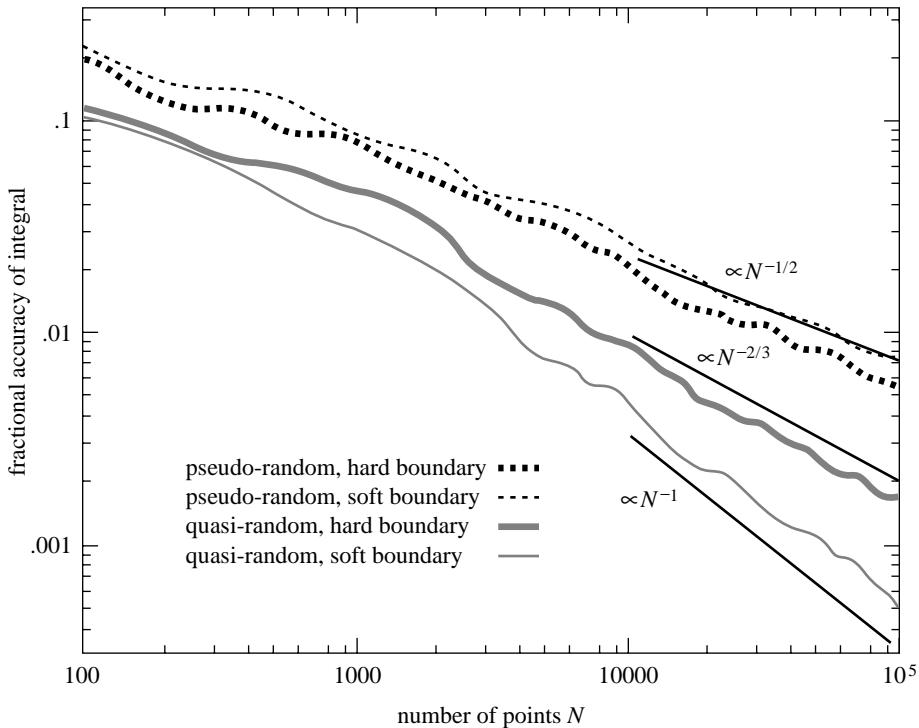

Figure 7.7.2. Fractional accuracy of Monte Carlo integrations as a function of number of points sampled, for two different integrands and two different methods of choosing random points. The quasi-random Sobol' sequence converges much more rapidly than a conventional pseudo-random sequence. Quasi-random sampling does better when the integrand is smooth ("soft boundary") than when it has step discontinuities ("hard boundary"). The curves shown are the r.m.s. average of 100 trials.

The Latin Hypercube

We might here give passing mention the unrelated technique of *Latin square* or *Latin hypercube* sampling, which is useful when you must sample an N -dimensional space *exceedingly* sparsely, at M points. For example, you may want to test the crashworthiness of cars as a simultaneous function of 4 different design parameters, but with a budget of only three expendable cars. (The issue is not whether this is a good plan — it isn't — but rather how to make the best of the situation!)

The idea is to partition each design parameter (dimension) into M segments, so that the whole space is partitioned into M^N cells. (You can choose the segments in each dimension to be equal or unequal, according to taste.) With 4 parameters and 3 cars, for example, you end up with $3 \times 3 \times 3 \times 3 = 81$ cells.

Next, choose M cells to contain the sample points by the following algorithm: Randomly choose one of the M^N cells for the first point. Now eliminate all cells that agree with this point on *any* of its parameters (that is, cross out all cells in the same row, column, etc.), leaving $(M - 1)^N$ candidates. Randomly choose one of these, eliminate new rows and columns, and continue the process until there is only one cell left, which then contains the final sample point.

The result of this construction is that *each* design parameter will have been tested in *every one* of its subranges. If the response of the system under test is

dominated by *one* of the design parameters, that parameter will be found with this sampling technique. On the other hand, if there is an important interaction among different design parameters, then the Latin hypercube gives no particular advantage. Use with care.

7.8 Adaptive and Recursive Monte Carlo Methods

This section discusses more advanced techniques of Monte Carlo integration. As examples of the use of these techniques, we include two rather different, fairly sophisticated, multidimensional Monte Carlo codes: `vegas` [1,2], and `miser` [3]. The techniques that we discuss all fall under the general rubric of *reduction of variance* (§7.6), but are otherwise quite distinct.

Importance Sampling

The use of *importance sampling* was already implicit in equations (7.6.6) and (7.6.7). We now return to it in a slightly more formal way. Suppose that an integrand f can be written as the product of a function h that is almost constant times another, positive, function g . Then its integral over a multidimensional volume V is

$$\int f \, dV = \int (f/g) \, gdV = \int h \, gdV \quad (7.8.1)$$

In equation (7.6.7) we interpreted equation (7.8.1) as suggesting a change of variable to G , the indefinite integral of g . That made gdV a perfect differential. We then proceeded to use the basic theorem of Monte Carlo integration, equation (7.6.1). A more general interpretation of equation (7.8.1) is that we can integrate f by instead sampling h — not, however, with uniform probability density dV , but rather with nonuniform density gdV . In this second interpretation, the first interpretation follows as the special case, where the *means* of generating the nonuniform sampling of gdV is via the transformation method, using the indefinite integral G (see §7.2).

More directly, one can go back and generalize the basic theorem (7.6.1) to the case of nonuniform sampling: Suppose that points x_i are chosen within the volume V with a probability density p satisfying

$$\int p \, dV = 1 \quad (7.8.2)$$

dominated by *one* of the design parameters, that parameter will be found with this sampling technique. On the other hand, if there is an important interaction among different design parameters, then the Latin hypercube gives no particular advantage. Use with care.

7.8 Adaptive and Recursive Monte Carlo Methods

This section discusses more advanced techniques of Monte Carlo integration. As examples of the use of these techniques, we include two rather different, fairly sophisticated, multidimensional Monte Carlo codes: `vegas` [1,2], and `miser` [3]. The techniques that we discuss all fall under the general rubric of *reduction of variance* (§7.6), but are otherwise quite distinct.

Importance Sampling

The use of *importance sampling* was already implicit in equations (7.6.6) and (7.6.7). We now return to it in a slightly more formal way. Suppose that an integrand f can be written as the product of a function h that is almost constant times another, positive, function g . Then its integral over a multidimensional volume V is

$$\int f \, dV = \int (f/g) \, gdV = \int h \, gdV \quad (7.8.1)$$

In equation (7.6.7) we interpreted equation (7.8.1) as suggesting a change of variable to G , the indefinite integral of g . That made gdV a perfect differential. We then proceeded to use the basic theorem of Monte Carlo integration, equation (7.6.1). A more general interpretation of equation (7.8.1) is that we can integrate f by instead sampling h — not, however, with uniform probability density dV , but rather with nonuniform density gdV . In this second interpretation, the first interpretation follows as the special case, where the *means* of generating the nonuniform sampling of gdV is via the transformation method, using the indefinite integral G (see §7.2).

More directly, one can go back and generalize the basic theorem (7.6.1) to the case of nonuniform sampling: Suppose that points x_i are chosen within the volume V with a probability density p satisfying

$$\int p \, dV = 1 \quad (7.8.2)$$

The generalized fundamental theorem is that the integral of any function f is estimated, using N sample points x_1, \dots, x_N , by

$$I \equiv \int f dV = \int \frac{f}{p} pdV \approx \left\langle \frac{f}{p} \right\rangle \pm \sqrt{\frac{\langle f^2/p^2 \rangle - \langle f/p \rangle^2}{N}} \quad (7.8.3)$$

where angle brackets denote arithmetic means over the N points, exactly as in equation (7.6.2). As in equation (7.6.1), the “plus-or-minus” term is a one standard deviation error estimate. Notice that equation (7.6.1) is in fact the special case of equation (7.8.3), with $p = \text{constant} = 1/V$.

What is the best choice for the sampling density p ? Intuitively, we have already seen that the idea is to make $h = f/p$ as close to constant as possible. We can be more rigorous by focusing on the numerator inside the square root in equation (7.8.3), which is the variance per sample point. Both angle brackets are themselves Monte Carlo estimators of integrals, so we can write

$$S \equiv \left\langle \frac{f^2}{p^2} \right\rangle - \left\langle \frac{f}{p} \right\rangle^2 \approx \int \frac{f^2}{p^2} pdV - \left[\int \frac{f}{p} pdV \right]^2 = \int \frac{f^2}{p} dV - \left[\int f dV \right]^2 \quad (7.8.4)$$

We now find the optimal p subject to the constraint equation (7.8.2) by the functional variation

$$0 = \frac{\delta}{\delta p} \left(\int \frac{f^2}{p} dV - \left[\int f dV \right]^2 + \lambda \int p dV \right) \quad (7.8.5)$$

with λ a Lagrange multiplier. Note that the middle term does not depend on p . The variation (which comes inside the integrals) gives $0 = -f^2/p^2 + \lambda$ or

$$p = \frac{|f|}{\sqrt{\lambda}} = \frac{|f|}{\int |f| dV} \quad (7.8.6)$$

where λ has been chosen to enforce the constraint (7.8.2).

If f has one sign in the region of integration, then we get the obvious result that the optimal choice of p — if one can figure out a practical way of effecting the sampling — is that it be proportional to $|f|$. Then the variance is reduced to zero. Not so obvious, but seen to be true, is the fact that $p \propto |f|$ is optimal even if f takes on both signs. In that case the variance per sample point (from equations 7.8.4 and 7.8.6) is

$$S = S_{\text{optimal}} = \left(\int |f| dV \right)^2 - \left(\int f dV \right)^2 \quad (7.8.7)$$

One curiosity is that one can add a constant to the integrand to make it all of one sign, since this changes the integral by a known amount, constant $\times V$. Then, the optimal choice of p always gives zero variance, that is, a perfectly accurate integral! The resolution of this seeming paradox (already mentioned at the end of §7.6) is that perfect knowledge of p in equation (7.8.6) requires perfect knowledge of $\int |f| dV$, which is tantamount to already knowing the integral you are trying to compute!

If your function f takes on a known constant value in most of the volume V , it is certainly a good idea to add a constant so as to make that value zero. Having done that, the accuracy attainable by importance sampling depends in practice not on how small equation (7.8.7) is, but rather on how small is equation (7.8.4) for an *implementable* p , likely only a crude approximation to the ideal.

Stratified Sampling

The idea of *stratified sampling* is quite different from importance sampling. Let us expand our notation slightly and let $\langle\langle f \rangle\rangle$ denote the true average of the function f over the volume V (namely the integral divided by V), while $\langle f \rangle$ denotes as before the simplest (uniformly sampled) Monte Carlo *estimator* of that average:

$$\langle\langle f \rangle\rangle \equiv \frac{1}{V} \int f dV \quad \langle f \rangle \equiv \frac{1}{N} \sum_i f(x_i) \quad (7.8.8)$$

The variance of the estimator, $\text{Var}(\langle f \rangle)$, which measures the square of the error of the Monte Carlo integration, is asymptotically related to the variance of the function, $\text{Var}(f) \equiv \langle\langle f^2 \rangle\rangle - \langle\langle f \rangle\rangle^2$, by the relation

$$\text{Var}(\langle f \rangle) = \frac{\text{Var}(f)}{N} \quad (7.8.9)$$

(compare equation 7.6.1).

Suppose we divide the volume V into two equal, disjoint subvolumes, denoted a and b , and sample $N/2$ points in each subvolume. Then another estimator for $\langle\langle f \rangle\rangle$, different from equation (7.8.8), which we denote $\langle f \rangle'$, is

$$\langle f \rangle' \equiv \frac{1}{2} (\langle f \rangle_a + \langle f \rangle_b) \quad (7.8.10)$$

in other words, the mean of the sample averages in the two half-regions. The variance of estimator (7.8.10) is given by

$$\begin{aligned} \text{Var}(\langle f \rangle') &= \frac{1}{4} [\text{Var}(\langle f \rangle_a) + \text{Var}(\langle f \rangle_b)] \\ &= \frac{1}{4} \left[\frac{\text{Var}_a(f)}{N/2} + \frac{\text{Var}_b(f)}{N/2} \right] \\ &= \frac{1}{2N} [\text{Var}_a(f) + \text{Var}_b(f)] \end{aligned} \quad (7.8.11)$$

Here $\text{Var}_a(f)$ denotes the variance of f in subregion a , that is, $\langle\langle f^2 \rangle\rangle_a - \langle\langle f \rangle\rangle_a^2$, and correspondingly for b .

From the definitions already given, it is not difficult to prove the relation

$$\text{Var}(f) = \frac{1}{2} [\text{Var}_a(f) + \text{Var}_b(f)] + \frac{1}{4} (\langle\langle f \rangle\rangle_a - \langle\langle f \rangle\rangle_b)^2 \quad (7.8.12)$$

(In physics, this formula for combining second moments is the “parallel axis theorem.”) Comparing equations (7.8.9), (7.8.11), and (7.8.12), one sees that the stratified (into two subvolumes) sampling gives a variance that is never larger than the simple Monte Carlo case — and smaller whenever the means of the stratified samples, $\langle\langle f \rangle\rangle_a$ and $\langle\langle f \rangle\rangle_b$, are different.

We have not yet exploited the possibility of sampling the two subvolumes with *different numbers* of points, say N_a in subregion a and $N_b \equiv N - N_a$ in subregion b . Let us do so now. Then the variance of the estimator is

$$\text{Var}(\langle f \rangle') = \frac{1}{4} \left[\frac{\text{Var}_a(f)}{N_a} + \frac{\text{Var}_b(f)}{N - N_a} \right] \quad (7.8.13)$$

which is minimized (one can easily verify) when

$$\frac{N_a}{N} = \frac{\sigma_a}{\sigma_a + \sigma_b} \quad (7.8.14)$$

Here we have adopted the shorthand notation $\sigma_a \equiv [\text{Var}_a(f)]^{1/2}$, and correspondingly for b . If N_a satisfies equation (7.8.14), then equation (7.8.13) reduces to

$$\text{Var}(\langle f \rangle') = \frac{(\sigma_a + \sigma_b)^2}{4N} \quad (7.8.15)$$

Equation (7.8.15) reduces to equation (7.8.9) if $\text{Var}(f) = \text{Var}_a(f) = \text{Var}_b(f)$, in which case stratifying the sample makes no difference.

A standard way to generalize the above result is to consider the volume V divided into more than two equal subregions. One can readily obtain the result that the optimal allocation of sample points among the regions is to have the number of points in each region j proportional to σ_j (that is, the square root of the variance of the function f in that subregion). In spaces of high dimensionality (say $d \gtrsim 4$) this is not in practice very useful, however. Dividing a volume into K segments along each dimension implies K^d subvolumes, typically much too large a number when one contemplates estimating all the corresponding σ_j 's.

Mixed Strategies

Importance sampling and stratified sampling seem, at first sight, inconsistent with each other. The former concentrates sample points where the magnitude of the integrand $|f|$ is largest, that latter where the variance of f is largest. How can both be right?

The answer is that (like so much else in life) it all depends on what you know and how well you know it. Importance sampling depends on already knowing some approximation to your integral, so that you are able to generate random points x_i with the desired probability density p . To the extent that your p is not ideal, you are left with an error that decreases only as $N^{-1/2}$. Things are particularly bad if your p is far from ideal in a region where the integrand f is changing rapidly, since then the sampled function $h = f/p$ will have a large variance. Importance sampling works by smoothing the values of the sampled function h , and is effective only to the extent that you succeed in this.

Stratified sampling, by contrast, does not necessarily require that you know anything about f . Stratified sampling works by smoothing out the fluctuations of the *number* of points in subregions, not by smoothing the values of the points. The simplest stratified strategy, dividing V into N equal subregions and choosing one point randomly in each subregion, already gives a method whose error decreases asymptotically as N^{-1} , much faster than $N^{-1/2}$. (Note that quasi-random numbers, §7.7, are another way of smoothing fluctuations in the density of points, giving nearly as good a result as the “blind” stratification strategy.)

However, “asymptotically” is an important caveat: For example, if the integrand is negligible in all but a single subregion, then the resulting one-sample integration is all but useless. Information, even very crude, allowing importance sampling to put many points in the active subregion would be much better than blind stratified sampling.

Stratified sampling really comes into its own if you have some way of estimating the variances, so that you can put unequal numbers of points in different subregions, according to (7.8.14) or its generalizations, *and* if you can find a way of dividing a region into a practical number of subregions (notably *not* K^d with large dimension d), while yet significantly reducing the variance of the function in each subregion compared to its variance in the full volume. Doing this requires a lot of knowledge about f , though different knowledge from what is required for importance sampling.

In practice, importance sampling and stratified sampling are not incompatible. In many, if not most, cases of interest, the integrand f is small everywhere in V except for a small fractional volume of “active regions.” In these regions the magnitude of $|f|$ and the standard deviation $\sigma = [\text{Var}(f)]^{1/2}$ are comparable in size, so both techniques will give about the same concentration of points. In more sophisticated implementations, it is also possible to “nest” the two techniques, so that (e.g.) importance sampling on a crude grid is followed by stratification within each grid cell.

Adaptive Monte Carlo: VEGAS

The VEGAS algorithm, invented by Peter Lepage [1,2], is widely used for multidimensional integrals that occur in elementary particle physics. VEGAS is primarily based on importance sampling, but it also does some stratified sampling if the dimension d is small enough to avoid K^d explosion (specifically, if $(K/2)^d < N/2$, with N the number of sample

points). The basic technique for importance sampling in VEGAS is to construct, adaptively, a multidimensional weight function g that is *separable*,

$$p \propto g(x, y, z, \dots) = g_x(x)g_y(y)g_z(z) \dots \quad (7.8.16)$$

Such a function avoids the K^d explosion in two ways: (i) It can be stored in the computer as d separate one-dimensional functions, each defined by K tabulated values, say — so that $K \times d$ replaces K^d . (ii) It can be sampled as a probability density by consecutively sampling the d one-dimensional functions to obtain coordinate vector components (x, y, z, \dots) .

The optimal separable weight function can be shown to be [1]

$$g_x(x) \propto \left[\int dy \int dz \dots \frac{f^2(x, y, z, \dots)}{g_y(y)g_z(z) \dots} \right]^{1/2} \quad (7.8.17)$$

(and correspondingly for y, z, \dots). Notice that this reduces to $g \propto |f|$ (7.8.6) in one dimension. Equation (7.8.17) immediately suggests VEGAS' adaptive strategy: Given a set of g -functions (initially all constant, say), one samples the function f , accumulating not only the overall estimator of the integral, but also the Kd estimators (K subdivisions of the independent variable in each of d dimensions) of the right-hand side of equation (7.8.17). These then determine improved g functions for the next iteration.

When the integrand f is concentrated in one, or at most a few, regions in d -space, then the weight function g 's quickly become large at coordinate values that are the projections of these regions onto the coordinate axes. The accuracy of the Monte Carlo integration is then enormously enhanced over what simple Monte Carlo would give.

The weakness of VEGAS is the obvious one: To the extent that the projection of the function f onto individual coordinate directions is uniform, VEGAS gives no concentration of sample points in those dimensions. The worst case for VEGAS, e.g., is an integrand that is concentrated close to a body diagonal line, e.g., one from $(0, 0, 0, \dots)$ to $(1, 1, 1, \dots)$. Since this geometry is completely nonseparable, VEGAS can give no advantage at all. More generally, VEGAS may not do well when the integrand is concentrated in one-dimensional (or higher) curved trajectories (or hypersurfaces), unless these happen to be oriented close to the coordinate directions.

The routine `vegas` that follows is essentially Lepage's standard version, minimally modified to conform to our conventions. (We thank Lepage for permission to reproduce the program here.) For consistency with other versions of the VEGAS algorithm in circulation, we have preserved original variable names. The parameter `NDMX` is what we have called K , the maximum number of increments along each axis; `MXDIM` is the maximum value of d ; some other parameters are explained in the comments.

The `vegas` routine performs $m = \text{itm}x$ statistically independent evaluations of the desired integral, each with $N = \text{ncall}$ function evaluations. While statistically independent, these iterations do assist each other, since each one is used to refine the sampling grid for the next one. The results of all iterations are combined into a single best answer, and its estimated error, by the relations

$$I_{\text{best}} = \sum_{i=1}^m \frac{I_i}{\sigma_i^2} \Bigg/ \sum_{i=1}^m \frac{1}{\sigma_i^2} \quad \sigma_{\text{best}} = \left(\sum_{i=1}^m \frac{1}{\sigma_i^2} \right)^{-1/2} \quad (7.8.18)$$

Also returned is the quantity

$$\chi^2/m \equiv \frac{1}{m-1} \sum_{i=1}^m \frac{(I_i - I_{\text{best}})^2}{\sigma_i^2} \quad (7.8.19)$$

If this is significantly larger than 1, then the results of the iterations are statistically inconsistent, and the answers are suspect.

The input flag `init` can be used to advantage. One might have a call with `init=0, ncall=1000, itm=5` immediately followed by a call with `init=1, ncall=100000, itm=1`. The effect would be to develop a sampling grid over 5 iterations of a small number of samples, then to do a single high accuracy integration on the optimized grid.

Note that the user-supplied integrand function, `fxn`, has an argument `wgt` in addition to the expected evaluation point `x`. In most applications you ignore `wgt` inside the function. Occasionally, however, you may want to integrate some additional function or functions along with the principal function f . The integral of any such function g can be estimated by

$$I_g = \sum_i w_i g(\mathbf{x}) \quad (7.8.20)$$

where the w_i 's and \mathbf{x} 's are the arguments `wgt` and `x`, respectively. It is straightforward to accumulate this sum inside your function `fxn`, and to pass the answer back to your main program via a common block. Of course, $g(\mathbf{x})$ had better resemble the principal function f to some degree, since the sampling will be optimized for f .

```

INTEGER init,itmx,ncall,ndim,npnrn,NDMX,MXDIM
REAL tgral,chi2a,sd,region(2*ndim),fxn,ALPH,TINY
PARAMETER (ALPH=1.5,NDMX=50,MXDIM=10,TINY=1.e-30)
EXTERNAL fxn
C USES fxn,ran2,rebin
    Performs Monte Carlo integration of a user-supplied ndim-dimensional function fxn over
    a rectangular volume specified by region, a 2×ndim vector consisting of ndim "lower left"
    coordinates of the region followed by ndim "upper right" coordinates. The integration
    consists of itmx iterations, each with approximately ncall calls to the function. After each
    iteration the grid is refined; more than 5 or 10 iterations are rarely useful. The input flag
    init signals whether this call is a new start, or a subsequent call for additional iterations
    (see comments below). The input flag npnrn (normally 0) controls the amount of diagnostic
    output. Returned answers are tgral (the best estimate of the integral), sd (its standard
    deviation), and chi2a ( $\chi^2$  per degree of freedom, an indicator of whether consistent results
    are being obtained). See text for further details.

Recursive Stratified Sampling

The problem with stratified sampling, we have seen, is that it may not avoid the K^d explosion inherent in the obvious, Cartesian, tessellation of a d -dimensional volume. A technique called *recursive stratified sampling* [3] attempts to do this by successive bisections of a volume, not along all d dimensions, but rather along only one dimension at a time. The starting points are equations (7.8.10) and (7.8.13), applied to bisections of successively smaller subregions.

Suppose that we have a quota of N evaluations of the function f , and want to evaluate $\langle f \rangle'$ in the rectangular parallelepiped region $R = (\mathbf{x}_a, \mathbf{x}_b)$. (We denote such a region by the two coordinate vectors of its diagonally opposite corners.) First, we allocate a fraction p of N towards exploring the variance of f in R : We sample pN function values uniformly in R and accumulate the sums that will give the d different pairs of variances corresponding to the d different coordinate directions along which R can be bisected. In other words, in pN samples, we estimate $\text{Var}(f)$ in each of the regions resulting from a possible bisection of R ,

$$\begin{aligned} R_{ai} &\equiv (\mathbf{x}_a, \mathbf{x}_b - \frac{1}{2}\mathbf{e}_i \cdot (\mathbf{x}_b - \mathbf{x}_a)\mathbf{e}_i) \\ R_{bi} &\equiv (\mathbf{x}_a + \frac{1}{2}\mathbf{e}_i \cdot (\mathbf{x}_b - \mathbf{x}_a)\mathbf{e}_i, \mathbf{x}_b) \end{aligned} \tag{7.8.21}$$

Here \mathbf{e}_i is the unit vector in the i th coordinate direction, $i = 1, 2, \dots, d$.

Second, we inspect the variances to find the most favorable dimension i to bisect. By equation (7.8.15), we could, for example, choose that i for which the sum of the square roots of the variance estimators in regions R_{ai} and R_{bi} is minimized. (Actually, as we will explain, we do something slightly different.)

Third, we allocate the remaining $(1 - p)N$ function evaluations between the regions R_{ai} and R_{bi} . If we used equation (7.8.15) to choose i , we should do this allocation according to equation (7.8.14).

We now have two parallelepipeds each with its own allocation of function evaluations for estimating the mean of f . Our “RSS” algorithm now shows itself to be *recursive*: To evaluate the mean in each region, we go back to the sentence beginning “First,...” in the paragraph above equation (7.8.21). (Of course, when the allocation of points to a region falls below some number, we resort to simple Monte Carlo rather than continue with the recursion.)

Finally, we combine the means, and also estimated variances of the two subvolumes, using equation (7.8.10) and the first line of equation (7.8.11).

This completes the RSS algorithm in its simplest form. Before we describe some additional tricks under the general rubric of “implementation details,” we need to return briefly to equations (7.8.13)–(7.8.15) and derive the equations that we actually use instead of these. The right-hand side of equation (7.8.13) applies the familiar scaling law of equation (7.8.9) twice, once to a and again to b . This would be correct if the estimates $\langle f \rangle_a$ and $\langle f \rangle_b$ were each made by simple Monte Carlo, with uniformly random sample points. However, the two estimates of the mean are in fact made recursively. Thus, there is no reason to expect equation (7.8.9) to hold. Rather, we might substitute for equation (7.8.13) the relation,

$$\text{Var}(\langle f \rangle') = \frac{1}{4} \left[\frac{\text{Var}_a(f)}{N_a^\alpha} + \frac{\text{Var}_b(f)}{(N - N_a)^\alpha} \right] \quad (7.8.22)$$

where α is an unknown constant ≥ 1 (the case of equality corresponding to simple Monte Carlo). In that case, a short calculation shows that $\text{Var}(\langle f \rangle')$ is minimized when

$$\frac{N_a}{N} = \frac{\text{Var}_a(f)^{1/(1+\alpha)}}{\text{Var}_a(f)^{1/(1+\alpha)} + \text{Var}_b(f)^{1/(1+\alpha)}} \quad (7.8.23)$$

and that its minimum value is

$$\text{Var}(\langle f \rangle') \propto \left[\text{Var}_a(f)^{1/(1+\alpha)} + \text{Var}_b(f)^{1/(1+\alpha)} \right]^{1+\alpha} \quad (7.8.24)$$

Equations (7.8.22)–(7.8.24) reduce to equations (7.8.13)–(7.8.15) when $\alpha = 1$. Numerical experiments to find a self-consistent value for α find that $\alpha \approx 2$. That is, when equation (7.8.23) with $\alpha = 2$ is used recursively to allocate sample opportunities, the observed variance of the RSS algorithm goes approximately as N^{-2} , while any other value of α in equation (7.8.23) gives a poorer fall-off. (The sensitivity to α is, however, not very great; it is not known whether $\alpha = 2$ is an analytically justifiable result, or only a useful heuristic.)

Turn now to the routine, `miser`, which implements the RSS method. A bit of FORTRAN wizardry is its implementation of the required recursion. This is done by dimensioning an array `stack`, and a shorter “stack frame” `stf`; the latter has components that are equivalenced to variables that need to be preserved during the recursion, including a flag indicating where program control should return. A recursive call then consists of copying the stack frame onto the stack, incrementing the stack pointer `jstack`, and transferring control. A recursive return analogously pops the stack and transfers control to the saved location. Stack growth in `miser` is only logarithmic in N , since at each bifurcation one of the subvolumes can be processed immediately.

The principal difference between `miser`’s implementation and the algorithm as described thus far lies in how the variances on the right-hand side of equation (7.8.23) are estimated. We find empirically that it is somewhat more robust to use the square of the difference of maximum and minimum sampled function values, instead of the genuine second moment of the samples. This estimator is of course increasingly biased with increasing sample size; however, equation (7.8.23) uses it only to compare two subvolumes (a and b) having approximately equal numbers of samples. The “max minus min” estimator proves its worth when the preliminary sampling yields only a single point, or small number of points, in active regions of the integrand. In many realistic cases, these are indicators of nearby regions of even greater importance, and it is useful to let them attract the greater sampling weight that “max minus min” provides.

A second modification embodied in the code is the introduction of a “dithering parameter,” `dith`, whose nonzero value causes subvolumes to be divided not exactly down the middle, but

rather into fractions $0.5 \pm \text{dith}$, with the sign of the \pm randomly chosen by a built-in random number routine. Normally `dith` can be set to zero. However, there is a large advantage in taking `dith` to be nonzero if some special symmetry of the integrand puts the active region exactly at the midpoint of the region, or at the center of some power-of-two submultiple of the region. One wants to avoid the extreme case of the active region being evenly divided into 2^d abutting corners of a d -dimensional space. A typical nonzero value of `dith`, on those occasions when it is useful, might be 0.1. Of course, when the dithering parameter is nonzero, we must take the differing sizes of the subvolumes into account; the code does this through the variable `frac1`.

One final feature in the code deserves mention. The RSS algorithm uses a single set of sample points to evaluate equation (7.8.23) in all d directions. At bottom levels of the recursion, the number of sample points can be quite small. Although rare, it can happen that in one direction all the samples are in one half of the volume; in that case, that direction is ignored as a candidate for bifurcation. Even more rare is the possibility that all of the samples are in one half of the volume in *all* directions. In this case, a random direction is chosen. If this happens too often in your application, then you should increase `MNPT` (see line `if (jb.eq.0)... in the code).`

Note that `miser`, as given, returns as `ave` an estimate of the average function value $\langle\langle f \rangle\rangle$, not the integral of f over the region. The routine `vegas`, adopting the other convention, returns as `tgral` the integral. The two conventions are of course trivially related, by equation (7.8.8), since the volume V of the rectangular region is known.

```
SUBROUTINE miser(func,region,ndim,npts,dith,ave,var)
INTEGER ndim,npts,MNPT,MNBS,MAXD,NSTACK
REAL ave,dith,var,region(2*ndim),func,TINY,BIG,PFAC
PARAMETER (MNPT=15,MNBS=4*MNPT,MAXD=10,TINY=1.e-30,BIG=1.e30,
*           NSTACK=1000,PFAC=0.1)
EXTERNAL func
C USES func,ranpt
      Monte Carlo samples a user-supplied ndim-dimensional function func in a rectangular
      volume specified by region, a 2×ndim vector consisting of ndim "lower-left" coordinates
      of the region followed by ndim "upper-right" coordinates. The function is sampled a total
      of npts times, at locations determined by the method of recursive stratified sampling. The
      mean value of the function in the region is returned as ave; an estimate of the statistical
      uncertainty of ave (square of standard deviation) is returned as var. The input parameter
      dith should normally be set to zero, but can be set to (e.g.) 0.1 if func's active region
      falls on the boundary of a power-of-two subdivision of region.
      Parameters: PFAC is the fraction of remaining function evaluations used at each stage to
      explore the variance of func. At least MNPT function evaluations are performed in any
      terminal subregion; a subregion is further bisected only if at least MNBS function evaluations
      are available. MAXD is the largest value of ndim. NSTACK is the total size of the stack.

    goto (10,20),naddr
    pause 'miser: never get here'
endif
return
END

```

The `miser` routine calls a short subroutine `ranpt` to get a random point within a specified d -dimensional region. The following version of `ranpt` makes consecutive calls to a uniform random number generator and does the obvious scaling. One can easily modify `ranpt` to generate its points via the quasi-random routine `sobseq` (§7.7). We find that `miser` with `sobseq` can be considerably more accurate than `miser` with uniform random deviates. Since the use of RSS and the use of quasi-random numbers are completely separable, however, we have not made the code given here dependent on `sobseq`. A similar remark might be made regarding importance sampling, which could in principle be combined with RSS. (One could in principle combine `vegas` and `miser`, although the programming would be intricate.)

```

SUBROUTINE ranpt(pt,region,n)
INTEGER n,idum
REAL pt(n),region(2*n)
COMMON /ranno/ idum
SAVE /ranno/
C USES ran1
      Returns a uniformly random point pt in an n-dimensional rectangular region. Used by
      miser; calls ran1 for uniform deviates. Your main program should initialize idum, through
      the COMMON block /ranno/, to a negative seed integer.
      INTEGER j
      REAL ran1
      do 11 j=1,n
          pt(j)=region(j)+(region(j+n)-region(j))*ran1(idum)
      enddo 11
      return
END

```

Chapter 8. Sorting

8.0 Introduction

This chapter almost doesn't belong in a book on *numerical* methods. However, some practical knowledge of techniques for sorting is an indispensable part of any good programmer's expertise. We would not want you to consider yourself expert in numerical techniques while remaining ignorant of so basic a subject.

In conjunction with numerical work, sorting is frequently necessary when data (either experimental or numerically generated) are being handled. One has tables or lists of numbers, representing one or more independent (or "control") variables, and one or more dependent (or "measured") variables. One may wish to arrange these data, in various circumstances, in order by one or another of these variables. Alternatively, one may simply wish to identify the "median" value, or the "upper quartile" value of one of the lists of values. This task, closely related to sorting, is called *selection*.

Here, more specifically, are the tasks that this chapter will deal with:

- Sort, i.e., rearrange, an array of numbers into numerical order.
- Rearrange an array into numerical order while performing the corresponding rearrangement of one or more additional arrays, so that the correspondence between elements in all arrays is maintained.
- Given an array, prepare an *index table* for it, i.e., a table of pointers telling which number array element comes first in numerical order, which second, and so on.
- Given an array, prepare a *rank table* for it, i.e., a table telling what is the numerical rank of the first array element, the second array element, and so on.
- Select the M th largest element from an array.

For the basic task of sorting N elements, the best algorithms require on the order of several times $N \log_2 N$ operations. The algorithm inventor tries to reduce the constant in front of this estimate to as small a value as possible. Two of the best algorithms are *Quicksort* (§8.2), invented by the inimitable C.A.R. Hoare, and *Heapsort* (§8.3), invented by J.W.J. Williams.

For large N (say > 1000), Quicksort is faster, on most machines, by a factor of 1.5 or 2; it requires a bit of extra memory, however, and is a moderately complicated program. Heapsort is a true "sort in place," and is somewhat more compact to program and therefore a bit easier to modify for special purposes. On balance, we recommend Quicksort because of its speed, but we implement both routines.

For small N one does better to use an algorithm whose operation count goes as a higher, i.e., poorer, power of N , if the constant in front is small enough. For $N < 20$, roughly, the method of *straight insertion* (§8.1) is concise and fast enough. We include it with some trepidation: It is an N^2 algorithm, whose potential for misuse (by using it for too large an N) is great. The resultant waste of computer time is so awesome, that we were tempted not to include any N^2 routine at all. We *will* draw the line, however, at the inefficient N^2 algorithm, beloved of elementary computer science texts, called *bubble sort*. If you know what bubble sort is, wipe it from your mind; if you don't know, make a point of never finding out!

For $N < 50$, roughly, *Shell's method* (§8.1), only slightly more complicated to program than straight insertion, is competitive with the more complicated Quicksort on many machines. This method goes as $N^{3/2}$ in the worst case, but is usually faster.

See references [1,2] for further information on the subject of sorting, and for detailed references to the literature.

8.1 Straight Insertion and Shell's Method

Straight insertion is an N^2 routine, and should be used only for small N , say < 20 .

The technique is exactly the one used by experienced card players to sort their cards: Pick out the second card and put it in order with respect to the first; then pick out the third card and insert it into the sequence among the first two; and so on until the last card has been picked out and inserted.

```
SUBROUTINE piksrt(n,arr)
INTEGER n
REAL arr(n)
        Sorts an array arr(1:n) into ascending numerical order, by straight insertion. n is input;
        arr is replaced on output by its sorted rearrangement.
INTEGER i,j
REAL a
do 12 j=2,n                Pick out each element in turn.
        a=arr(j)
        do 11 i=j-1,1,-1          Look for the place to insert it.
                if(arr(i).le.a)goto 10
                arr(i+1)=arr(i)
        enddo 11
        i=0
10      arr(i+1)=a            Insert it.
enddo 12
return
END
```

What if you also want to rearrange an array *brr* at the same time as you sort *arr*? Simply move an element of *brr* whenever you move an element of *arr*:

INTEGER i,j
REAL a
do 12 j=2,n                Pick out each element in turn.
        a=arr(j)
        do 11 i=j-1,1,-1          Look for the place to insert it.
                if(arr(i).le.a)goto 10
                arr(i+1)=arr(i)
        enddo 11
        i=0
10      arr(i+1)=a            Insert it.
enddo 12
return
END
```

What if you also want to rearrange an array *brr* at the same time as you sort *arr*? Simply move an element of *brr* whenever you move an element of *arr*:

```

SUBROUTINE piksr2(n,arr,brr)
INTEGER n
REAL arr(n),brr(n)
Sorts an array arr(1:n) into ascending numerical order, by straight insertion, while making
the corresponding rearrangement of the array brr(1:n).
INTEGER i,j
REAL a,b
do 12 j=2,n           Pick out each element in turn.
    a=arr(j)
    b=brr(j)
    do 11 i=j-1,1,-1     Look for the place to insert it.
        if(arr(i).le.a)goto 10
        arr(i+1)=arr(i)
        brr(i+1)=brr(i)
    enddo 11
    i=0
10   arr(i+1)=a           Insert it.
    brr(i+1)=b
12   enddo 12
return
END

```

For the case of rearranging a larger number of arrays by sorting on one of them, see §8.4.

Shell's Method

This is actually a variant on straight insertion, but a very powerful variant indeed. The rough idea, e.g., for the case of sorting 16 numbers $n_1 \dots n_{16}$, is this: First sort, by straight insertion, each of the 8 groups of 2 ((n_1, n_9) , (n_2, n_{10}) , ..., (n_8, n_{16})). Next, sort each of the 4 groups of 4 ((n_1, n_5, n_9, n_{13}) , ..., $(n_4, n_8, n_{12}, n_{16})$). Next sort the 2 groups of 8 records, beginning with $(n_1, n_3, n_5, n_7, n_9, n_{11}, n_{13}, n_{15})$. Finally, sort the whole list of 16 numbers.

Of course, only the *last* sort is *necessary* for putting the numbers into order. So what is the purpose of the previous partial sorts? The answer is that the previous sorts allow numbers efficiently to filter up or down to positions close to their final resting places. Therefore, the straight insertion passes on the final sort rarely have to go past more than a “few” elements before finding the right place. (Think of sorting a hand of cards that are already almost in order.)

The spacings between the numbers sorted on each pass through the data (8,4,2,1 in the above example) are called the *increments*, and a Shell sort is sometimes called a *diminishing increment sort*. There has been a lot of research into how to choose a good set of increments, but the optimum choice is not known. The set ..., 8, 4, 2, 1 is in fact not a good choice, especially for N a power of 2. A much better choice is the sequence

$$(3^k - 1)/2, \dots, 40, 13, 4, 1 \quad (8.1.1)$$

which can be generated by the recurrence

$$i_1 = 1, \quad i_{k+1} = 3i_k + 1, \quad k = 1, 2, \dots \quad (8.1.2)$$

It can be shown (see [1]) that for this sequence of increments the number of operations required in all is of order $N^{3/2}$ for the worst possible ordering of the original data.

For “randomly” ordered data, the operations count goes approximately as $N^{1.25}$, at least for $N < 60000$. For $N > 50$, however, Quicksort is generally faster. The program follows:

```
SUBROUTINE shell(n,a)
INTEGER n
REAL a(n)
Sorts an array a(1:n) into ascending numerical order by Shell's method (diminishing increment sort). n is input; a is replaced on output by its sorted rearrangement.
INTEGER i,j,inc
REAL v
inc=1
1 inc=3*inc+1
if(inc.le.n)goto 1
2 continue
inc=inc/3
do 11 i=inc+1,n
v=a(i)
j=i
3 if(a(j-inc).gt.v)then
   a(j)=a(j-inc)
   j=j-inc
   if(j.le.inc)goto 4
  goto 3
endif
4 a(j)=v
enddo 11
if(inc.gt.1)goto 2
return
END
```

Sedgewick, R. 1988, *Algorithms*, 2nd ed. (Reading, MA: Addison-Wesley), Chapter 8.

8.2 Quicksort

Quicksort is, on most machines, on average, for large N , the fastest known sorting algorithm. It is a “partition-exchange” sorting method: A “partitioning element” a is selected from the array. Then by pairwise exchanges of elements, the original array is partitioned into two subarrays. At the end of a round of partitioning, the element a is in its final place in the array. All elements in the left subarray are $\leq a$, while all elements in the right subarray are $\geq a$. The process is then repeated on the left and right subarrays independently, and so on.

The partitioning process is carried out by selecting some element, say the leftmost, as the partitioning element a . Scan a pointer up the array until you find an element $> a$, and then scan another pointer down from the end of the array until you find an element $< a$. These two elements are clearly out of place for the final partitioned array, so exchange them. Continue this process until the pointers

For “randomly” ordered data, the operations count goes approximately as $N^{1.25}$, at least for $N < 60000$. For $N > 50$, however, Quicksort is generally faster. The program follows:

```
SUBROUTINE shell(n,a)
INTEGER n
REAL a(n)
Sorts an array a(1:n) into ascending numerical order by Shell's method (diminishing increment sort). n is input; a is replaced on output by its sorted rearrangement.
INTEGER i,j,inc
REAL v
inc=1
1 inc=3*inc+1
if(inc.le.n)goto 1
2 continue
inc=inc/3
do 11 i=inc+1,n
v=a(i)
j=i
3 if(a(j-inc).gt.v)then
   a(j)=a(j-inc)
   j=j-inc
   if(j.le.inc)goto 4
  goto 3
endif
4 a(j)=v
enddo 11
if(inc.gt.1)goto 2
return
END
```

8.2 Quicksort

Quicksort is, on most machines, on average, for large N , the fastest known sorting algorithm. It is a “partition-exchange” sorting method: A “partitioning element” a is selected from the array. Then by pairwise exchanges of elements, the original array is partitioned into two subarrays. At the end of a round of partitioning, the element a is in its final place in the array. All elements in the left subarray are $\leq a$, while all elements in the right subarray are $\geq a$. The process is then repeated on the left and right subarrays independently, and so on.

The partitioning process is carried out by selecting some element, say the leftmost, as the partitioning element a . Scan a pointer up the array until you find an element $> a$, and then scan another pointer down from the end of the array until you find an element $< a$. These two elements are clearly out of place for the final partitioned array, so exchange them. Continue this process until the pointers

cross. This is the right place to insert a , and that round of partitioning is done. The question of the best strategy when an element is equal to the partitioning element is subtle; we refer you to Sedgewick [1] for a discussion. (Answer: You should stop and do an exchange.)

Quicksort requires an auxiliary array of storage, of length $2 \log_2 N$, which it uses as a push-down stack for keeping track of the pending subarrays. When a subarray has gotten down to some size M , it becomes faster to sort it by straight insertion (§8.1), so we will do this. The optimal setting of M is machine dependent, but $M = 7$ is not too far wrong. Some people advocate leaving the short subarrays unsorted until the end, and then doing one giant insertion sort at the end. Since each element moves at most 7 places, this is just as efficient as doing the sorts immediately, and saves on the overhead. However, on modern machines with paged memory, there is increased overhead when dealing with a large array all at once. We have not found any advantage in saving the insertion sorts till the end.

As already mentioned, Quicksort's *average* running time is fast, but its *worst case* running time can be very slow: For the worst case it is, in fact, an N^2 method! And for the most straightforward implementation of Quicksort it turns out that the worst case is achieved for an input array that is already in order! This ordering of the input array might easily occur in practice. One way to avoid this is to use a little random number generator to choose a random element as the partitioning element. Another is to use instead the median of the first, middle, and last elements of the current subarray.

The great speed of Quicksort comes from the simplicity and efficiency of its inner loop. Simply adding one unnecessary test (for example, a test that your pointer has not moved off the end of the array) can almost double the running time! One avoids such unnecessary tests by placing “sentinels” at either end of the subarray being partitioned. The leftmost sentinel is $\leq a$, the rightmost $\geq a$. With the “median-of-three” selection of a partitioning element, we can use the two elements that were not the median to be the sentinels for that subarray.

Our implementation closely follows [1]:

```
SUBROUTINE sort(n,arr)
INTEGER n,M,NSTACK
REAL arr(n)
PARAMETER (M=7,NSTACK=50)
Sorts an array arr(1:n) into ascending numerical order using the Quicksort algorithm. n
is input; arr is replaced on output by its sorted rearrangement.
Parameters: M is the size of subarrays sorted by straight insertion and NSTACK is the required
auxiliary storage.
INTEGER i,ir,j,jstack,k,l,istack(NSTACK)
REAL a,temp
jstack=0
l=1
ir=n
1 if(ir-l.lt.M)then           Insertion sort when subarray small enough.
    do 12 j=l+1,ir
        a=arr(j)
        do 11 i=j-1,l,-1
            if(arr(i).le.a)goto 2
            arr(i+1)=arr(i)
        enddo 11
        i=l-1
        arr(i+1)=a
    enddo 12
```

```

if(jstack.eq.0) return          Pop stack and begin a new round of partitioning.
ir=istack(jstack)
l=istack(jstack-1)
jstack=jstack-2
else
    k=(l+ir)/2
    temp=arr(k)
    arr(k)=arr(l+1)
    arr(l+1)=temp
    if(arr(l).gt.arr(ir))then
        temp=arr(1)
        arr(1)=arr(ir)
        arr(ir)=temp
    endif
    if(arr(l+1).gt.arr(ir))then
        temp=arr(l+1)
        arr(l+1)=arr(ir)
        arr(ir)=temp
    endif
    if(arr(1).gt.arr(l+1))then
        temp=arr(1)
        arr(1)=arr(l+1)
        arr(l+1)=temp
    endif
    i=l+1                      Initialize pointers for partitioning.
    j=ir
    a=arr(l+1)
    continue
        i=i+1
    if(arr(i).lt.a)goto 3      Partitioning element.
    3
    continue
        j=j-1
    if(arr(j).gt.a)goto 4      Beginning of innermost loop.
    4
    if(j.lt.i)goto 5
    temp=arr(i)
    arr(i)=arr(j)
    arr(j)=temp
    goto 3
    5
    arr(l+1)=arr(j)
    arr(j)=a
    jstack=jstack+2
    Push pointers to larger subarray on stack, process smaller subarray immediately.
    if(jstack.gt.NSTACK)pause 'NSTACK too small in sort'
    if(ir-i+1.ge.j-l)then
        istack(jstack)=ir
        istack(jstack-1)=i
        ir=j-1
    else
        istack(jstack)=j-1
        istack(jstack-1)=l
        l=i
    endif
    endif
    goto 1
END

```

As usual you can move any other arrays around at the same time as you sort arr. At the risk of being repetitious:

```

SUBROUTINE sort2(n,arr,brr)
INTEGER n,M,NSTACK
REAL arr(n),brr(n)
PARAMETER (M=7,NSTACK=50)
      Sorts an array arr(1:n) into ascending order using Quicksort, while making the corre-
      sponding rearrangement of the array brr(1:n).
INTEGER i,ir,j,jstack,k,l,istack(NSTACK)
REAL a,b,temp
jstack=0
l=1
ir=n
1  if(ir-l.lt.M)then           Insertion sort when subarray small enough.
      do 12 j=l+1,ir
          a=arr(j)
          b=brr(j)

8.3 Heapsort

While usually not quite as fast as Quicksort, Heapsort is one of our favorite sorting routines. It is a true “in-place” sort, requiring no auxiliary storage. It is an $N \log_2 N$ process, not only on average, but also for the worst-case order of input data. In fact, its worst case is only 20 percent or so worse than its average running time.

It is beyond our scope to give a complete exposition on the theory of Heapsort. We will mention the general principles, then let you refer to the references [1,2], or analyze the program yourself, if you want to understand the details.

A set of N numbers a_i , $i = 1, \dots, N$, is said to form a “heap” if it satisfies the relation

$$a_{j/2} \geq a_j \quad \text{for } 1 \leq j/2 < j \leq N \tag{8.3.1}$$

```

8.3 Heapsort

While usually not quite as fast as Quicksort, Heapsort is one of our favorite sorting routines. It is a true “in-place” sort, requiring no auxiliary storage. It is an $N \log_2 N$ process, not only on average, but also for the worst-case order of input data. In fact, its worst case is only 20 percent or so worse than its average running time.

It is beyond our scope to give a complete exposition on the theory of Heapsort. We will mention the general principles, then let you refer to the references [1,2], or analyze the program yourself, if you want to understand the details.

A set of N numbers a_i , $i = 1, \dots, N$, is said to form a “heap” if it satisfies the relation

$$a_{j/2} \geq a_j \quad \text{for } 1 \leq j/2 < j \leq N \tag{8.3.1}$$

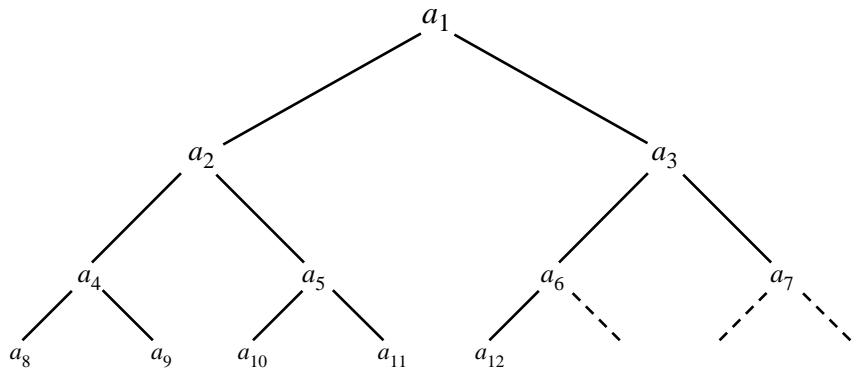

Figure 8.3.1. Ordering implied by a “heap,” here of 12 elements. Elements connected by an upward path are sorted with respect to one another, but there is not necessarily any ordering among elements related only “laterally.”

Here the division in $j/2$ means “integer divide,” i.e., is an exact integer or else is rounded down to the closest integer. Definition (8.3.1) will make sense if you think of the numbers a_i as being arranged in a binary tree, with the top, “boss,” node being a_1 , the two “underling” nodes being a_2 and a_3 , *their* four underling nodes being a_4 through a_7 , etc. (See Figure 8.3.1.) In this form, a heap has every “supervisor” greater than or equal to its two “supervisees,” down through the levels of the hierarchy.

If you have managed to rearrange your array into an order that forms a heap, then sorting it is very easy: You pull off the “top of the heap,” which will be the largest element yet unsorted. Then you “promote” to the top of the heap its largest underling. Then you promote *its* largest underling, and so on. The process is like what happens (or is supposed to happen) in a large corporation when the chairman of the board retires. You then repeat the whole process by retiring the new chairman of the board. Evidently the whole thing is an $N \log_2 N$ process, since each retiring chairman leads to $\log_2 N$ promotions of underlings.

Well, how do you arrange the array into a heap in the first place? The answer is again a “sift-up” process like corporate promotion. Imagine that the corporation starts out with $N/2$ employees on the production line, but with no supervisors. Now a supervisor is hired to supervise two workers. If he is less capable than one of his workers, that one is promoted in his place, and he joins the production line. After supervisors are hired, then supervisors of supervisors are hired, and so on up the corporate ladder. Each employee is brought in at the top of the tree, but then immediately sifted down, with more capable workers promoted until their proper corporate level has been reached.

In the Heapsort implementation, the same “sift-up” code can be used for the initial creation of the heap and for the subsequent retirement-and-promotion phase. One execution of the Heapsort subroutine represents the entire life-cycle of a giant corporation: $N/2$ workers are hired; $N/2$ potential supervisors are hired; there is a sifting up in the ranks, a sort of super Peter Principle: in due course, each of the original employees gets promoted to chairman of the board.

8.4 Indexing and Ranking

The concept of *keys* plays a prominent role in the management of data files. A data *record* in such a file may contain several items, or *fields*. For example, a record in a file of weather observations may have fields recording time, temperature, and

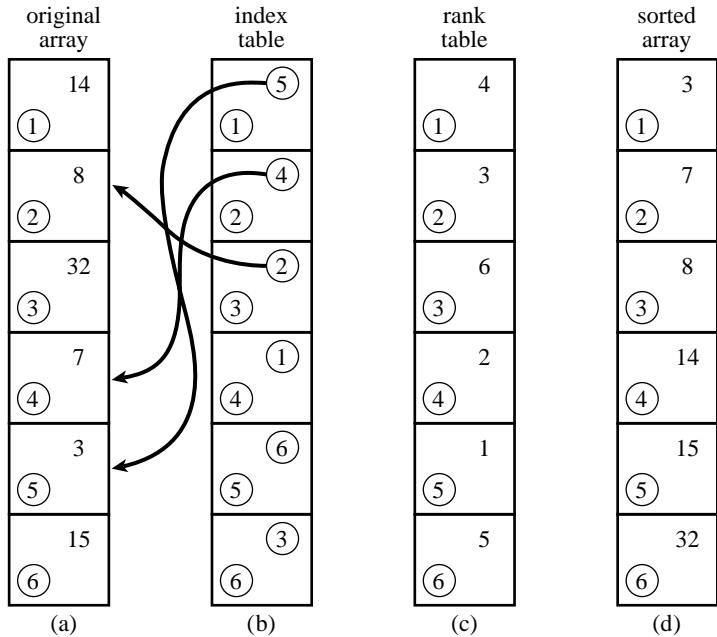

Figure 8.4.1. (a) An unsorted array of six numbers. (b) Index table, whose entries are pointers to the elements of (a) in ascending order. (c) Rank table, whose entries are the ranks of the corresponding elements of (a). (d) Sorted array of the elements in (a).

wind velocity. When we sort the records, we must decide which of these fields we want to be brought into sorted order. The other fields in a record just come along for the ride, and will not, in general, end up in any particular order. The field on which the sort is performed is called the *key* field.

For a data file with many records and many fields, the actual movement of N records into the sorted order of their keys K_i , $i = 1, \dots, N$, can be a daunting task. Instead, one can construct an *index table* I_j , $j = 1, \dots, N$, such that the smallest K_i has $i = I_1$, the second smallest has $i = I_2$, and so on up to the largest K_i with $i = I_N$. In other words, the array

$$K_{I_j} \quad j = 1, 2, \dots, N \quad (8.4.1)$$

is in sorted order when indexed by j . When an index table is available, one need not move records from their original order. Further, different index tables can be made from the same set of records, indexing them to different keys.

The algorithm for constructing an index table is straightforward: Initialize the index array with the integers from 1 to N , then perform the Quicksort algorithm, moving the elements around *as if* one were sorting the keys. The integer that initially numbered the smallest key thus ends up in the number one position, and so on.

```
SUBROUTINE indexx(n,arr,idx)

```

If you want to sort an array while making the corresponding rearrangement of several or many other arrays, you should first make an index table, then use it to rearrange each array in turn. This requires two arrays of working space: one to hold the index, and another into which an array is temporarily moved, and from which it is redeposited back on itself in the rearranged order. For 3 arrays, the procedure looks like this:

```

SUBROUTINE sort3(n,ra,rb,rc,wksp,iwksp)
INTEGER n,iwksp(n)
REAL ra(n),rb(n),rc(n),wksp(n)
C USES indexx
      Sorts an array ra(1:n) into ascending numerical order while making the corresponding
      rearrangements of the arrays rb(1:n) and rc(1:n). An index table is constructed via the
      routine indexx.
      INTEGER j
      call indexx(n,ra,iwksp)      Make the index table.
      do 11 j=1,n                 Save the array ra.
         wksp(j)=ra(j)
      enddo 11
      do 12 j=1,n                 Copy it back in the rearranged order.
         ra(j)=wksp(iwksp(j))
      enddo 12
      do 13 j=1,n                 Ditto rb.
         wksp(j)=rb(j)
      enddo 13
      do 14 j=1,n                 Ditto rc.
         rb(j)=wksp(iwksp(j))
      enddo 14
      do 15 j=1,n
         wksp(j)=rc(j)
      enddo 15
      do 16 j=1,n
         rc(j)=wksp(iwksp(j))
      enddo 16
      return
END

```

The generalization to any other number of arrays is obviously straightforward.

A *rank table* is different from an index table. A rank table's j th entry gives the rank of the j th element of the original array of keys, ranging from 1 (if that element was the smallest) to N (if that element was the largest). One can easily construct a rank table from an index table, however:

```
SUBROUTINE rank(n,indx,irank)
INTEGER n,indx(n),irank(n)
  Given indx(1:n) as output from the routine indexx, this routine returns an array irank(1:n),
  the corresponding table of ranks.
INTEGER j
do 11 j=1,n
  irank(indx(j))=j
11 enddo
return
END
```

Figure 8.4.1 summarizes the concepts discussed in this section.

8.5 Selecting the Mth Largest

Selection is sorting’s austere sister. (Say *that* five times quickly!) Where sorting demands the rearrangement of an entire data array, selection politely asks for a single returned value: What is the k th smallest (or, equivalently, the $m = N + 1 - k$ th largest) element out of N elements? The fastest methods for selection do, unfortunately, rearrange the array for their own computational purposes, typically putting all smaller elements to the left of the k th, all larger elements to the right, and scrambling the order within each subset. This side effect is at best innocuous, at worst downright inconvenient. When the array is very long, so that making a scratch copy of it is taxing on memory, or when the computational burden of the selection is a negligible part of a larger calculation, one turns to selection algorithms without side effects, which leave the original array undisturbed. Such *in place* selection is slower than the faster selection methods by a factor of about 10. We give routines of both types, below.

The most common use of selection is in the statistical characterization of a set of data. One often wants to know the median element in an array, or the top and bottom quartile elements. When N is odd, the median is the k th element, with $k = (N + 1)/2$. When N is even, statistics books define the median as the arithmetic mean of the elements $k = N/2$ and $k = N/2 + 1$ (that is, $N/2$ from the bottom and $N/2$ from the top). If you accept such pedantry, you must perform two separate selections to find these elements. For $N > 100$ we usually define $k = N/2$ to be the median element, pedants be damned.

The fastest general method for selection, allowing rearrangement, is *partitioning*, exactly as was done in the Quicksort algorithm (§8.2). Selecting a “random” partition element, one marches through the array, forcing smaller elements to the left, larger elements to the right. As in Quicksort, it is important to optimize the inner loop, using “sentinels” (§8.2) to minimize the number of comparisons. For sorting, one would then proceed to further partition both subsets. For selection, we can ignore one subset and attend only to the one that contains our desired k th element. Selection by partitioning thus does not need a stack of pending operations, and its operations count scales as N rather than as $N \log N$ (see [1]). Comparison with sort in §8.2 should make the following routine obvious:

```
SUBROUTINE rank(n,indx,irank)
INTEGER n,indx(n),irank(n)
  Given indx(1:n) as output from the routine indexx, this routine returns an array irank(1:n),
  the corresponding table of ranks.
INTEGER j
do 11 j=1,n
  irank(indx(j))=j
11 enddo
return
END
```

Figure 8.4.1 summarizes the concepts discussed in this section.

8.5 Selecting the Mth Largest

Selection is sorting’s austere sister. (Say *that* five times quickly!) Where sorting demands the rearrangement of an entire data array, selection politely asks for a single returned value: What is the k th smallest (or, equivalently, the $m = N + 1 - k$ th largest) element out of N elements? The fastest methods for selection do, unfortunately, rearrange the array for their own computational purposes, typically putting all smaller elements to the left of the k th, all larger elements to the right, and scrambling the order within each subset. This side effect is at best innocuous, at worst downright inconvenient. When the array is very long, so that making a scratch copy of it is taxing on memory, or when the computational burden of the selection is a negligible part of a larger calculation, one turns to selection algorithms without side effects, which leave the original array undisturbed. Such *in place* selection is slower than the faster selection methods by a factor of about 10. We give routines of both types, below.

The most common use of selection is in the statistical characterization of a set of data. One often wants to know the median element in an array, or the top and bottom quartile elements. When N is odd, the median is the k th element, with $k = (N + 1)/2$. When N is even, statistics books define the median as the arithmetic mean of the elements $k = N/2$ and $k = N/2 + 1$ (that is, $N/2$ from the bottom and $N/2$ from the top). If you accept such pedantry, you must perform two separate selections to find these elements. For $N > 100$ we usually define $k = N/2$ to be the median element, pedants be damned.

The fastest general method for selection, allowing rearrangement, is *partitioning*, exactly as was done in the Quicksort algorithm (§8.2). Selecting a “random” partition element, one marches through the array, forcing smaller elements to the left, larger elements to the right. As in Quicksort, it is important to optimize the inner loop, using “sentinels” (§8.2) to minimize the number of comparisons. For sorting, one would then proceed to further partition both subsets. For selection, we can ignore one subset and attend only to the one that contains our desired k th element. Selection by partitioning thus does not need a stack of pending operations, and its operations count scales as N rather than as $N \log N$ (see [1]). Comparison with sort in §8.2 should make the following routine obvious:

```

FUNCTION select(k,n,arr)
INTEGER k,n
REAL select,arr(n)
    Returns the kth smallest value in the array arr(1:n). The input array will be rearranged
    to have this value in location arr(k), with all smaller elements moved to arr(1:k-1) (in
    arbitrary order) and all larger elements in arr[k+1..n] (also in arbitrary order).
INTEGER i,ir,j,l,mid
REAL a,temp
l=1
ir=n
1  if(ir-l.le.1)then           Active partition contains 1 or 2 elements.
    if(ir-l.eq.1)then          Active partition contains 2 elements.
        if(arr(ir).lt.arr(l))then
            temp=arr(l)
            arr(l)=arr(ir)
            arr(ir)=temp
        endif
    endif
    select=arr(k)
    return
else
    mid=(l+ir)/2
    temp=arr(mid)
    arr(mid)=arr(l+1)
    arr(l+1)=temp
    if(arr(l).gt.arr(ir))then
        temp=arr(l)
        arr(l)=arr(ir)
        arr(ir)=temp
    endif
    if(arr(l+1).gt.arr(ir))then
        temp=arr(l+1)
        arr(l+1)=arr(ir)
        arr(ir)=temp
    endif
    if(arr(l).gt.arr(l+1))then
        temp=arr(l)
        arr(l)=arr(l+1)
        arr(l+1)=temp
    endif
    endiff
    i=l+1
    j=ir
    a=arr(l+1)
    continue
    i=i+1
    if(arr(i).lt.a)goto 3
3   if(arr(i).lt.a)goto 3
    continue
    j=j-1
    if(arr(j).gt.a)goto 4
    if(j.lt.i)goto 5
    temp=arr(i)
    arr(i)=arr(j)
    arr(j)=temp
    goto 3
    arr(l+1)=arr(j)
    arr(j)=a
    if(j.ge.k)ir=j-1
    if(j.le.k)l=i
    endif
    goto 1
END

```

Choose median of left, center, and right elements as partitioning element a . Also rearrange so that $\text{arr}(1) \leq \text{arr}(l+1)$, $\text{arr}(ir) \geq \text{arr}(l+1)$.

Initialize pointers for partitioning.

Partitioning element.

Beginning of innermost loop.

Scan up to find element $> a$.

Scan down to find element $< a$.

Pointers crossed. Exit with partitioning complete.

Exchange elements.

End of innermost loop.

Insert partitioning element.

Keep active the partition that contains the k th element.

In-place, nondestructive, selection is conceptually simple, but it requires a lot of bookkeeping, and it is correspondingly slower. The general idea is to pick some number M of elements at random, to sort them, and then to make a pass through the array *counting* how many elements fall in each of the $M + 1$ intervals defined by these elements. The k th largest will fall in one such interval — call it the “live” interval. One then does a second round, first picking M random elements in the live interval, and then determining which of the new, finer, $M + 1$ intervals all presently live elements fall into. And so on, until the k th element is finally localized within a single array of size M , at which point direct selection is possible.

How shall we pick M ? The number of rounds, $\log_M N = \log_2 N / \log_2 M$, will be smaller if M is larger; but the work to locate each element among $M + 1$ subintervals will be larger, scaling as $\log_2 M$ for bisection, say. Each round requires looking at all N elements, if only to find those that are still alive, while the bisections are dominated by the N that occur in the first round. Minimizing $O(N \log_M N) + O(N \log_2 M)$ thus yields the result

$$M \sim 2\sqrt{\log_2 N} \quad (8.5.1)$$

The square root of the logarithm is so slowly varying that secondary considerations of machine timing become important. We use $M = 64$ as a convenient constant value.

Two minor additional tricks in the following routine, *selip*, are (i) augmenting the set of M random values by an $M + 1$ st, the arithmetic mean, and (ii) choosing the M random values “on the fly” in a pass through the data, by a method that makes later values no less likely to be chosen than earlier ones. (The underlying idea is to give element $m > M$ an M/m chance of being brought into the set. You can prove by induction that this yields the desired result.)

```

FUNCTION selip(k,n,arr)
INTEGER k,n,M
REAL selip,arr(n),BIG
PARAMETER (M=64,BIG=1.E30)
      Returns the kth smallest value in the array arr(1:n). The input array is not altered.
C   USES shell
INTEGER i,j,jl,jm,ju,kk,mm,nlo,nxtmm,isel(M+2)
REAL ahi,alo,sum,sel(M+2)
if(k.lt.1.or.k.gt.n.or.n.le.0) pause 'bad input to selip'
kk=k
ahi=BIG
alo=-BIG
1  continue
      Main iteration loop, until desired element is isolated.
      mm=0
      nlo=0
      sum=0.
      nxtmm=M+1
      do 11 i=1,n           Make a pass through the whole array.
          if(arr(i).ge.alo.and.arr(i).le.ahi)then    Consider only elements in the cur-
              mm=mm+1                                rent brackets.
              if(arr(i).eq.alo) nlo=nlo+1            In case of ties for low bracket.
              if(mm.le.M)then          Statistical procedure for selecting m in-range elements
                  sel(mm)=arr(i)                with equal probability, even without knowing in
              else if(mm.eq.nxtmm)then    advance how many there are!
                  nxtmm=mm+mm/M
                  sel(1+mod(i+mm+kk,M))=arr(i)      The mod function provides a some-
                  sum=sum+arr(i)                    what random number.
          endif
      end

```

```

        endif
    enddo 11
    if(kk.le.nlo)then           Desired element is tied for lower bound; return it.
        selip=alo
        return
    else if(mm.le.M)then        All in-range elements were kept. So return answer by
        call shell(mm,sel)
        selip=sel(kk)
        return
    endif
    sel(M+1)=sum/mm            Augment selected set by mean value (fixes degeneracies), and sort it.
    call shell(M+1,sel)
    sel(M+2)=ahi
    do 12 j=1,M+2             Zero the count array.
        isel(j)=0
    enddo 12
    do 13 i=1,n               Make another pass through the whole array.
        if(arr(i).ge.alo.and.arr(i).le.ahi)then   For each in-range element...
            jl=0
            ju=M+2
            if(ju-jl.gt.1)then ...find its position among the select by bisection...
                jm=(ju+jl)/2
                if(arr(i).ge.sel(jm))then
                    jl=jm
                else
                    ju=jm
                endif
                goto 2
            endif
            isel(ju)=isel(ju)+1 ...and increment the counter.
        endif
    enddo 13
    j=1
    3 if(kk.gt.isel(j))then    Now we can narrow the bounds to just one bin, that
        alo=sel(j)              is, by a factor of order m.
        kk=kk-isel(j)
        j=j+1
    goto 3
    endif
    ahi=sel(j)
    goto 1
END

```

Approximate timings: `selip` is about 10 times slower than `select`. Indeed, for N in the range of $\sim 10^5$, `selip` is about 1.5 times slower than a full sort with `sort`, while `select` is about 6 times faster than `sort`. You should weigh time against memory and convenience carefully.

Of course neither of the above routines should be used for the trivial cases of finding the largest, or smallest, element in an array. Those cases, you code by hand as simple do loops. There are also good ways to code the case where k is modest in comparison to N , so that extra memory of order k is not burdensome. An example is to use the method of Heapsort (§8.3) to make a single pass through an array of length N while saving the m largest elements. The advantage of the heap structure is that only $\log m$, rather than m , comparisons are required every time a new element is added to the candidate list. This becomes a real savings when $m > O(\sqrt{N})$, but it never hurts otherwise and is easy to code. The following program gives the idea.

```
SUBROUTINE hpsel(m,n,arr,heap)
INTEGER m,n
```

```

REAL arr(n),heap(m)
C USES sort
      Returns in heap(1:m) the largest m elements of the array arr(1:n), with heap(1) guaranteed to be the the mth largest element. The array arr is not altered. For efficiency, this routine should be used only when m ≪ n.
INTEGER i,j,k
REAL swap
if (m.gt.n/2.or.m.lt.1) pause 'probable misuse of hpsel'
do 11 i=1,m
    heap(i)=arr(i)
enddo 11
call sort(m,heap)           Create initial heap by overkill! We assume m ≪ n.
do 12 i=m+1,n              For each remaining element...
    if(arr(i).gt.heap(1))then Put it on the heap?
        heap(1)=arr(i)
        j=1
1     continue                 Sift down.
        k=2*j
        if(k.gt.m)goto 2
        if(k.ne.m)then
            if(heap(k).gt.heap(k+1))k=k+1
        endif
        if(heap(j).le.heap(k))goto 2
        swap=heap(k)
        heap(k)=heap(j)
        heap(j)=swap
        j=k
    goto 1
    continue
2    endif
enddo 12
return
end

```

8.6 Determination of Equivalence Classes

A number of techniques for sorting and searching relate to data structures whose details are beyond the scope of this book, for example, trees, linked lists, etc. These structures and their manipulations are the bread and butter of computer science, as distinct from numerical analysis, and there is no shortage of books on the subject.

In working with experimental data, we have found that one particular such manipulation, namely the determination of equivalence classes, arises sufficiently often to justify inclusion here.

The problem is this: There are N “elements” (or “data points” or whatever), numbered $1, \dots, N$. You are given pairwise information about whether elements are in the same *equivalence class* of “sameness,” by whatever criterion happens to be of interest. For example, you may have a list of facts like: “Element 3 and element 7 are in the same class; element 19 and element 4 are in the same class; element 7 and element 12 are in the same class,” Alternatively, you may have a procedure, given the numbers of two elements j and k , for

8.6 Determination of Equivalence Classes

A number of techniques for sorting and searching relate to data structures whose details are beyond the scope of this book, for example, trees, linked lists, etc. These structures and their manipulations are the bread and butter of computer science, as distinct from numerical analysis, and there is no shortage of books on the subject.

In working with experimental data, we have found that one particular such manipulation, namely the determination of equivalence classes, arises sufficiently often to justify inclusion here.

The problem is this: There are N “elements” (or “data points” or whatever), numbered $1, \dots, N$. You are given pairwise information about whether elements are in the same *equivalence class* of “sameness,” by whatever criterion happens to be of interest. For example, you may have a list of facts like: “Element 3 and element 7 are in the same class; element 19 and element 4 are in the same class; element 7 and element 12 are in the same class,” Alternatively, you may have a procedure, given the numbers of two elements j and k , for

deciding whether they are in the same class or different classes. (Recall that an equivalence relation can be anything satisfying the *RST properties*: reflexive, symmetric, transitive. This is compatible with any intuitive definition of “sameness.”)

The desired output is an assignment to each of the N elements of an equivalence class number, such that two elements are in the same class if and only if they are assigned the same class number.

Efficient algorithms work like this: Let $F(j)$ be the class or “family” number of element j . Start off with each element in its own family, so that $F(j) = j$. The array $F(j)$ can be interpreted as a tree structure, where $F(j)$ denotes the parent of j . If we arrange for each family to be its own tree, disjoint from all the other “family trees,” then we can label each family (equivalence class) by its most senior great-great...grandparent. The detailed topology of the tree doesn’t matter at all, as long as we graft each related element onto it *somewhere*.

Therefore, we process each elemental datum “ j is equivalent to k ” by (i) tracking j up to its highest ancestor, (ii) tracking k up to its highest ancestor, (iii) giving j to k as a new parent, or vice versa (it makes no difference). After processing all the relations, we go through all the elements j and reset their $F(j)$ ’s to their highest possible ancestors, which then label the equivalence classes.

The following routine, based on Knuth [1], assumes that there are m elemental pieces of information, stored in two arrays of length m , `lista`, `listb`, the interpretation being that `lista(j)` and `listb(j)`, $j=1\dots m$, are the numbers of two elements which (we are thus told) are related.

```
SUBROUTINE eclass(nf,n,lista,listb,m)
INTEGER m,n,lista(m),listb(m),nf(n)

Given m equivalences between pairs of n individual elements in the form of the input arrays
lista(1:m) and listb(1:m), this routine returns in nf(1:n) the number of the equivalence
class of each of the n elements, integers between 1 and n (not all such integers used).

INTEGER j,k,l
do 11 k=1,n                         Initialize each element its own class.
  nf(k)=k
enddo 11
do 12 l=1,m                         For each piece of input information...
  j=lista(l)
  if(nf(j).ne.j)then                 Track first element up to its ancestor.
    j=nf(j)
    goto 1
  endif
  k=listb(l)
  if(nf(k).ne.k)then                 Track second element up to its ancestor.
    k=nf(k)
    goto 2
  endif
  if(j.ne.k)nf(j)=k                  If they are not already related, make them so.
enddo 12
do 13 j=1,n                         Final sweep up to highest ancestors.
  if(nf(j).ne.nf(nf(j)))then
    nf(j)=nf(nf(j))
    goto 3
  endif
enddo 13
return
END
```

Alternatively, we may be able to construct a procedure `equiv(j,k)` that returns a value `.true.` if elements j and k are related, or `.false.` if they are not. Then we want to loop over all pairs of elements to get the complete picture. D. Eardley has devised a clever way of doing this while simultaneously sweeping the tree up to high ancestors in a manner that keeps it current and obviates most of the final sweep phase:

```

SUBROUTINE eclazz(nf,n,quiv)
INTEGER n,nf(n)
LOGICAL quiv
EXTERNAL quiv
    Given a user-supplied logical function quiv which tells whether a pair of elements, each
    in the range 1...n, are related, return in nf equivalence class numbers for each element.
INTEGER jj,kk
nf(1)=1
do 12 jj=2,n           Loop over first element of all pairs.
    nf(jj)=jj
    do 11 kk=1,jj-1       Loop over second element of all pairs.
        nf(kk)=nf(nf(kk)) Sweep it up this much.
        if (quiv(jj,kk)) nf(nf(nf(kk)))=jj   Good exercise for the reader to figure
            enddo 11          out why this much ancestry is
        enddo 12             necessary!
do 13 jj=1,n           Only this much sweeping is needed finally.
    nf(jj)=nf(nf(jj))
enddo 13
return
END

```

Chapter 9. Root Finding and Nonlinear Sets of Equations

9.0 Introduction

We now consider that most basic of tasks, solving equations numerically. While most equations are born with both a right-hand side and a left-hand side, one traditionally moves all terms to the left, leaving

$$f(x) = 0 \tag{9.0.1}$$

whose solution or solutions are desired. When there is only one independent variable, the problem is *one-dimensional*, namely to find the root or roots of a function.

With more than one independent variable, more than one equation can be satisfied simultaneously. You likely once learned the *implicit function theorem* which (in this context) gives us the hope of satisfying N equations in N unknowns simultaneously. Note that we have only hope, not certainty. A nonlinear set of equations may have no (real) solutions at all. Contrariwise, it may have more than one solution. The implicit function theorem tells us that “generically” the solutions will be distinct, pointlike, and separated from each other. If, however, life is so unkind as to present you with a nongeneric, i.e., degenerate, case, then you can get a continuous family of solutions. In vector notation, we want to find one or more N -dimensional solution vectors \mathbf{x} such that

$$\mathbf{f}(\mathbf{x}) = \mathbf{0} \tag{9.0.2}$$

where \mathbf{f} is the N -dimensional vector-valued function whose components are the individual equations to be satisfied simultaneously.

Don’t be fooled by the apparent notational similarity of equations (9.0.2) and (9.0.1). Simultaneous solution of equations in N dimensions is *much* more difficult than finding roots in the one-dimensional case. The principal difference between one and many dimensions is that, in one dimension, it is possible to bracket or “trap” a root between bracketing values, and then hunt it down like a rabbit. In multidimensions, you can never be sure that the root is there at all until you have found it.

Except in linear problems, root finding invariably proceeds by iteration, and this is equally true in one or in many dimensions. Starting from some approximate trial solution, a useful algorithm will improve the solution until some predetermined convergence criterion is satisfied. For smoothly varying functions, good algorithms

will always converge, *provided* that the initial guess is good enough. Indeed one can even determine in advance the rate of convergence of most algorithms.

It cannot be overemphasized, however, how crucially success depends on having a good first guess for the solution, especially for multidimensional problems. This crucial beginning usually depends on analysis rather than numerics. Carefully crafted initial estimates reward you not only with reduced computational effort, but also with understanding and increased self-esteem. Hamming's motto, "the purpose of computing is insight, not numbers," is particularly apt in the area of finding roots. You should repeat this motto aloud whenever your program converges, with ten-digit accuracy, to the wrong root of a problem, or whenever it fails to converge because there is actually *no* root, or because there is a root but your initial estimate was not sufficiently close to it.

"This talk of insight is all very well, but what do I actually do?" For one-dimensional root finding, it is possible to give some straightforward answers: You should try to get some idea of what your function looks like before trying to find its roots. If you need to mass-produce roots for many different functions, then you should at least know what some typical members of the ensemble look like. Next, you should always bracket a root, that is, know that the function changes sign in an identified interval, before trying to converge to the root's value.

Finally (this is advice with which some daring souls might disagree, but we give it nonetheless) never let your iteration method get outside of the best bracketing bounds obtained at any stage. We will see below that some pedagogically important algorithms, such as *secant method* or *Newton-Raphson*, can violate this last constraint, and are thus not recommended unless certain fixups are implemented.

Multiple roots, or very close roots, are a real problem, especially if the multiplicity is an even number. In that case, there may be no readily apparent sign change in the function, so the notion of bracketing a root — and maintaining the bracket — becomes difficult. We are hard-liners: we nevertheless insist on bracketing a root, even if it takes the minimum-searching techniques of Chapter 10 to determine whether a tantalizing dip in the function really does cross zero or not. (You can easily modify the simple golden section routine of §10.1 to return early if it detects a sign change in the function. And, if the minimum of the function is exactly zero, then you have found a *double* root.)

As usual, we want to discourage you from using routines as black boxes without understanding them. However, as a guide to beginners, here are some reasonable starting points:

- Brent's algorithm in §9.3 is the method of choice to find a bracketed root of a general one-dimensional function, when you cannot easily compute the function's derivative. Ridders' method (§9.2) is concise, and a close competitor.
- When you can compute the function's derivative, the routine `rtsafe` in §9.4, which combines the Newton-Raphson method with some bookkeeping on bounds, is recommended. Again, you must first bracket your root.
- Roots of polynomials are a special case. Laguerre's method, in §9.5, is recommended as a starting point. Beware: Some polynomials are ill-conditioned!
- Finally, for multidimensional problems, the only elementary method is Newton-Raphson (§9.6), which works *very* well if you can supply a

good first guess of the solution. Try it. Then read the more advanced material in §9.7 for some more complicated, but globally more convergent, alternatives.

Avoiding implementations for specific computers, this book must generally steer clear of interactive or graphics-related routines. We make an exception right now. The following routine, which produces a crude function plot with interactively scaled axes, can save you a lot of grief as you enter the world of root finding.

```

SUBROUTINE scrsho(fx)
INTEGER ISCR,JSCR

9.1 Bracketing and Bisection

We will say that a root is *bracketed* in the interval (a, b) if $f(a)$ and $f(b)$ have opposite signs. If the function is continuous, then at least one root must lie in that interval (the *intermediate value theorem*). If the function is discontinuous, but bounded, then instead of a root there might be a step discontinuity which crosses zero (see Figure 9.1.1). For numerical purposes, that might as well be a root, since the behavior is indistinguishable from the case of a continuous function whose zero crossing occurs in between two “adjacent” floating-point numbers in a machine’s finite-precision representation. Only for functions with singularities is there the possibility that a bracketed root is not really there, as for example

$$f(x) = \frac{1}{x - c} \quad (9.1.1)$$

Some root-finding algorithms (e.g., bisection in this section) will readily converge to c in (9.1.1). Luckily there is not much possibility of your mistaking c , or any number x close to it, for a root, since mere evaluation of $|f(x)|$ will give a very large, rather than a very small, result.

If you are given a function in a black box, there is no sure way of bracketing its roots, or of even determining that it has roots. If you like pathological examples, think about the problem of locating the two real roots of equation (3.0.1), which dips below zero only in the ridiculously small interval of about $x = \pi \pm 10^{-667}$.

In the next chapter we will deal with the related problem of bracketing a function’s minimum. There it is possible to give a procedure that always succeeds; in essence, “Go downhill, taking steps of increasing size, until your function starts back uphill.” There is no analogous procedure for roots. The procedure “go downhill until your function changes sign,” can be foiled by a function that has a simple extremum. Nevertheless, if you are prepared to deal with a “failure” outcome, this procedure is often a good first start; success is usual if your function has opposite signs in the limit $x \rightarrow \pm\infty$.

9.1 Bracketing and Bisection

We will say that a root is *bracketed* in the interval (a, b) if $f(a)$ and $f(b)$ have opposite signs. If the function is continuous, then at least one root must lie in that interval (the *intermediate value theorem*). If the function is discontinuous, but bounded, then instead of a root there might be a step discontinuity which crosses zero (see Figure 9.1.1). For numerical purposes, that might as well be a root, since the behavior is indistinguishable from the case of a continuous function whose zero crossing occurs in between two “adjacent” floating-point numbers in a machine’s finite-precision representation. Only for functions with singularities is there the possibility that a bracketed root is not really there, as for example

$$f(x) = \frac{1}{x - c} \quad (9.1.1)$$

Some root-finding algorithms (e.g., bisection in this section) will readily converge to c in (9.1.1). Luckily there is not much possibility of your mistaking c , or any number x close to it, for a root, since mere evaluation of $|f(x)|$ will give a very large, rather than a very small, result.

If you are given a function in a black box, there is no sure way of bracketing its roots, or of even determining that it has roots. If you like pathological examples, think about the problem of locating the two real roots of equation (3.0.1), which dips below zero only in the ridiculously small interval of about $x = \pi \pm 10^{-667}$.

In the next chapter we will deal with the related problem of bracketing a function’s minimum. There it is possible to give a procedure that always succeeds; in essence, “Go downhill, taking steps of increasing size, until your function starts back uphill.” There is no analogous procedure for roots. The procedure “go downhill until your function changes sign,” can be foiled by a function that has a simple extremum. Nevertheless, if you are prepared to deal with a “failure” outcome, this procedure is often a good first start; success is usual if your function has opposite signs in the limit $x \rightarrow \pm\infty$.

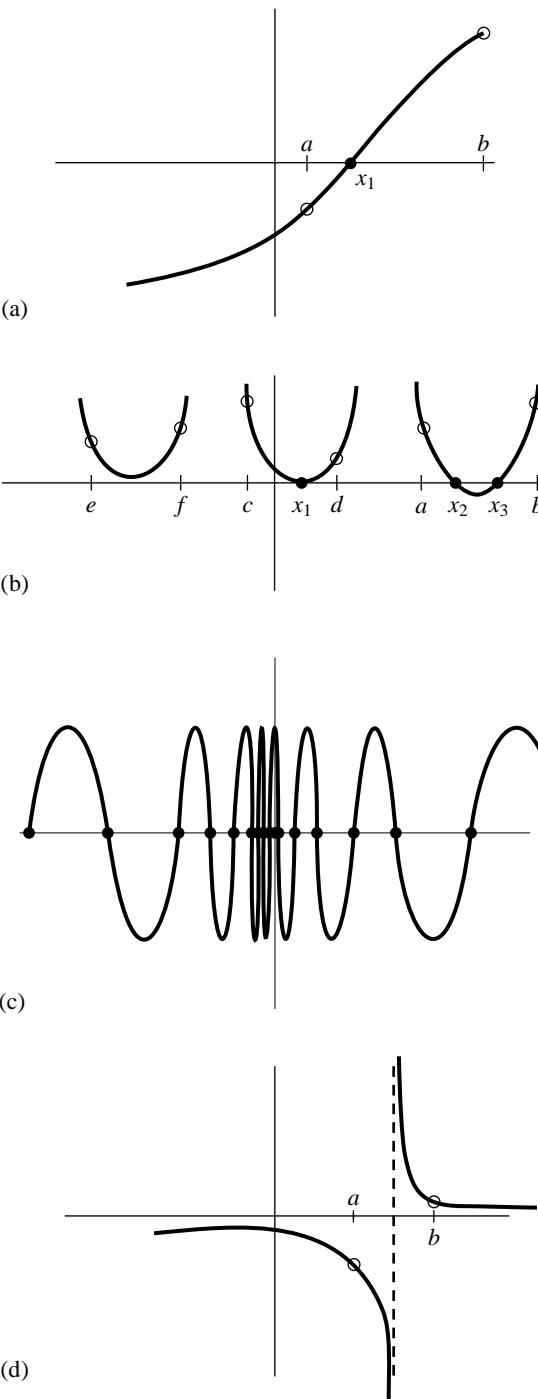

Figure 9.1.1. Some situations encountered while root finding: (a) shows an isolated root x_1 bracketed by two points a and b at which the function has opposite signs; (b) illustrates that there is not necessarily a sign change in the function near a double root (in fact, there is not necessarily a root!); (c) is a pathological function with many roots; in (d) the function has opposite signs at points a and b , but the points bracket a singularity, not a root.

```

SUBROUTINE zbrac(func,x1,x2,succes)
INTEGER NTRY
REAL x1,x2,func,FACTOR
EXTERNAL func
PARAMETER (FACTOR=1.6,NTRY=50)
    Given a function func and an initial guessed range x1 to x2, the routine expands the range
    geometrically until a root is bracketed by the returned values x1 and x2 (in which case
    succes returns as .true.) or until the range becomes unacceptably large (in which case
    succes returns as .false.).
INTEGER j
REAL f1,f2
LOGICAL succes
if(x1.eq.x2)pause 'you have to guess an initial range in zbrac'
f1=func(x1)
f2=func(x2)
succes=.true.

    endif
enddo :: 
succes=.false.
return
END

```

Alternatively, you might want to “look inward” on an initial interval, rather than “look outward” from it, asking if there are any roots of the function $f(x)$ in the interval from x_1 to x_2 when a search is carried out by subdivision into n equal intervals. The following subroutine returns brackets for up to nb distinct intervals which each contain one or more roots.

```

SUBROUTINE zbrak(fx,x1,x2,n,xb1,xb2,nb)
INTEGER n,nb
REAL x1,x2,xb1(nb),xb2(nb),fx
EXTERNAL fx
    Given a function fx defined on the interval from x1–x2 subdivide the interval into n equally
    spaced segments, and search for zero crossings of the function. nb is input as the maxi-
    mum number of roots sought, and is reset to the number of bracketing pairs xb1(1:nb),
    xb2(1:nb) that are found.
INTEGER i,nbb
REAL dx,fc,fp,x
nbb=0
x=x1
dx=(x2-x1)/n                Determine the spacing appropriate to the mesh.
fp=fx(x)
do :: i=1,n                  Loop over all intervals
    x=x+dx
    fc=fx(x)
    if(fc*fp.le.0.) then      If a sign change occurs then record values for the bounds.
        nbb=nbb+1
        xb1(nbb)=x-dx
        xb2(nbb)=x
        if(nbb.eq.nb)goto 1
    endif
    fp=fc
enddo :: 

```

```

1 continue
nb=nbb
return
END

```

Bisection Method

Once we know that an interval contains a root, several classical procedures are available to refine it. These proceed with varying degrees of speed and sureness towards the answer. Unfortunately, the methods that are guaranteed to converge plod along most slowly, while those that rush to the solution in the best cases can also dash rapidly to infinity without warning if measures are not taken to avoid such behavior.

The *bisection method* is one that cannot fail. It is thus not to be sneered at as a method for otherwise badly behaved problems. The idea is simple. Over some interval the function is known to pass through zero because it changes sign. Evaluate the function at the interval's midpoint and examine its sign. Use the midpoint to replace whichever limit has the same sign. After each iteration the bounds containing the root decrease by a factor of two. If after n iterations the root is known to be within an interval of size ϵ_n , then after the next iteration it will be bracketed within an interval of size

$$\epsilon_{n+1} = \epsilon_n / 2 \quad (9.1.2)$$

neither more nor less. Thus, we know in advance the number of iterations required to achieve a given tolerance in the solution,

$$n = \log_2 \frac{\epsilon_0}{\epsilon} \quad (9.1.3)$$

where ϵ_0 is the size of the initially bracketing interval, ϵ is the desired ending tolerance.

Bisection *must* succeed. If the interval happens to contain two or more roots, bisection will find one of them. If the interval contains no roots and merely straddles a singularity, it will converge on the singularity.

When a method converges as a factor (less than 1) times the previous uncertainty to the first power (as is the case for bisection), it is said to converge *linearly*. Methods that converge as a higher power,

$$\epsilon_{n+1} = \text{constant} \times (\epsilon_n)^m \quad m > 1 \quad (9.1.4)$$

are said to converge superlinearly. In other contexts “linear” convergence would be termed “exponential,” or “geometrical.” That is not too bad at all: Linear convergence means that successive significant figures are won linearly with computational effort.

It remains to discuss practical criteria for convergence. It is crucial to keep in mind that computers use a fixed number of binary digits to represent floating-point numbers. While your function might analytically pass through zero, it is possible that its computed value is never zero, for any floating-point argument. One must decide what accuracy on the root is attainable: Convergence to within 10^{-6} in absolute value is reasonable when the root lies near 1, but certainly unachievable if

the root lies near 10^{26} . One might thus think to specify convergence by a relative (fractional) criterion, but this becomes unworkable for roots near zero. To be most general, the routines below will require you to specify an absolute tolerance, such that iterations continue until the interval becomes smaller than this tolerance in absolute units. Usually you may wish to take the tolerance to be $\epsilon(|x_1| + |x_2|)/2$ where ϵ is the machine precision and x_1 and x_2 are the initial brackets. When the root lies near zero you ought to consider carefully what reasonable tolerance means for your function. The following routine quits after 40 bisections in any event, with $2^{-40} \approx 10^{-12}$.

```

FUNCTION rtbis(func,x1,x2,xacc)

pause 'too many bisections in rtbis'
END

```

9.2 Secant Method, False Position Method, and Ridders' Method

For functions that are smooth near a root, the methods known respectively as *false position* (or *regula falsi*) and *secant method* generally converge faster than bisection. In both of these methods the function is assumed to be approximately linear in the local region of interest, and the next improvement in the root is taken as the point where the approximating line crosses the axis. After each iteration one of the previous boundary points is discarded in favor of the latest estimate of the root.

The *only* difference between the methods is that secant retains the most recent of the prior estimates (Figure 9.2.1; this requires an arbitrary choice on the first iteration), while false position retains that prior estimate for which the function value

the root lies near 10^{26} . One might thus think to specify convergence by a relative (fractional) criterion, but this becomes unworkable for roots near zero. To be most general, the routines below will require you to specify an absolute tolerance, such that iterations continue until the interval becomes smaller than this tolerance in absolute units. Usually you may wish to take the tolerance to be $\epsilon(|x_1| + |x_2|)/2$ where ϵ is the machine precision and x_1 and x_2 are the initial brackets. When the root lies near zero you ought to consider carefully what reasonable tolerance means for your function. The following routine quits after 40 bisections in any event, with $2^{-40} \approx 10^{-12}$.

```

9.2 Secant Method, False Position Method, and Ridders' Method

For functions that are smooth near a root, the methods known respectively as *false position* (or *regula falsi*) and *secant method* generally converge faster than bisection. In both of these methods the function is assumed to be approximately linear in the local region of interest, and the next improvement in the root is taken as the point where the approximating line crosses the axis. After each iteration one of the previous boundary points is discarded in favor of the latest estimate of the root.

The *only* difference between the methods is that secant retains the most recent of the prior estimates (Figure 9.2.1; this requires an arbitrary choice on the first iteration), while false position retains that prior estimate for which the function value

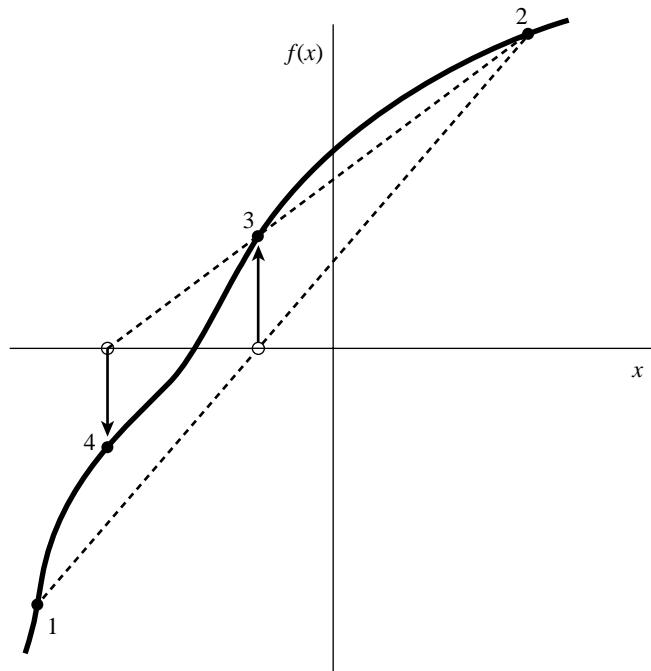

Figure 9.2.1. Secant method. Extrapolation or interpolation lines (dashed) are drawn through the two most recently evaluated points, whether or not they bracket the function. The points are numbered in the order that they are used.

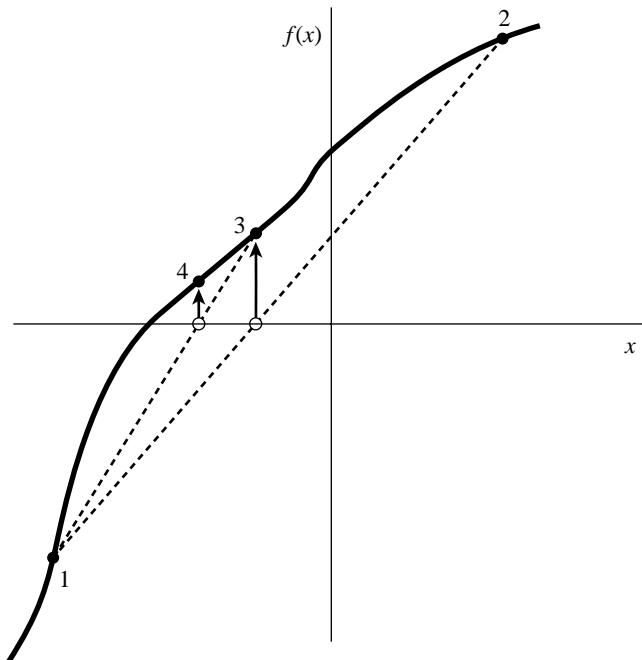

Figure 9.2.2. False position method. Interpolation lines (dashed) are drawn through the most recent points that bracket the root. In this example, point 1 thus remains “active” for many steps. False position converges less rapidly than the secant method, but it is more certain.

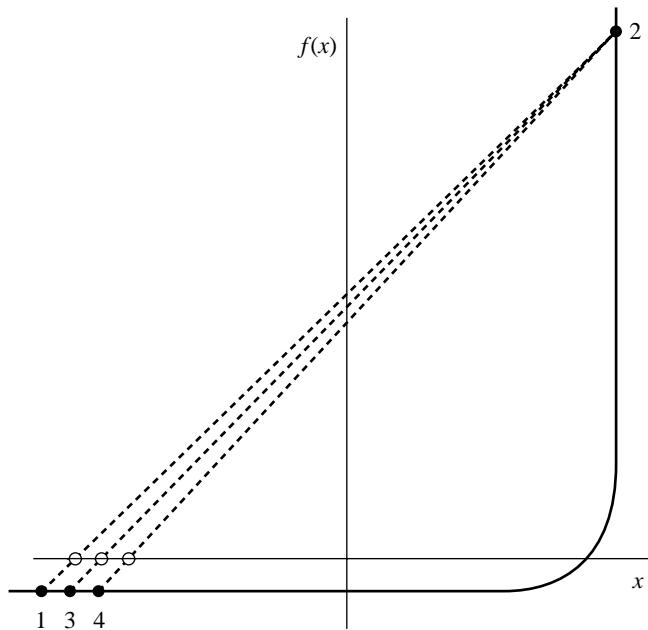

Figure 9.2.3. Example where both the secant and false position methods will take many iterations to arrive at the true root. This function would be difficult for many other root-finding methods.

has opposite sign from the function value at the current best estimate of the root, so that the two points continue to bracket the root (Figure 9.2.2). Mathematically, the secant method converges more rapidly near a root of a sufficiently continuous function. Its order of convergence can be shown to be the “golden ratio” $1.618\dots$, so that

$$\lim_{k \rightarrow \infty} |\epsilon_{k+1}| \approx \text{const} \times |\epsilon_k|^{1.618} \quad (9.2.1)$$

The secant method has, however, the disadvantage that the root does not necessarily remain bracketed. For functions that are *not* sufficiently continuous, the algorithm can therefore not be guaranteed to converge: Local behavior might send it off towards infinity.

False position, since it sometimes keeps an older rather than newer function evaluation, has a lower order of convergence. Since the newer function value will *sometimes* be kept, the method is often superlinear, but estimation of its exact order is not so easy.

Here are sample implementations of these two related methods. While these methods are standard textbook fare, *Ridders' method*, described below, or *Brent's method*, in the next section, are almost always better choices. Figure 9.2.3 shows the behavior of secant and false-position methods in a difficult situation.

```

enddo !!
pause 'rtsec exceed maximum iterations'
END

```

Ridders' Method

A powerful variant on false position is due to Ridders [1]. When a root is bracketed between x_1 and x_2 , Ridders' method first evaluates the function at the midpoint $x_3 = (x_1 + x_2)/2$. It then factors out that unique exponential function which turns the residual function into a straight line. Specifically, it solves for a factor e^Q that gives

$$f(x_1) - 2f(x_3)e^Q + f(x_2)e^{2Q} = 0 \quad (9.2.2)$$

This is a quadratic equation in e^Q , which can be solved to give

$$e^Q = \frac{f(x_3) + \text{sign}[f(x_2)]\sqrt{f(x_3)^2 - f(x_1)f(x_2)}}{f(x_2)} \quad (9.2.3)$$

Now the false position method is applied, not to the values $f(x_1), f(x_3), f(x_2)$, but to the values $f(x_1), f(x_3)e^Q, f(x_2)e^{2Q}$, yielding a new guess for the root, x_4 . The overall updating formula (incorporating the solution 9.2.3) is

$$x_4 = x_3 + (x_3 - x_1) \frac{\text{sign}[f(x_1) - f(x_2)]f(x_3)}{\sqrt{f(x_3)^2 - f(x_1)f(x_2)}} \quad (9.2.4)$$

Equation (9.2.4) has some very nice properties. First, x_4 is guaranteed to lie in the interval (x_1, x_2) , so the method never jumps out of its brackets. Second, the convergence of successive applications of equation (9.2.4) is *quadratic*, that is, $m = 2$ in equation (9.1.4). Since each application of (9.2.4) requires two function evaluations, the actual order of the method is $\sqrt{2}$, not 2; but this is still quite respectably superlinear: the number of significant digits in the answer approximately *doubles* with each two function evaluations. Third, taking out the function's "bend" via exponential (that is, ratio) factors, rather than via a polynomial technique (e.g., fitting a parabola), turns out to give an extraordinarily robust algorithm. In both reliability and speed, Ridders' method is generally competitive with the more highly developed and better established (but more complicated) method of Van Wijngaarden, Dekker, and Brent, which we next discuss.

```

FUNCTION zriddr(func,x1,x2,xacc)
INTEGER MAXIT
REAL zriddr,x1,x2,xacc,func,UNUSED
PARAMETER (MAXIT=60,UNUSED=-1.11E30)
EXTERNAL func
C USES func
      Using Ridders' method, return the root of a function func known to lie between x1 and
      x2. The root, returned as zriddr, will be refined to an approximate accuracy xacc.
      INTEGER j

9.3 Van Wijngaarden–Dekker–Brent Method

While secant and false position formally converge faster than bisection, one finds in practice pathological functions for which bisection converges more rapidly.

These can be choppy, discontinuous functions, or even smooth functions if the second derivative changes sharply near the root. Bisection always halves the interval, while secant and false position can sometimes spend many cycles slowly pulling distant bounds closer to a root. Ridders' method does a much better job, but it too can sometimes be fooled. Is there a way to combine superlinear convergence with the sureness of bisection?

Yes. We can keep track of whether a supposedly superlinear method is actually converging the way it is supposed to, and, if it is not, we can intersperse bisection steps so as to guarantee *at least* linear convergence. This kind of super-strategy requires attention to bookkeeping detail, and also careful consideration of how roundoff errors can affect the guiding strategy. Also, we must be able to determine reliably when convergence has been achieved.

An excellent algorithm that pays close attention to these matters was developed in the 1960s by van Wijngaarden, Dekker, and others at the Mathematical Center in Amsterdam, and later improved by Brent [1]. For brevity, we refer to the final form of the algorithm as *Brent's method*. The method is *guaranteed* (by Brent) to converge, so long as the function can be evaluated within the initial interval known to contain a root.

Brent's method combines root bracketing, bisection, and *inverse quadratic interpolation* to converge from the neighborhood of a zero crossing. While the false position and secant methods assume approximately linear behavior between two prior root estimates, inverse quadratic interpolation uses three prior points to fit an inverse quadratic function (x as a quadratic function of y) whose value at $y = 0$ is taken as the next estimate of the root x . Of course one must have contingency plans for what to do if the root falls outside of the brackets. Brent's method takes care of all that. If the three point pairs are $[a, f(a)]$, $[b, f(b)]$, $[c, f(c)]$ then the interpolation formula (cf. equation 3.1.1) is

$$x = \frac{[y - f(a)][y - f(b)]c}{[f(c) - f(a)][f(c) - f(b)]} + \frac{[y - f(b)][y - f(c)]a}{[f(a) - f(b)][f(a) - f(c)]} \\ + \frac{[y - f(c)][y - f(a)]b}{[f(b) - f(c)][f(b) - f(a)]} \quad (9.3.1)$$

Setting y to zero gives a result for the next root estimate, which can be written as

$$x = b + P/Q \quad (9.3.2)$$

where, in terms of

$$R \equiv f(b)/f(c), \quad S \equiv f(b)/f(a), \quad T \equiv f(a)/f(c) \quad (9.3.3)$$

we have

$$P = S [T(R - T)(c - b) - (1 - R)(b - a)] \quad (9.3.4)$$

$$Q = (T - 1)(R - 1)(S - 1) \quad (9.3.5)$$

In practice b is the current best estimate of the root and P/Q ought to be a “small” correction. Quadratic methods work well only when the function behaves smoothly;

they run the serious risk of giving very bad estimates of the next root or causing machine failure by an inappropriate division by a very small number ($Q \approx 0$). Brent's method guards against this problem by maintaining brackets on the root and checking where the interpolation would land before carrying out the division. When the correction P/Q would not land within the bounds, or when the bounds are not collapsing rapidly enough, the algorithm takes a bisection step. Thus, Brent's method combines the sureness of bisection with the speed of a higher-order method when appropriate. We recommend it as the method of choice for general one-dimensional root finding where a function's values only (and not its derivative or functional form) are available.

```

FUNCTION zbrent(func,x1,x2,tol)
INTEGER ITMAX
REAL zbrent,tol,x1,x2,func,EPS
EXTERNAL func
PARAMETER (ITMAX=100,EPS=3.e-8)
    Using Brent's method, find the root of a function func known to lie between x1 and x2.
    The root, returned as zbrent, will be refined until its accuracy is tol.
    Parameters: Maximum allowed number of iterations, and machine floating-point precision.

9.4 Newton-Raphson Method Using Derivative

Perhaps the most celebrated of all one-dimensional root-finding routines is *Newton's method*, also called the *Newton-Raphson method*. This method is distinguished from the methods of previous sections by the fact that it requires the evaluation of both the function $f(x)$, and the derivative $f'(x)$, at arbitrary points x . The Newton-Raphson formula consists geometrically of extending the tangent line at a current point x_i until it crosses zero, then setting the next guess x_{i+1} to the abscissa of that zero-crossing (see Figure 9.4.1). Algebraically, the method derives from the familiar Taylor series expansion of a function in the neighborhood of a point,

$$f(x + \delta) \approx f(x) + f'(x)\delta + \frac{f''(x)}{2}\delta^2 + \dots \quad (9.4.1)$$

For small enough values of δ , and for well-behaved functions, the terms beyond linear are unimportant, hence $f(x + \delta) = 0$ implies

$$\delta = -\frac{f(x)}{f'(x)}. \quad (9.4.2)$$

9.4 Newton-Raphson Method Using Derivative

Perhaps the most celebrated of all one-dimensional root-finding routines is *Newton's method*, also called the *Newton-Raphson method*. This method is distinguished from the methods of previous sections by the fact that it requires the evaluation of both the function $f(x)$, and the derivative $f'(x)$, at arbitrary points x . The Newton-Raphson formula consists geometrically of extending the tangent line at a current point x_i until it crosses zero, then setting the next guess x_{i+1} to the abscissa of that zero-crossing (see Figure 9.4.1). Algebraically, the method derives from the familiar Taylor series expansion of a function in the neighborhood of a point,

$$f(x + \delta) \approx f(x) + f'(x)\delta + \frac{f''(x)}{2}\delta^2 + \dots \quad (9.4.1)$$

For small enough values of δ , and for well-behaved functions, the terms beyond linear are unimportant, hence $f(x + \delta) = 0$ implies

$$\delta = -\frac{f(x)}{f'(x)}. \quad (9.4.2)$$

Newton-Raphson is not restricted to one dimension. The method readily generalizes to multiple dimensions, as we shall see in §9.6 and §9.7, below.

Far from a root, where the higher-order terms in the series *are* important, the Newton-Raphson formula can give grossly inaccurate, meaningless corrections. For instance, the initial guess for the root might be so far from the true root as to let the search interval include a local maximum or minimum of the function. This can be death to the method (see Figure 9.4.2). If an iteration places a trial guess near such a local extremum, so that the first derivative nearly vanishes, then Newton-Raphson sends its solution off to limbo, with vanishingly small hope of recovery. Like most powerful tools, Newton-Raphson can be destructive used in inappropriate circumstances. Figure 9.4.3 demonstrates another possible pathology.

Why do we call Newton-Raphson powerful? The answer lies in its rate of convergence: Within a small distance ϵ of x the function and its derivative are approximately:

$$\begin{aligned} f(x + \epsilon) &= f(x) + \epsilon f'(x) + \epsilon^2 \frac{f''(x)}{2} + \dots, \\ f'(x + \epsilon) &= f'(x) + \epsilon f''(x) + \dots \end{aligned} \quad (9.4.3)$$

By the Newton-Raphson formula,

$$x_{i+1} = x_i - \frac{f(x_i)}{f'(x_i)}, \quad (9.4.4)$$

so that

$$\epsilon_{i+1} = \epsilon_i - \frac{f(x_i)}{f'(x_i)}. \quad (9.4.5)$$

When a trial solution x_i differs from the true root by ϵ_i , we can use (9.4.3) to express $f(x_i), f'(x_i)$ in (9.4.4) in terms of ϵ_i and derivatives at the root itself. The result is a recurrence relation for the deviations of the trial solutions

$$\epsilon_{i+1} = -\epsilon_i^2 \frac{f''(x)}{2f'(x)}. \quad (9.4.6)$$

Equation (9.4.6) says that Newton-Raphson converges *quadratically* (cf. equation 9.2.3). Near a root, the number of significant digits approximately *doubles* with each step. This very strong convergence property makes Newton-Raphson the method of choice for any function whose derivative can be evaluated efficiently, and whose derivative is continuous and nonzero in the neighborhood of a root.

Even where Newton-Raphson is rejected for the early stages of convergence (because of its poor global convergence properties), it is very common to “polish up” a root with one or two steps of Newton-Raphson, which can multiply by two or four its number of significant figures!

For an efficient realization of Newton-Raphson the user provides a routine that evaluates both $f(x)$ and its first derivative $f'(x)$ at the point x . The Newton-Raphson formula can also be applied using a numerical difference to approximate the true local derivative,

$$f'(x) \approx \frac{f(x + dx) - f(x)}{dx}. \quad (9.4.7)$$

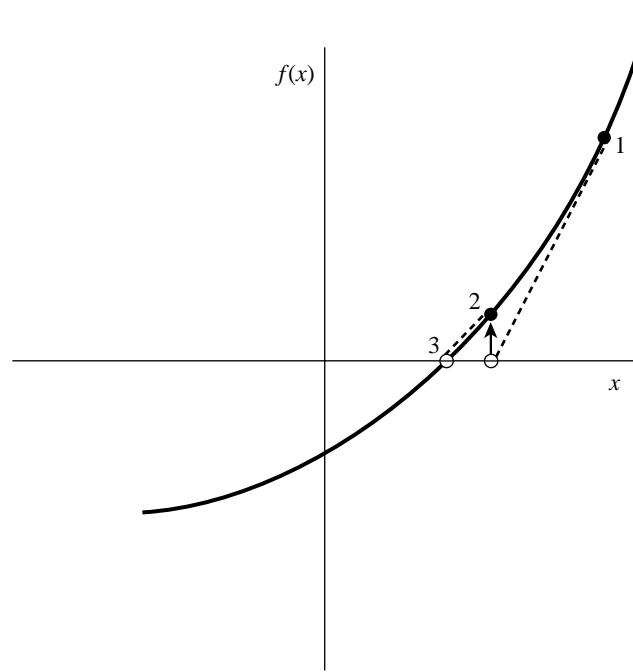

Figure 9.4.1. Newton's method extrapolates the local derivative to find the next estimate of the root. In this example it works well and converges quadratically.

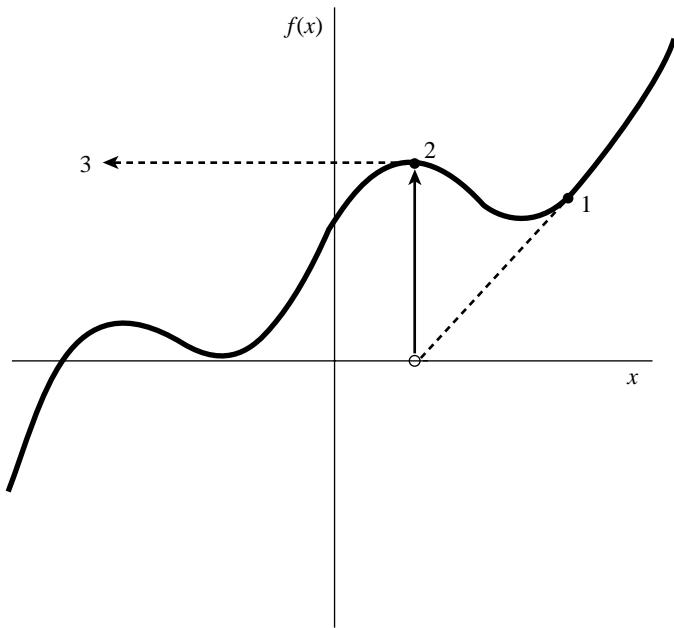

Figure 9.4.2. Unfortunate case where Newton's method encounters a local extremum and shoots off to outer space. Here bracketing bounds, as in `rtsafe`, would save the day.

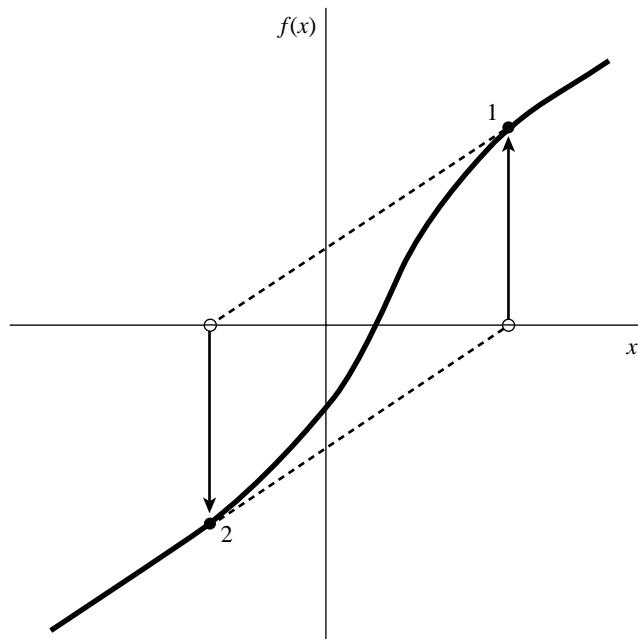

Figure 9.4.3. Unfortunate case where Newton's method enters a nonconvergent cycle. This behavior is often encountered when the function f is obtained, in whole or in part, by table interpolation. With a better initial guess, the method would have succeeded.

This is not, however, a recommended procedure for the following reasons: (i) You are doing two function evaluations per step, so *at best* the superlinear order of convergence will be only $\sqrt{2}$. (ii) If you take dx too small you will be wiped out by roundoff, while if you take it too large your order of convergence will be only linear, no better than using the *initial* evaluation $f'(x_0)$ for all subsequent steps. Therefore, Newton-Raphson with numerical derivatives is (in one dimension) always dominated by the secant method of §9.2. (In multidimensions, where there is a paucity of available methods, Newton-Raphson with numerical derivatives must be taken more seriously. See §§9.6–9.7.)

The following subroutine calls a user supplied subroutine `funcd(x,fn,df)` which returns the function value as `fn` and the derivative as `df`. We have included input bounds on the root simply to be consistent with previous root-finding routines: Newton does not adjust bounds, and works only on local information at the point `x`. The bounds are used only to pick the midpoint as the first guess, and to reject the solution if it wanders outside of the bounds.

```

FUNCTION rtnewt(funcd,x1,x2,xacc)
INTEGER JMAX
REAL rtnewt,x1,x2,xacc
EXTERNAL funcd
PARAMETER (JMAX=20)                                Set to maximum number of iterations.
Using the Newton-Raphson method, find the root of a function known to lie in the interval
[x1,x2]. The root rtnewt will be refined until its accuracy is known within ±xacc. funcd
is a user-supplied subroutine that returns both the function value and the first derivative
of the function at the point x.
INTEGER j
REAL df,dx,f

```

```

rtnewt=.5*(x1+x2)           Initial guess.
do 11 j=1,JMAX
  call funcd(rtnewt,f,df)
  dx=f/df
  rtnewt=rtnewt-dx
  if((x1-rtnewt)*(rtnewt-x2).lt.0.)
*       pause 'rtnewt jumped out of brackets'
  if(abs(dx).lt.xacc) return   Convergence.
11 enddo 11
pause 'rtnewt exceeded maximum iterations'
END

```

While Newton-Raphson's global convergence properties are poor, it is fairly easy to design a fail-safe routine that utilizes a combination of bisection and Newton-Raphson. The hybrid algorithm takes a bisection step whenever Newton-Raphson would take the solution out of bounds, or whenever Newton-Raphson is not reducing the size of the brackets rapidly enough.

```

FUNCTION rtsafe(funcd,x1,x2,xacc)
INTEGER MAXIT
REAL rtsafe,x1,x2,xacc
EXTERNAL funcd
PARAMETER (MAXIT=100)           Maximum allowed number of iterations.
                                  Using a combination of Newton-Raphson and bisection, find the root of a function bracketed
                                  between x1 and x2. The root, returned as the function value rtsafe, will be refined until
                                  its accuracy is known within  $\pm xacc$ . funcd is a user-supplied subroutine which returns
                                  both the function value and the first derivative of the function.

For many functions the derivative $f'(x)$ often converges to machine accuracy before the function $f(x)$ itself does. When that is the case one need not subsequently update $f'(x)$. This shortcut is recommended only when you confidently understand the generic behavior of your function, but it speeds computations when the derivative calculation is laborious. (Formally this makes the convergence only linear, but if the derivative isn't changing anyway, you can do no better.)

Newton-Raphson and Fractals

An interesting sidelight to our repeated warnings about Newton-Raphson's unpredictable global convergence properties — its very rapid local convergence notwithstanding — is to investigate, for some particular equation, the set of starting values from which the method does, or doesn't converge to a root.

Consider the simple equation

$$z^3 - 1 = 0 \quad (9.4.8)$$

whose single real root is $z = 1$, but which also has complex roots at the other two cube roots of unity, $\exp(\pm 2\pi i/3)$. Newton's method gives the iteration

$$z_{j+1} = z_j - \frac{z_j^3 - 1}{3z_j^2} \quad (9.4.9)$$

Up to now, we have applied an iteration like equation (9.4.9) only for real starting values z_0 , but in fact all of the equations in this section also apply in the complex plane. We can therefore map out the complex plane into regions from which a starting value z_0 , iterated in equation (9.4.9), will, or won't, converge to $z = 1$. Naively, we might expect to find a “basin of convergence” somehow surrounding the root $z = 1$. We surely do not expect the basin of convergence to fill the whole plane, because the plane must also contain regions that converge to each of the two complex roots. In fact, by symmetry, the three regions must have identical shapes. Perhaps they will be three symmetric 120° wedges, with one root centered in each?

Now take a look at Figure 9.4.4, which shows the result of a numerical exploration. The basin of convergence does indeed cover $1/3$ the area of the complex plane, but its boundary is highly irregular — in fact, *fractal*. (A fractal, so called, has self-similar structure that repeats on all scales of magnification.) How does this

Figure 9.4.4. The complex z plane with real and imaginary components in the range $(-2, 2)$. The black region is the set of points from which Newton's method converges to the root $z = 1$ of the equation $z^3 - 1 = 0$. Its shape is fractal.

fractal emerge from something as simple as Newton's method, and an equation as simple as (9.4.8)? The answer is already implicit in Figure 9.4.2, which showed how, on the real line, a local extremum causes Newton's method to shoot off to infinity. Suppose one is *slightly* removed from such a point. Then one might be shot off not to infinity, but — by luck — right into the basin of convergence of the desired root. But that means that in the neighborhood of an extremum there must be a tiny, perhaps distorted, copy of the basin of convergence — a kind of “one-bounce away” copy. Similar logic shows that there can be “two-bounce” copies, “three-bounce” copies, and so on. A fractal thus emerges.

Notice that, for equation (9.4.8), almost the whole real axis is in the domain of convergence for the root $z = 1$. We say “almost” because of the peculiar discrete points on the negative real axis whose convergence is indeterminate (see figure). What happens if you start Newton's method from one of these points? (Try it.)

9.5 Roots of Polynomials

Here we present a few methods for finding roots of polynomials. These will serve for most practical problems involving polynomials of low-to-moderate degree or for well-conditioned polynomials of higher degree. Not as well appreciated as it ought to be is the fact that some polynomials are exceedingly ill-conditioned. The tiniest changes in a polynomial's coefficients can, in the worst case, send its roots sprawling all over the complex plane. (An infamous example due to Wilkinson is detailed by Acton [1].)

Recall that a polynomial of degree n will have n roots. The roots can be real or complex, and they might not be distinct. If the coefficients of the polynomial are real, then complex roots will occur in pairs that are conjugate, i.e., if $x_1 = a + bi$ is a root then $x_2 = a - bi$ will also be a root. When the coefficients are complex, the complex roots need not be related.

Multiple roots, or closely spaced roots, produce the most difficulty for numerical algorithms (see Figure 9.5.1). For example, $P(x) = (x - a)^2$ has a double real root at $x = a$. However, we cannot bracket the root by the usual technique of identifying neighborhoods where the function changes sign, nor will slope-following methods such as Newton-Raphson work well, because both the function and its derivative vanish at a multiple root. Newton-Raphson *may* work, but slowly, since large roundoff errors can occur. When a root is known in advance to be multiple, then special methods of attack are readily devised. Problems arise when (as is generally the case) we do not know in advance what pathology a root will display.

Deflation of Polynomials

When seeking several or all roots of a polynomial, the total effort can be significantly reduced by the use of *deflation*. As each root r is found, the polynomial is factored into a product involving the root and a reduced polynomial of degree one less than the original, i.e., $P(x) = (x - r)Q(x)$. Since the roots of Q are exactly the remaining roots of P , the effort of finding additional roots decreases, because we work with polynomials of lower and lower degree as we find successive roots. Even more important, with deflation we can avoid the blunder of having our iterative method converge twice to the same (nonmultiple) root instead of separately to two different roots.

Deflation, which amounts to synthetic division, is a simple operation that acts on the array of polynomial coefficients. The concise code for synthetic division by a monomial factor was given in §5.3 above. You can deflate complex roots either by converting that code to complex data type, or else — in the case of a polynomial with real coefficients but possibly complex roots — by deflating by a quadratic factor,

$$[x - (a + ib)][x - (a - ib)] = x^2 - 2ax + (a^2 + b^2) \quad (9.5.1)$$

9.5 Roots of Polynomials

Here we present a few methods for finding roots of polynomials. These will serve for most practical problems involving polynomials of low-to-moderate degree or for well-conditioned polynomials of higher degree. Not as well appreciated as it ought to be is the fact that some polynomials are exceedingly ill-conditioned. The tiniest changes in a polynomial's coefficients can, in the worst case, send its roots sprawling all over the complex plane. (An infamous example due to Wilkinson is detailed by Acton [1].)

Recall that a polynomial of degree n will have n roots. The roots can be real or complex, and they might not be distinct. If the coefficients of the polynomial are real, then complex roots will occur in pairs that are conjugate, i.e., if $x_1 = a + bi$ is a root then $x_2 = a - bi$ will also be a root. When the coefficients are complex, the complex roots need not be related.

Multiple roots, or closely spaced roots, produce the most difficulty for numerical algorithms (see Figure 9.5.1). For example, $P(x) = (x - a)^2$ has a double real root at $x = a$. However, we cannot bracket the root by the usual technique of identifying neighborhoods where the function changes sign, nor will slope-following methods such as Newton-Raphson work well, because both the function and its derivative vanish at a multiple root. Newton-Raphson *may* work, but slowly, since large roundoff errors can occur. When a root is known in advance to be multiple, then special methods of attack are readily devised. Problems arise when (as is generally the case) we do not know in advance what pathology a root will display.

Deflation of Polynomials

When seeking several or all roots of a polynomial, the total effort can be significantly reduced by the use of *deflation*. As each root r is found, the polynomial is factored into a product involving the root and a reduced polynomial of degree one less than the original, i.e., $P(x) = (x - r)Q(x)$. Since the roots of Q are exactly the remaining roots of P , the effort of finding additional roots decreases, because we work with polynomials of lower and lower degree as we find successive roots. Even more important, with deflation we can avoid the blunder of having our iterative method converge twice to the same (nonmultiple) root instead of separately to two different roots.

Deflation, which amounts to synthetic division, is a simple operation that acts on the array of polynomial coefficients. The concise code for synthetic division by a monomial factor was given in §5.3 above. You can deflate complex roots either by converting that code to complex data type, or else — in the case of a polynomial with real coefficients but possibly complex roots — by deflating by a quadratic factor,

$$[x - (a + ib)][x - (a - ib)] = x^2 - 2ax + (a^2 + b^2) \quad (9.5.1)$$

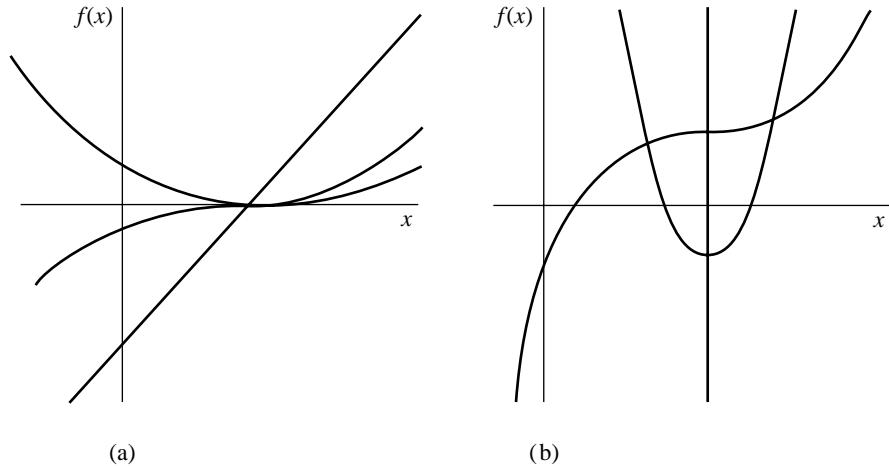

Figure 9.5.1. (a) Linear, quadratic, and cubic behavior at the roots of polynomials. Only under high magnification (b) does it become apparent that the cubic has one, not three, roots, and that the quadratic has two roots rather than none.

The routine `poldiv` in §5.3 can be used to divide the polynomial by this factor.

Deflation must, however, be utilized with care. Because each new root is known with only finite accuracy, errors creep into the determination of the coefficients of the successively deflated polynomial. Consequently, the roots can become more and more inaccurate. It matters a lot whether the inaccuracy creeps in stably (plus or minus a few multiples of the machine precision at each stage) or unstably (erosion of successive significant figures until the results become meaningless). Which behavior occurs depends on just how the root is divided out. *Forward deflation*, where the new polynomial coefficients are computed in the order from the highest power of x down to the constant term, was illustrated in §5.3. This turns out to be stable if the root of smallest absolute value is divided out at each stage. Alternatively, one can do *backward deflation*, where new coefficients are computed in order from the constant term up to the coefficient of the highest power of x . This is stable if the remaining root of *largest* absolute value is divided out at each stage.

A polynomial whose coefficients are interchanged “end-to-end,” so that the constant becomes the highest coefficient, etc., has its roots mapped into their reciprocals. (Proof: Divide the whole polynomial by its highest power x^n and rewrite it as a polynomial in $1/x$.) The algorithm for backward deflation is therefore virtually identical to that of forward deflation, except that the original coefficients are taken in reverse order and the reciprocal of the deflating root is used. Since we will use forward deflation below, we leave to you the exercise of writing a concise coding for backward deflation (as in §5.3). For more on the stability of deflation, consult [2].

To minimize the impact of increasing errors (even stable ones) when using deflation, it is advisable to treat roots of the successively deflated polynomials as only *tentative* roots of the original polynomial. One then *polishes* these tentative roots by taking them as initial guesses that are to be re-solved for, using the *nondeflated* original polynomial P . Again you must beware lest two deflated roots are inaccurate enough that, under polishing, they both converge to the same undeflated root; in that case you gain a spurious root-multiplicity and lose a distinct root. This is detectable,

since you can compare each polished root for equality to previous ones from distinct tentative roots. When it happens, you are advised to deflate the polynomial just once (and for this root only), then again polish the tentative root, or to use Maehly's procedure (see equation 9.5.29 below).

Below we say more about techniques for polishing real and complex-conjugate tentative roots. First, let's get back to overall strategy.

There are two schools of thought about how to proceed when faced with a polynomial of real coefficients. One school says to go after the easiest quarry, the real, distinct roots, by the same kinds of methods that we have discussed in previous sections for general functions, i.e., trial-and-error bracketing followed by a safe Newton-Raphson as in `rtsafe`. Sometimes you are *only* interested in real roots, in which case the strategy is complete. Otherwise, you then go after quadratic factors of the form (9.5.1) by any of a variety of methods. One such is Bairstow's method, which we will discuss below in the context of root polishing. Another is Muller's method, which we here briefly discuss.

Muller's Method

Muller's method generalizes the secant method, but uses quadratic interpolation among three points instead of linear interpolation between two. Solving for the zeros of the quadratic allows the method to find complex pairs of roots. Given *three* previous guesses for the root x_{i-2} , x_{i-1} , x_i , and the values of the polynomial $P(x)$ at those points, the next approximation x_{i+1} is produced by the following formulas,

$$\begin{aligned} q &\equiv \frac{x_i - x_{i-1}}{x_{i-1} - x_{i-2}} \\ A &\equiv qP(x_i) - q(1+q)P(x_{i-1}) + q^2P(x_{i-2}) \\ B &\equiv (2q+1)P(x_i) - (1+q)^2P(x_{i-1}) + q^2P(x_{i-2}) \\ C &\equiv (1+q)P(x_i) \end{aligned} \tag{9.5.2}$$

followed by

$$x_{i+1} = x_i - (x_i - x_{i-1}) \left[\frac{2C}{B \pm \sqrt{B^2 - 4AC}} \right] \tag{9.5.3}$$

where the sign in the denominator is chosen to make its absolute value or modulus as large as possible. You can start the iterations with any three values of x that you like, e.g., three equally spaced values on the real axis. Note that you must allow for the possibility of a complex denominator, and subsequent complex arithmetic, in implementing the method.

Muller's method is sometimes also used for finding complex zeros of analytic functions (not just polynomials) in the complex plane, for example in the IMSL routine `ZANLY` [3].

Laguerre's Method

The second school regarding overall strategy happens to be the one to which we belong. That school advises you to use one of a very small number of methods that will converge (though with greater or lesser efficiency) to all types of roots: real, complex, single, or multiple. Use such a method to get tentative values for all n roots of your n th degree polynomial. Then go back and polish them as you desire.

Laguerre's method is by far the most straightforward of these general, complex methods. It does require complex arithmetic, even while converging to real roots; however, for polynomials with all real roots, it is guaranteed to converge to a root from any starting point. For polynomials with some complex roots, little is theoretically proved about the method's convergence. Much empirical experience, however, suggests that nonconvergence is extremely unusual, and, further, can almost always be fixed by a simple scheme to break a nonconverging limit cycle. (This is implemented in our routine, below.) An example of a polynomial that requires this cycle-breaking scheme is one of high degree ($\gtrsim 20$), with all its roots just outside of the complex unit circle, approximately equally spaced around it. When the method converges on a simple complex zero, it is known that its convergence is third order.

In some instances the complex arithmetic in the Laguerre method is no disadvantage, since the polynomial itself may have complex coefficients.

To motivate (although not rigorously derive) the Laguerre formulas we can note the following relations between the polynomial and its roots and derivatives

$$P_n(x) = (x - x_1)(x - x_2) \dots (x - x_n) \quad (9.5.4)$$

$$\ln |P_n(x)| = \ln |x - x_1| + \ln |x - x_2| + \dots + \ln |x - x_n| \quad (9.5.5)$$

$$\frac{d \ln |P_n(x)|}{dx} = +\frac{1}{x - x_1} + \frac{1}{x - x_2} + \dots + \frac{1}{x - x_n} = \frac{P'_n}{P_n} \equiv G \quad (9.5.6)$$

$$\begin{aligned} -\frac{d^2 \ln |P_n(x)|}{dx^2} &= +\frac{1}{(x - x_1)^2} + \frac{1}{(x - x_2)^2} + \dots + \frac{1}{(x - x_n)^2} \\ &= \left[\frac{P'_n}{P_n} \right]^2 - \frac{P''_n}{P_n} \equiv H \end{aligned} \quad (9.5.7)$$

Starting from these relations, the Laguerre formulas make what Acton [1] nicely calls “a rather drastic set of assumptions”: The root x_1 that we seek is assumed to be located some distance a from our current guess x , while *all other roots* are assumed to be located at a distance b

$$x - x_1 = a \quad ; \quad x - x_i = b \quad i = 2, 3, \dots, n \quad (9.5.8)$$

Then we can express (9.5.6), (9.5.7) as

$$\frac{1}{a} + \frac{n-1}{b} = G \quad (9.5.9)$$

$$\frac{1}{a^2} + \frac{n-1}{b^2} = H \quad (9.5.10)$$

which yields as the solution for a

$$a = \frac{n}{G \pm \sqrt{(n-1)(nH-G^2)}} \quad (9.5.11)$$

where the sign should be taken to yield the largest magnitude for the denominator. Since the factor inside the square root can be negative, a can be complex. (A more rigorous justification of equation 9.5.11 is in [4].)

The method operates iteratively: For a trial value x , a is calculated by equation (9.5.11). Then $x - a$ becomes the next trial value. This continues until a is sufficiently small.

The following routine implements the Laguerre method to find one root of a given polynomial of degree m , whose coefficients can be complex. As usual, the first coefficient $a(1)$ is the constant term, while $a(m+1)$ is the coefficient of the highest power of x . The routine implements a simplified version of an elegant stopping criterion due to Adams [5], which neatly balances the desire to achieve full machine accuracy, on the one hand, with the danger of iterating forever in the presence of roundoff error, on the other.

```

SUBROUTINE laguer(a,m,x,its)
INTEGER m,its,MAXIT,MR,MT
REAL EPSS
COMPLEX a(m+1),x
PARAMETER (EPSS=2.e-7,MR=8,MT=10,MAXIT=MT*MR)

Given the degree m and the complex coefficients a(1:m+1) of the polynomial  $\sum_{i=1}^{m+1} a(i)x^{i-1}$ , and given a complex value x, this routine improves x by Laguerre's method until it converges, within the achievable roundoff limit, to a root of the given polynomial. The number of iterations taken is returned as its.

Parameters: EPSS is the estimated fractional roundoff error. We try to break (rare) limit cycles with MR different fractional values, once every MT steps, for MAXIT total allowed iterations.

```

Here is a driver routine that calls `laguer` in succession for each root, performs the deflation, optionally polishes the roots by the same Laguerre method — if you are not going to polish in some other way — and finally sorts the roots by their real parts. (We will use this routine in Chapter 13.)

```

SUBROUTINE zroots(a,m,roots,polish)
INTEGER m,MAXM
REAL EPS
COMPLEX a(m+1),roots(m)
LOGICAL polish
PARAMETER (EPS=1.e-6,MAXM=101) A small number and maximum anticipated value of m+1.
C USES laguer
Given the degree m and the complex coefficients a(1:m+1) of the polynomial  $\sum_{i=1}^{m+1} a(i)x^{i-1}$ , this routine successively calls laguer and finds all m complex roots. The logical variable polish should be input as .true. if polishing (also by Laguerre's method) is desired, .false. if the roots will be subsequently polished by other means.
INTEGER i,j,jj,its
COMPLEX ad(MAXM),x,b,c
do ii j=1,m+1                  Copy of coefficients for successive deflation.
    ad(j)=a(j)
endo ii
do i3 j=m,1,-1                 Loop over each root to be found.
    x=cmplx(0.,0.)              Start at zero to favor convergence to smallest remaining root.
    call laguer(ad,j,x,its)     Find the root.
    if(abs(aimag(x)).le.2.*EPS**2*abs(real(x))) x=cmplx(real(x),0.)
    roots(j)=x
    b=ad(j+1)                   Forward deflation.
    do i2 jj=j,1,-1
        c=ad(jj)
        ad(jj)=b
        b=x*b+c
    enddo i2
endo i3
if (polish) then
    do i4 j=1,m                 Polish the roots using the undeflated coefficients.
        call laguer(a,m,roots(j),its)
    enddo i4
endif
do i6 j=2,m                     Sort roots by their real parts by straight insertion.
    x=roots(j)
    do i5 i=j-1,1,-1
        if(real(roots(i)).le.real(x))goto 10
        roots(i+1)=roots(i)
    enddo i5
    i=0

```

```

10      roots(i+1)=x
enddo 16
return
END

```

Eigenvalue Methods

The eigenvalues of a matrix \mathbf{A} are the roots of the “characteristic polynomial” $P(x) = \det[\mathbf{A} - x\mathbf{I}]$. However, as we will see in Chapter 11, root-finding is not generally an efficient way to find eigenvalues. Turning matters around, we can use the more efficient eigenvalue methods that are discussed in Chapter 11 to find the roots of arbitrary polynomials. You can easily verify (see, e.g., [6]) that the characteristic polynomial of the special $m \times m$ *companion matrix*

$$\mathbf{A} = \begin{pmatrix} -\frac{a_m}{a_{m+1}} & -\frac{a_{m-1}}{a_{m+1}} & \cdots & -\frac{a_2}{a_{m+1}} & -\frac{a_1}{a_{m+1}} \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & & & & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{pmatrix} \quad (9.5.12)$$

is equivalent to the general polynomial

$$P(x) = \sum_{i=1}^{m+1} a_i x^{i-1} \quad (9.5.13)$$

If the coefficients a_i are real, rather than complex, then the eigenvalues of \mathbf{A} can be found using the routines `balanc` and `hqr` in §§11.5–11.6 (see discussion there). This method, implemented in the routine `zrhqr` following, is typically about a factor 2 slower than `zroots` (above). However, for some classes of polynomials, it is a more robust technique, largely because of the fairly sophisticated convergence methods embodied in `hqr`. If your polynomial has real coefficients, and you are having trouble with `zroots`, then `zrhqr` is a recommended alternative.

```

SUBROUTINE zrhqr(a,m,rtr,rti)
INTEGER m,MAXM
REAL a(m+1),rtr(m),rti(m)
PARAMETER (MAXM=50)
C USES balanc,hqr
      Find all the roots of a polynomial with real coefficients,  $\sum_{i=1}^{m+1} a(i)x^{i-1}$ , given the degree
      m and the coefficients a(1:m+1). The method is to construct an upper Hessenberg matrix
      whose eigenvalues are the desired roots, and then use the routines balanc and hqr. The
      real and imaginary parts of the roots are returned in rtr(1:m) and rti(1:m), respectively.
      INTEGER j,k
      REAL hess(MAXM,MAXM),xr,xi
      if (m.gt.MAXM.or.a(m+1).eq.0.) pause 'bad args in zrhqr'
      do 12 k=1,m               Construct the matrix.
      hess(1,k)=-a(m+1-k)/a(m+1)
      do 11 j=2,m
      hess(j,k)=0.
      enddo 11
      if (k.ne.m) hess(k+1,k)=1.
      enddo 12

```

```

call balanc(hess,m,MAXM)      Find its eigenvalues.
call hqr(hess,m,MAXM,rtr,rti)

Other Sure-Fire Techniques

The *Jenkins-Traub method* has become practically a standard in black-box polynomial root-finders, e.g., in the IMSL library [3]. The method is too complicated to discuss here, but is detailed, with references to the primary literature, in [4].

The *Lehmer-Schur algorithm* is one of a class of methods that isolate roots in the complex plane by generalizing the notion of one-dimensional bracketing. It is possible to determine efficiently whether there are any polynomial roots within a circle of given center and radius. From then on it is a matter of bookkeeping to hunt down all the roots by a series of decisions regarding where to place new trial circles. Consult [1] for an introduction.

Techniques for Root-Polishing

Newton-Raphson works very well for real roots once the neighborhood of a root has been identified. The polynomial and its derivative can be efficiently simultaneously evaluated as in §5.3. For a polynomial of degree $n-1$ with coefficients $c(1)\dots c(n)$, the following segment of code embodies one cycle of Newton-Raphson:

```

p=c(n)*x+c(n-1)
p1=c(n)
do 11 i=n-2,1,-1
  p1=p+p1*x
  p=c(i)+p*x
enddo 11
if (p1.eq.0.) pause 'derivative should not vanish'
x=x-p/p1

```

Once all real roots of a polynomial have been polished, one must polish the complex roots, either directly, or by looking for quadratic factors.

Direct polishing by Newton-Raphson is straightforward for complex roots if the above code is converted to complex data types. With real polynomial coefficients, note that your starting guess (tentative root) *must* be off the real axis, otherwise you will never get off that axis — and may get shot off to infinity by a minimum or maximum of the polynomial.

For real polynomials, the alternative means of polishing complex roots (or, for that matter, double real roots) is *Bairstow's method*, which seeks quadratic factors. The advantage of going after quadratic factors is that it avoids all complex arithmetic. Bairstow's method seeks a quadratic factor that embodies the two roots $x = a \pm ib$, namely

$$x^2 - 2ax + (a^2 + b^2) \equiv x^2 + Bx + C \quad (9.5.14)$$

In general if we divide a polynomial by a quadratic factor, there will be a linear remainder

$$P(x) = (x^2 + Bx + C)Q(x) + Rx + S. \quad (9.5.15)$$

Given B and C , R and S can be readily found, by polynomial division (§5.3). We can consider R and S to be adjustable functions of B and C , and they will be zero if the quadratic factor is a divisor of $P(x)$.

In the neighborhood of a root a first-order Taylor series expansion approximates the variation of R, S with respect to small changes in B, C

$$R(B + \delta B, C + \delta C) \approx R(B, C) + \frac{\partial R}{\partial B} \delta B + \frac{\partial R}{\partial C} \delta C \quad (9.5.16)$$

$$S(B + \delta B, C + \delta C) \approx S(B, C) + \frac{\partial S}{\partial B} \delta B + \frac{\partial S}{\partial C} \delta C \quad (9.5.17)$$

To evaluate the partial derivatives, consider the derivative of (9.5.15) with respect to C . Since $P(x)$ is a fixed polynomial, it is independent of C , hence

$$0 = (x^2 + Bx + C) \frac{\partial Q}{\partial C} + Q(x) + \frac{\partial R}{\partial C} x + \frac{\partial S}{\partial C} \quad (9.5.18)$$

which can be rewritten as

$$-Q(x) = (x^2 + Bx + C) \frac{\partial Q}{\partial C} + \frac{\partial R}{\partial C} x + \frac{\partial S}{\partial C} \quad (9.5.19)$$

Similarly, $P(x)$ is independent of B , so differentiating (9.5.15) with respect to B gives

$$-xQ(x) = (x^2 + Bx + C) \frac{\partial Q}{\partial B} + \frac{\partial R}{\partial B} x + \frac{\partial S}{\partial B} \quad (9.5.20)$$

Now note that equation (9.5.19) matches equation (9.5.15) in form. Thus if we perform a second synthetic division of $P(x)$, i.e., a division of $Q(x)$, yielding a remainder $R_1 x + S_1$, then

$$\frac{\partial R}{\partial C} = -R_1 \quad \frac{\partial S}{\partial C} = -S_1 \quad (9.5.21)$$

To get the remaining partial derivatives, evaluate equation (9.5.20) at the two roots of the quadratic, x_+ and x_- . Since

$$Q(x_{\pm}) = R_1 x_{\pm} + S_1 \quad (9.5.22)$$

we get

$$\frac{\partial R}{\partial B} x_{\pm} + \frac{\partial S}{\partial B} = -x_{\pm}(R_1 x_{\pm} + S_1) \quad (9.5.23)$$

$$\frac{\partial R}{\partial B} x_{-} + \frac{\partial S}{\partial B} = -x_{-}(R_1 x_{-} + S_1) \quad (9.5.24)$$

Solve these two equations for the partial derivatives, using

$$x_{+} + x_{-} = -B \quad x_{+} x_{-} = C \quad (9.5.25)$$

and find

$$\frac{\partial R}{\partial B} = BR_1 - S_1 \quad \frac{\partial S}{\partial B} = CR_1 \quad (9.5.26)$$

Bairstow's method now consists of using Newton-Raphson in two dimensions (which is actually the subject of the next section) to find a simultaneous zero of R and S . Synthetic division is used twice per cycle to evaluate R, S and their partial derivatives with respect to B, C . Like one-dimensional Newton-Raphson, the method works well in the vicinity of a root pair (real or complex), but it can fail miserably when started at a random point. We therefore recommend it only in the context of polishing tentative complex roots.

```

We have already remarked on the annoyance of having two tentative roots collapse to one value under polishing. You are left not knowing whether your polishing procedure has lost a root, or whether there *is* actually a double root, which was split only by roundoff errors in your previous deflation. One solution is deflate-and-repolish; but deflation is what we are trying to avoid at the polishing stage. An alternative is *Maehly's procedure*. Maehly pointed out that the derivative of the reduced polynomial

$$P_j(x) \equiv \frac{P(x)}{(x - x_1) \cdots (x - x_j)} \quad (9.5.27)$$

can be written as

$$P'_j(x) = \frac{P'(x)}{(x - x_1) \cdots (x - x_j)} - \frac{P(x)}{(x - x_1) \cdots (x - x_j)} \sum_{i=1}^j (x - x_i)^{-1} \quad (9.5.28)$$

Hence one step of Newton-Raphson, taking a guess x_k into a new guess x_{k+1} , can be written as

$$x_{k+1} = x_k - \frac{P(x_k)}{P'(x_k) - P(x_k) \sum_{i=1}^j (x_k - x_i)^{-1}} \quad (9.5.29)$$

This equation, if used with i ranging over the roots already polished, will prevent a tentative root from spuriously hopping to another one's true root. It is an example of so-called *zero suppression* as an alternative to true deflation.

Muller's method, which was described above, can also be useful at the polishing stage.

9.6 Newton-Raphson Method for Nonlinear Systems of Equations

We make an extreme, but wholly defensible, statement: There are *no* good, general methods for solving systems of more than one nonlinear equation. Furthermore, it is not hard to see why (very likely) there *never will be* any good, general methods: Consider the case of two dimensions, where we want to solve simultaneously

$$\begin{aligned} f(x, y) &= 0 \\ g(x, y) &= 0 \end{aligned} \tag{9.6.1}$$

The functions f and g are two arbitrary functions, each of which has zero contour lines that divide the (x, y) plane into regions where their respective function is positive or negative. These zero contour boundaries are of interest to us. The solutions that we seek are those points (if any) that are common to the zero contours of f and g (see Figure 9.6.1). Unfortunately, the functions f and g have, in general, no relation to each other at all! There is nothing special about a common point from either f 's point of view, or from g 's. In order to find all common points, which are the solutions of our nonlinear equations, we will (in general) have to do neither more nor less than map out the full zero contours of both functions. Note further that the zero contours will (in general) consist of an unknown number of disjoint closed curves. How can we ever hope to know when we have found all such disjoint pieces?

For problems in more than two dimensions, we need to find points mutually common to N unrelated zero-contour hypersurfaces, each of dimension $N - 1$. You

The functions f and g are two arbitrary functions, each of which has zero contour lines that divide the (x, y) plane into regions where their respective function is positive or negative. These zero contour boundaries are of interest to us. The solutions that we seek are those points (if any) that are common to the zero contours of f and g (see Figure 9.6.1). Unfortunately, the functions f and g have, in general, no relation to each other at all! There is nothing special about a common point from either f 's point of view, or from g 's. In order to find all common points, which are the solutions of our nonlinear equations, we will (in general) have to do neither more nor less than map out the full zero contours of both functions. Note further that the zero contours will (in general) consist of an unknown number of disjoint closed curves. How can we ever hope to know when we have found all such disjoint pieces?

For problems in more than two dimensions, we need to find points mutually common to N unrelated zero-contour hypersurfaces, each of dimension $N - 1$. You

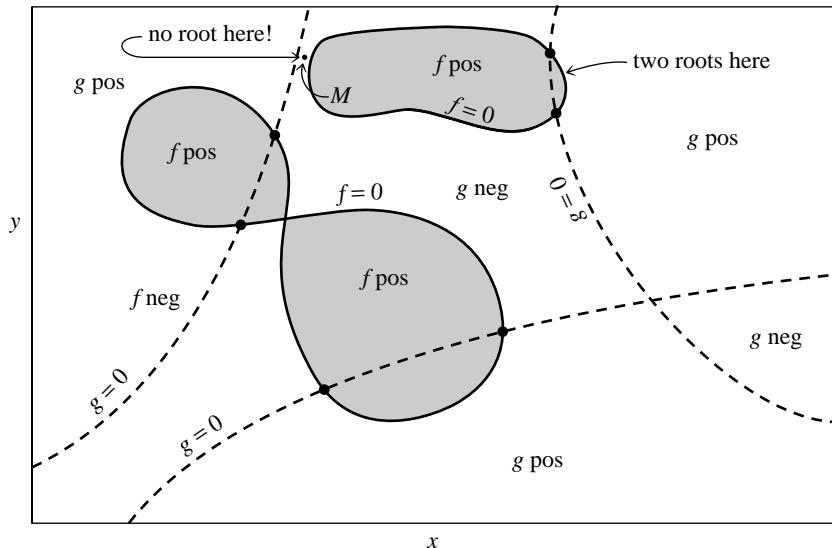

Figure 9.6.1. Solution of two nonlinear equations in two unknowns. Solid curves refer to $f(x, y)$, dashed curves to $g(x, y)$. Each equation divides the (x, y) plane into positive and negative regions, bounded by zero curves. The desired solutions are the intersections of these unrelated zero curves. The number of solutions is *a priori* unknown.

see that root finding becomes virtually impossible without insight! You will almost always have to use additional information, specific to your particular problem, to answer such basic questions as, “Do I expect a unique solution?” and “Approximately where?” Acton [1] has a good discussion of some of the particular strategies that can be tried.

In this section we will discuss the simplest multidimensional root finding method, Newton-Raphson. This method gives you a very efficient means of converging to a root, if you have a sufficiently good initial guess. It can also spectacularly fail to converge, indicating (though not proving) that your putative root does not exist nearby. In §9.7 we discuss more sophisticated implementations of the Newton-Raphson method, which try to improve on Newton-Raphson’s poor global convergence. A multidimensional generalization of the secant method, called Broyden’s method, is also discussed in §9.7.

A typical problem gives N functional relations to be zeroed, involving variables $x_i, i = 1, 2, \dots, N$:

$$F_i(x_1, x_2, \dots, x_N) = 0 \quad i = 1, 2, \dots, N. \quad (9.6.2)$$

We let \mathbf{x} denote the entire vector of values x_i and \mathbf{F} denote the entire vector of functions F_i . In the neighborhood of \mathbf{x} , each of the functions F_i can be expanded in Taylor series

$$F_i(\mathbf{x} + \delta\mathbf{x}) = F_i(\mathbf{x}) + \sum_{j=1}^N \frac{\partial F_i}{\partial x_j} \delta x_j + O(\delta\mathbf{x}^2). \quad (9.6.3)$$

The matrix of partial derivatives appearing in equation (9.6.3) is the *Jacobian* matrix \mathbf{J} :

$$J_{ij} \equiv \frac{\partial F_i}{\partial x_j}. \quad (9.6.4)$$

In matrix notation equation (9.6.3) is

$$\mathbf{F}(\mathbf{x} + \delta\mathbf{x}) = \mathbf{F}(\mathbf{x}) + \mathbf{J} \cdot \delta\mathbf{x} + O(\delta\mathbf{x}^2). \quad (9.6.5)$$

By neglecting terms of order $\delta\mathbf{x}^2$ and higher and by setting $\mathbf{F}(\mathbf{x} + \delta\mathbf{x}) = 0$, we obtain a set of linear equations for the corrections $\delta\mathbf{x}$ that move each function closer to zero simultaneously, namely

$$\mathbf{J} \cdot \delta\mathbf{x} = -\mathbf{F}. \quad (9.6.6)$$

Matrix equation (9.6.6) can be solved by *LU* decomposition as described in §2.3. The corrections are then added to the solution vector,

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \delta\mathbf{x} \quad (9.6.7)$$

and the process is iterated to convergence. In general it is a good idea to check the degree to which both functions and variables have converged. Once either reaches machine accuracy, the other won't change.

The following routine `mnewt` performs `ntrial` iterations starting from an initial guess at the solution vector \mathbf{x} of length `n` variables. Iteration stops if either the sum of the magnitudes of the functions F_i is less than some tolerance `tolf`, or the sum of the absolute values of the corrections to δx_i is less than some tolerance `tolx`. `mnewt` calls a user supplied subroutine `usrfun` which must return the function values \mathbf{F} and the Jacobian matrix \mathbf{J} . If \mathbf{J} is difficult to compute analytically, you can try having `usrfun` call the routine `fdjac` of §9.7 to compute the partial derivatives by finite differences. You should not make `ntrial` too big; rather inspect to see what is happening before continuing for some further iterations.

```
SUBROUTINE mnewt(ntrial,x,n,tolx,tolf)
INTEGER n,ntrial,NP
REAL tolx,tolf,x(n)
PARAMETER (NP=15)           Up to NP variables.
C USES lubksb,ludcmp,usrfun
  Given an initial guess x for a root in n dimensions, take ntrial Newton-Raphson steps to
  improve the root. Stop if the root converges in either summed absolute variable increments
  tolx or summed absolute function values tolf.

    x(i)=x(i)+p(i)
enddo 13
if(errx.le.tolx) return
endo 14
return
END

```

Newton's Method versus Minimization

In the next chapter, we will find that there *are* efficient general techniques for finding a minimum of a function of many variables. Why is that task (relatively) easy, while multidimensional root finding is often quite hard? Isn't minimization equivalent to finding a zero of an N -dimensional gradient vector, not so different from zeroing an N -dimensional function? No! The components of a gradient vector are not independent, arbitrary functions. Rather, they obey so-called integrability conditions that are highly restrictive. Put crudely, you can always find a minimum by sliding downhill on a single surface. The test of "downhillness" is thus one-dimensional. There is no analogous conceptual procedure for finding a multidimensional root, where "downhill" must mean simultaneously downhill in N separate function spaces, thus allowing a multitude of trade-offs, as to how much progress in one dimension is worth compared with progress in another.

It might occur to you to carry out multidimensional root finding by collapsing all these dimensions into one: Add up the sums of squares of the individual functions F_i to get a master function F which (i) is positive definite, and (ii) has a global minimum of zero exactly at all solutions of the original set of nonlinear equations. Unfortunately, as you will see in the next chapter, the efficient algorithms for finding minima come to rest on global and local minima indiscriminately. You will often find, to your great dissatisfaction, that your function F has a great number of local minima. In Figure 9.6.1, for example, there is likely to be a local minimum wherever the zero contours of f and g make a close approach to each other. The point labeled M is such a point, and one sees that there are no nearby roots.

However, we will now see that sophisticated strategies for multidimensional root finding can in fact make use of the idea of minimizing a master function F , by *combining* it with Newton's method applied to the full set of functions F_i . While such methods can still occasionally fail by coming to rest on a local minimum of F , they often succeed where a direct attack via Newton's method alone fails. The next section deals with these methods.

9.7 Globally Convergent Methods for Nonlinear Systems of Equations

We have seen that Newton's method for solving nonlinear equations has an unfortunate tendency to wander off into the wild blue yonder if the initial guess is not sufficiently close to the root. A *global* method is one that converges to a solution from almost any starting point. In this section we will develop an algorithm that combines the rapid local convergence of Newton's method with a globally convergent strategy that will guarantee some progress towards the solution at each iteration. The algorithm is closely related to the quasi-Newton method of minimization which we will describe in §10.7.

Recall our discussion of §9.6: the Newton step for the set of equations

$$\mathbf{F}(\mathbf{x}) = 0 \quad (9.7.1)$$

is

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \delta\mathbf{x} \quad (9.7.2)$$

where

$$\delta\mathbf{x} = -\mathbf{J}^{-1} \cdot \mathbf{F} \quad (9.7.3)$$

Here \mathbf{J} is the Jacobian matrix. How do we decide whether to accept the Newton step $\delta\mathbf{x}$? A reasonable strategy is to require that the step decrease $|\mathbf{F}|^2 = \mathbf{F} \cdot \mathbf{F}$. This is the same requirement we would impose if we were trying to minimize

$$f = \frac{1}{2}\mathbf{F} \cdot \mathbf{F} \quad (9.7.4)$$

(The $\frac{1}{2}$ is for later convenience.) Every solution to (9.7.1) minimizes (9.7.4), but there may be local minima of (9.7.4) that are not solutions to (9.7.1). Thus, as already mentioned, simply applying one of our minimum finding algorithms from Chapter 10 to (9.7.4) is *not* a good idea.

To develop a better strategy, note that the Newton step (9.7.3) is a *descent direction* for f :

$$\nabla f \cdot \delta\mathbf{x} = (\mathbf{F} \cdot \mathbf{J}) \cdot (-\mathbf{J}^{-1} \cdot \mathbf{F}) = -\mathbf{F} \cdot \mathbf{F} < 0 \quad (9.7.5)$$

Thus our strategy is quite simple: We always first try the full Newton step, because once we are close enough to the solution we will get quadratic convergence. However, we check at each iteration that the proposed step reduces f . If not, we *backtrack* along the Newton direction until we have an acceptable step. Because the Newton step is a descent direction for f , we are guaranteed to find an acceptable step by backtracking. We will discuss the backtracking algorithm in more detail below.

Note that this method essentially minimizes f by taking Newton steps designed to bring \mathbf{F} to zero. This is *not* equivalent to minimizing f directly by taking Newton steps designed to bring ∇f to zero. While the method can still occasionally fail by landing on a local minimum of f , this is quite rare in practice. The routine `newt` below will warn you if this happens. The remedy is to try a new starting point.

9.7 Globally Convergent Methods for Nonlinear Systems of Equations

We have seen that Newton's method for solving nonlinear equations has an unfortunate tendency to wander off into the wild blue yonder if the initial guess is not sufficiently close to the root. A *global* method is one that converges to a solution from almost any starting point. In this section we will develop an algorithm that combines the rapid local convergence of Newton's method with a globally convergent strategy that will guarantee some progress towards the solution at each iteration. The algorithm is closely related to the quasi-Newton method of minimization which we will describe in §10.7.

Recall our discussion of §9.6: the Newton step for the set of equations

$$\mathbf{F}(\mathbf{x}) = 0 \quad (9.7.1)$$

is

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \delta\mathbf{x} \quad (9.7.2)$$

where

$$\delta\mathbf{x} = -\mathbf{J}^{-1} \cdot \mathbf{F} \quad (9.7.3)$$

Here \mathbf{J} is the Jacobian matrix. How do we decide whether to accept the Newton step $\delta\mathbf{x}$? A reasonable strategy is to require that the step decrease $|\mathbf{F}|^2 = \mathbf{F} \cdot \mathbf{F}$. This is the same requirement we would impose if we were trying to minimize

$$f = \frac{1}{2}\mathbf{F} \cdot \mathbf{F} \quad (9.7.4)$$

(The $\frac{1}{2}$ is for later convenience.) Every solution to (9.7.1) minimizes (9.7.4), but there may be local minima of (9.7.4) that are not solutions to (9.7.1). Thus, as already mentioned, simply applying one of our minimum finding algorithms from Chapter 10 to (9.7.4) is *not* a good idea.

To develop a better strategy, note that the Newton step (9.7.3) is a *descent direction* for f :

$$\nabla f \cdot \delta\mathbf{x} = (\mathbf{F} \cdot \mathbf{J}) \cdot (-\mathbf{J}^{-1} \cdot \mathbf{F}) = -\mathbf{F} \cdot \mathbf{F} < 0 \quad (9.7.5)$$

Thus our strategy is quite simple: We always first try the full Newton step, because once we are close enough to the solution we will get quadratic convergence. However, we check at each iteration that the proposed step reduces f . If not, we *backtrack* along the Newton direction until we have an acceptable step. Because the Newton step is a descent direction for f , we are guaranteed to find an acceptable step by backtracking. We will discuss the backtracking algorithm in more detail below.

Note that this method essentially minimizes f by taking Newton steps designed to bring \mathbf{F} to zero. This is *not* equivalent to minimizing f directly by taking Newton steps designed to bring ∇f to zero. While the method can still occasionally fail by landing on a local minimum of f , this is quite rare in practice. The routine `newt` below will warn you if this happens. The remedy is to try a new starting point.

Line Searches and Backtracking

When we are not close enough to the minimum of f , taking the full Newton step $\mathbf{p} = \delta\mathbf{x}$ need not decrease the function; we may move too far for the quadratic approximation to be valid. All we are guaranteed is that *initially* f decreases as we move in the Newton direction. So the goal is to move to a new point \mathbf{x}_{new} along the *direction* of the Newton step \mathbf{p} , but not necessarily all the way:

$$\mathbf{x}_{\text{new}} = \mathbf{x}_{\text{old}} + \lambda\mathbf{p}, \quad 0 < \lambda \leq 1 \quad (9.7.6)$$

The aim is to find λ so that $f(\mathbf{x}_{\text{old}} + \lambda\mathbf{p})$ has decreased sufficiently. Until the early 1970s, standard practice was to choose λ so that \mathbf{x}_{new} exactly minimizes f in the direction \mathbf{p} . However, we now know that it is extremely wasteful of function evaluations to do so. A better strategy is as follows: Since \mathbf{p} is always the Newton direction in our algorithms, we first try $\lambda = 1$, the full Newton step. This will lead to quadratic convergence when \mathbf{x} is sufficiently close to the solution. However, if $f(\mathbf{x}_{\text{new}})$ does not meet our acceptance criteria, we *backtrack* along the Newton direction, trying a smaller value of λ , until we find a suitable point. Since the Newton direction is a descent direction, we are guaranteed to decrease f for sufficiently small λ .

What should the criterion for accepting a step be? It is *not* sufficient to require merely that $f(\mathbf{x}_{\text{new}}) < f(\mathbf{x}_{\text{old}})$. This criterion can fail to converge to a minimum of f in one of two ways. First, it is possible to construct a sequence of steps satisfying this criterion with f decreasing too slowly relative to the step lengths. Second, one can have a sequence where the step lengths are too small relative to the initial rate of decrease of f . (For examples of such sequences, see [1], p. 117.)

A simple way to fix the first problem is to require the *average* rate of decrease of f to be at least some fraction α of the *initial* rate of decrease $\nabla f \cdot \mathbf{p}$:

$$f(\mathbf{x}_{\text{new}}) \leq f(\mathbf{x}_{\text{old}}) + \alpha \nabla f \cdot (\mathbf{x}_{\text{new}} - \mathbf{x}_{\text{old}}) \quad (9.7.7)$$

Here the parameter α satisfies $0 < \alpha < 1$. We can get away with quite small values of α ; $\alpha = 10^{-4}$ is a good choice.

The second problem can be fixed by requiring the rate of decrease of f at \mathbf{x}_{new} to be greater than some fraction β of the rate of decrease of f at \mathbf{x}_{old} . In practice, we will not need to impose this second constraint because our backtracking algorithm will have a built-in cutoff to avoid taking steps that are too small.

Here is the strategy for a practical backtracking routine: Define

$$g(\lambda) \equiv f(\mathbf{x}_{\text{old}} + \lambda\mathbf{p}) \quad (9.7.8)$$

so that

$$g'(\lambda) = \nabla f \cdot \mathbf{p} \quad (9.7.9)$$

If we need to backtrack, then we model g with the most current information we have and choose λ to minimize the model. We start with $g(0)$ and $g'(0)$ available. The first step is always the Newton step, $\lambda = 1$. If this step is not acceptable, we have available $g(1)$ as well. We can therefore model $g(\lambda)$ as a quadratic:

$$g(\lambda) \approx [g(1) - g(0) - g'(0)]\lambda^2 + g'(0)\lambda + g(0) \quad (9.7.10)$$

Taking the derivative of this quadratic, we find that it is a minimum when

$$\lambda = -\frac{g'(0)}{2[g(1) - g(0) - g'(0)]} \quad (9.7.11)$$

Since the Newton step failed, we can show that $\lambda \lesssim \frac{1}{2}$ for small α . We need to guard against too small a value of λ , however. We set $\lambda_{\min} = 0.1$.

On second and subsequent backtracks, we model g as a cubic in λ , using the previous value $g(\lambda_1)$ and the second most recent value $g(\lambda_2)$:

$$g(\lambda) = a\lambda^3 + b\lambda^2 + g'(0)\lambda + g(0) \quad (9.7.12)$$

Requiring this expression to give the correct values of g at λ_1 and λ_2 gives two equations that can be solved for the coefficients a and b :

$$\begin{bmatrix} a \\ b \end{bmatrix} = \frac{1}{\lambda_1 - \lambda_2} \begin{bmatrix} 1/\lambda_1^2 & -1/\lambda_2^2 \\ -\lambda_2/\lambda_1^2 & \lambda_1/\lambda_2^2 \end{bmatrix} \cdot \begin{bmatrix} g(\lambda_1) - g'(0)\lambda_1 - g(0) \\ g(\lambda_2) - g'(0)\lambda_2 - g(0) \end{bmatrix} \quad (9.7.13)$$

The minimum of the cubic (9.7.12) is at

$$\lambda = \frac{-b + \sqrt{b^2 - 3ag'(0)}}{3a} \quad (9.7.14)$$

We enforce that λ lie between $\lambda_{\max} = 0.5\lambda_1$ and $\lambda_{\min} = 0.1\lambda_1$.

The routine has two additional features, a minimum step length `alamin` and a maximum step length `stpmax`. `lnsrch` will also be used in the quasi-Newton minimization routine `dfrm` in the next section.

```
SUBROUTINE lnsrch(n,xold,fold,g,p,x,f,stpmx,check,func)
INTEGER n
LOGICAL check
REAL f,fold,stpmx,g(n),p(n),x(n),xold(n),func,ALF,TOLX
PARAMETER (ALF=1.e-4,TOLX=1.e-7)
EXTERNAL func
C USES func
      Given an n-dimensional point xold(1:n), the value of the function and gradient there,
      fold and g(1:n), and a direction p(1:n), finds a new point x(1:n) along the direction
      p from xold where the function func has decreased "sufficiently." The new function value
      is returned in f. stpmx is an input quantity that limits the length of the steps so that you
      do not try to evaluate the function in regions where it is undefined or subject to overflow.
      p is usually the Newton direction. The output quantity check is false on a normal exit.
      It is true when x is too close to xold. In a minimization algorithm, this usually signals
      convergence and can be ignored. However, in a zero-finding algorithm the calling program
      should check whether the convergence is spurious.
      Parameters: ALF ensures sufficient decrease in function value; TOLX is the convergence
      criterion on  $\Delta x$ .
      INTEGER i

END

```

Here now is the globally convergent Newton routine `newt` that uses `lnsrch`. A feature of `newt` is that you need not supply the Jacobian matrix analytically; the routine will attempt to compute the necessary partial derivatives of \mathbf{F} by finite differences in the routine `fdjac`. This routine uses some of the techniques described in §5.7 for computing numerical derivatives. Of course, you can always replace `fdjac` with a routine that calculates the Jacobian analytically if this is easy for you to do.

```

SUBROUTINE newt(x,n,check)
INTEGER n,nn,NP,MAXITS
LOGICAL check
REAL x(n),fvec,TOLF,TOLMIN,TOLX,STPMX
PARAMETER (NP=40,MAXITS=200,TOLF=1.e-4,TOLMIN=1.e-6,TOLX=1.e-7,
*           STPMX=100.)
COMMON /newtv/ fvec(NP),nn          Communicates with fmin.
SAVE /newtv/
C USES fdjac,fmin,lnsrch,lubksb,ludcmp
Given an initial guess  $x(1:n)$  for a root in  $n$  dimensions, find the root by a globally
convergent Newton's method. The vector of functions to be zeroed, called fvec(1:n)
in the routine below, is returned by a user-supplied subroutine that must be called funcv
and have the declaration subroutine funcv(n,x,fvec). The output quantity check
is false on a normal return and true if the routine has converged to a local minimum of the
function fmin defined below. In this case try restarting from a different initial guess.
Parameters:  $NP$  is the maximum expected value of  $n$ ;  $MAXITS$  is the maximum number of
iterations;  $TOLF$  sets the convergence criterion on function values;  $TOLMIN$  sets the criterion
for deciding whether spurious convergence to a minimum of fmin has occurred;  $TOLX$  is

```

the convergence criterion on δx ; STPMX is the scaled maximum step length allowed in line searches.

```

The routine $newt$ assumes that typical values of all components of \mathbf{x} and of \mathbf{F} are of order unity, and it can fail if this assumption is badly violated. You should rescale the variables by their typical values before invoking $newt$ if this problem occurs.

Multidimensional Secant Methods: Broyden's Method

Newton's method as implemented above is quite powerful, but it still has several disadvantages. One drawback is that the Jacobian matrix is needed. In many problems analytic derivatives are unavailable. If function evaluation is expensive, then the cost of finite-difference determination of the Jacobian can be prohibitive.

Just as the quasi-Newton methods to be discussed in §10.7 provide cheap approximations for the Hessian matrix in minimization algorithms, there are quasi-Newton methods that provide cheap approximations to the Jacobian for zero finding. These methods are often called *secant methods*, since they reduce to the secant method (§9.2) in one dimension (see, e.g., [1]). The best of these methods still seems to be the first one introduced, *Broyden's method* [2].

Let us denote the approximate Jacobian by \mathbf{B} . Then the i th quasi-Newton step $\delta\mathbf{x}_i$ is the solution of

$$\mathbf{B}_i \cdot \delta\mathbf{x}_i = -\mathbf{F}_i \quad (9.7.15)$$

where $\delta\mathbf{x}_i = \mathbf{x}_{i+1} - \mathbf{x}_i$ (cf. equation 9.7.3). The quasi-Newton or secant condition is that \mathbf{B}_{i+1} satisfy

$$\mathbf{B}_{i+1} \cdot \delta\mathbf{x}_i = \delta\mathbf{F}_i \quad (9.7.16)$$

where $\delta\mathbf{F}_i = \mathbf{F}_{i+1} - \mathbf{F}_i$. This is the generalization of the one-dimensional secant approximation to the derivative, $\delta F/\delta x$. However, equation (9.7.16) does not determine \mathbf{B}_{i+1} uniquely in more than one dimension.

Many different auxiliary conditions to pin down \mathbf{B}_{i+1} have been explored, but the best-performing algorithm in practice results from Broyden's formula. This formula is based on the idea of getting \mathbf{B}_{i+1} by making the least change to \mathbf{B}_i consistent with the secant equation (9.7.16). Broyden showed that the resulting formula is

$$\mathbf{B}_{i+1} = \mathbf{B}_i + \frac{(\delta\mathbf{F}_i - \mathbf{B}_i \cdot \delta\mathbf{x}_i) \otimes \delta\mathbf{x}_i}{\delta\mathbf{x}_i \cdot \delta\mathbf{x}_i} \quad (9.7.17)$$

You can easily check that \mathbf{B}_{i+1} satisfies (9.7.16).

Early implementations of Broyden's method used the Sherman-Morrison formula, equation (2.7.2), to invert equation (9.7.17) analytically,

$$\mathbf{B}_{i+1}^{-1} = \mathbf{B}_i^{-1} + \frac{(\delta\mathbf{x}_i - \mathbf{B}_i^{-1} \cdot \delta\mathbf{F}_i) \otimes \delta\mathbf{x}_i \cdot \mathbf{B}_i^{-1}}{\delta\mathbf{x}_i \cdot \mathbf{B}_i^{-1} \cdot \delta\mathbf{F}_i} \quad (9.7.18)$$

Then instead of solving equation (9.7.3) by e.g., *LU* decomposition, one determined

$$\delta\mathbf{x}_i = -\mathbf{B}_i^{-1} \cdot \mathbf{F}_i \quad (9.7.19)$$

by matrix multiplication in $O(N^2)$ operations. The disadvantage of this method is that it cannot easily be embedded in a globally convergent strategy, for which the gradient of equation (9.7.4) requires \mathbf{B} , not \mathbf{B}^{-1} ,

$$\nabla\left(\frac{1}{2}\mathbf{F} \cdot \mathbf{F}\right) \simeq \mathbf{B}^T \cdot \mathbf{F} \quad (9.7.20)$$

Accordingly, we implement the update formula in the form (9.7.17).

However, we can still preserve the $O(N^2)$ solution of (9.7.3) by using *QR* decomposition (§2.10) instead of *LU* decomposition. The reason is that because of the special form of equation (9.7.17), the *QR* decomposition of \mathbf{B}_i can be updated into the *QR* decomposition of \mathbf{B}_{i+1} in $O(N^2)$ operations (§2.10). All we need is an initial approximation \mathbf{B}_0 to start the ball rolling. It is often acceptable to start simply with the identity matrix, and then allow $O(N)$ updates to produce a reasonable approximation to the Jacobian. We prefer to spend the first N function evaluations on a finite-difference approximation to initialize \mathbf{B} via a call to `fdjac`.

Since \mathbf{B} is not the exact Jacobian, we are not guaranteed that $\delta\mathbf{x}$ is a descent direction for $f = \frac{1}{2}\mathbf{F} \cdot \mathbf{F}$ (cf. equation 9.7.5). Thus the line search algorithm can fail to return a suitable step if \mathbf{B} wanders far from the true Jacobian. In this case, we reinitialize \mathbf{B} by another call to `fdjac`.

Like the secant method in one dimension, Broyden's method converges superlinearly once you get close enough to the root. Embedded in a global strategy, it is almost as robust

as Newton's method, and often needs far fewer function evaluations to determine a zero. Note that the final value of \mathbf{B} is *not* always close to the true Jacobian at the root, even when the method converges.

The routine `broydn` given below is very similar to `newt` in organization. The principal differences are the use of QR decomposition instead of LU , and the updating formula instead of directly determining the Jacobian. The remarks at the end of `newt` about scaling the variables apply equally to `broydn`.

```
SUBROUTINE broydn(x,n,check)
INTEGER n,nn,NP,MAXITS
REAL x(n),fvec,EPS,TOLF,TOLMIN,TOLX,STPMX
LOGICAL check
PARAMETER (NP=40,MAXITS=200,EPS=1.e-7,TOLF=1.e-4,TOLMIN=1.e-6,
           TOLX=EPS,STPMX=100.)
COMMON /newtv/ fvec(NP),nn               Communicates with fmin.
SAVE /newtv/
C USES fdjac,fmin,lnsrch,qrdfcmp,qrupdt,rsolv
Given an initial guess x(1:n) for a root in n dimensions, find the root by Broyden's method
embedded in a globally convergent strategy. The vector of functions to be zeroed, called
fvec(1:n) in the routine below, is returned by a user-supplied subroutine that must be
called funcv and have the declaration subroutine funcv(n,x,fvec). The subroutine
fdjac and the function fmin from newt are used. The output quantity check is false on
a normal return and true if the routine has converged to a local minimum of the function
fmin or if Broyden's method can make no further progress. In this case try restarting from
a different initial guess.
Parameters: NP is the maximum expected value of n; MAXITS is the maximum number of
iterations; EPS is close to the machine precision; TOLF sets the convergence criterion on
function values; TOLMIN sets the criterion for deciding whether spurious convergence to a
minimum of fmin has occurred; TOLX is the convergence criterion on  $\delta\mathbf{x}$ ; STPMX is the
scaled maximum step length allowed in line searches.

More Advanced Implementations

One of the principal ways that the methods described so far can fail is if \mathbf{J} (in Newton's method) or \mathbf{B} in (Broyden's method) becomes singular or nearly singular, so that $\delta\mathbf{x}$ cannot be determined. If you are lucky, this situation will not occur very often in practice. Methods developed so far to deal with this problem involve monitoring the condition number of \mathbf{J} and perturbing \mathbf{J} if singularity or near singularity is detected. This is most easily implemented if the *QR* decomposition is used instead of *LU* in Newton's method (see [1] for details). Our personal experience is that, while such an algorithm can solve problems where \mathbf{J} is exactly singular and the standard Newton's method fails, it is occasionally less robust on other problems where *LU* decomposition succeeds. Clearly implementation details involving roundoff, underflow, etc., are important here and the last word is yet to be written.

Our global strategies both for minimization and zero finding have been based on line searches. Other global algorithms, such as the *hook step* and *dogleg step* methods, are based instead on the *model-trust region* approach, which is related to the Levenberg-Marquardt algorithm for nonlinear least-squares (§15.5). While somewhat more complicated than line searches, these methods have a reputation for robustness even when starting far from the desired zero or minimum [1].

Chapter 10. Minimization or Maximization of Functions

10.0 Introduction

In a nutshell: You are given a single function f that depends on one or more independent variables. You want to find the value of those variables where f takes on a maximum or a minimum value. You can then calculate what value of f is achieved at the maximum or minimum. The tasks of maximization and minimization are trivially related to each other, since one person's function f could just as well be another's $-f$. The computational desiderata are the usual ones: Do it quickly, cheaply, and in small memory. Often the computational effort is dominated by the cost of evaluating f (and also perhaps its partial derivatives with respect to all variables, if the chosen algorithm requires them). In such cases the desiderata are sometimes replaced by the simple surrogate: Evaluate f as few times as possible.

An extremum (maximum or minimum point) can be either *global* (truly the highest or lowest function value) or *local* (the highest or lowest in a finite neighborhood and not on the boundary of that neighborhood). (See Figure 10.0.1.) Finding a global extremum is, in general, a very difficult problem. Two standard heuristics are widely used: (i) find local extrema starting from widely varying starting values of the independent variables (perhaps chosen quasi-randomly, as in §7.7), and then pick the most extreme of these (if they are not all the same); or (ii) perturb a local extremum by taking a finite amplitude step away from it, and then see if your routine returns you to a better point, or “always” to the same one. Relatively recently, so-called “simulated annealing methods” (§10.9) have demonstrated important successes on a variety of global extremization problems.

Our chapter title could just as well be *optimization*, which is the usual name for this very large field of numerical research. The importance ascribed to the various tasks in this field depends strongly on the particular interests of whom you talk to. Economists, and some engineers, are particularly concerned with *constrained optimization*, where there are *a priori* limitations on the allowed values of independent variables. For example, the production of wheat in the U.S. must be a nonnegative number. One particularly well-developed area of constrained optimization is *linear programming*, where both the function to be optimized and the constraints happen to be linear functions of the independent variables. Section 10.8, which is otherwise somewhat disconnected from the rest of the material that we have chosen to include in this chapter, implements the so-called “simplex algorithm” for linear programming problems.

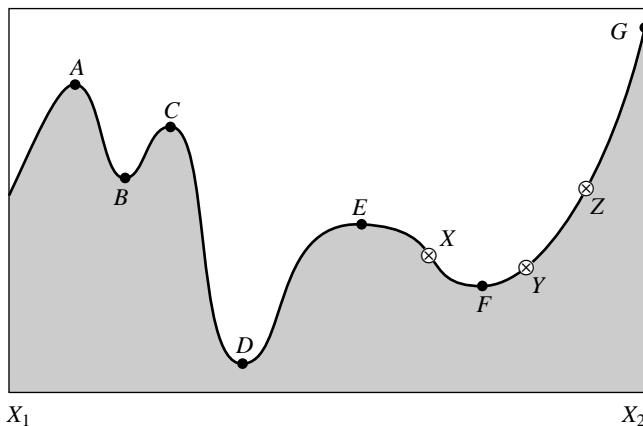

Figure 10.0.1. Extrema of a function in an interval. Points A , C , and E are local, but not global maxima. Points B and F are local, but not global minima. The global maximum occurs at G , which is on the boundary of the interval so that the derivative of the function need not vanish there. The global minimum is at D . At point E , derivatives higher than the first vanish, a situation which can cause difficulty for some algorithms. The points X , Y , and Z are said to “bracket” the minimum F , since Y is less than both X and Z .

One other section, §10.9, also lies outside of our main thrust, but for a different reason: so-called “annealing methods” are relatively new, so we do not yet know where they will ultimately fit into the scheme of things. However, these methods have solved some problems previously thought to be practically insoluble; they address directly the problem of finding global extrema in the presence of large numbers of undesired local extrema.

The other sections in this chapter constitute a selection of the best established algorithms in unconstrained minimization. (For definiteness, we will henceforth regard the optimization problem as that of minimization.) These sections are connected, with later ones depending on earlier ones. If you are just looking for the one “perfect” algorithm to solve your particular application, you may feel that we are telling you more than you want to know. Unfortunately, there is *no* perfect optimization algorithm. This is a case where we strongly urge you to try more than one method in comparative fashion. Your initial choice of method can be based on the following considerations:

- You must choose between methods that need only evaluations of the function to be minimized and methods that also require evaluations of the derivative of that function. In the multidimensional case, this derivative is the gradient, a vector quantity. Algorithms using the derivative are somewhat more powerful than those using only the function, but not always enough so as to compensate for the additional calculations of derivatives. We can easily construct examples favoring one approach or favoring the other. However, if you *can* compute derivatives, be prepared to try using them.
- For one-dimensional minimization (minimize a function of one variable) *without* calculation of the derivative, bracket the minimum as described in §10.1, and then use *Brent’s method* as described in §10.2. If your function has a discontinuous second (or lower) derivative, then the parabolic

interpolations of Brent's method are of no advantage, and you might wish to use the simplest form of *golden section search*, as described in §10.1.

- For one-dimensional minimization *with* calculation of the derivative, §10.3 supplies a variant of Brent's method which makes limited use of the first derivative information. We shy away from the alternative of using derivative information to construct high-order interpolating polynomials. In our experience the improvement in convergence very near a smooth, analytic minimum does not make up for the tendency of polynomials sometimes to give wildly wrong interpolations at early stages, especially for functions that may have sharp, “exponential” features.

We now turn to the multidimensional case, both with and without computation of first derivatives.

- You must choose between methods that require storage of order N^2 and those that require only of order N , where N is the number of dimensions. For moderate values of N and reasonable memory sizes this is not a serious constraint. There will be, however, the occasional application where storage may be critical.
- We give in §10.4 a sometimes overlooked *downhill simplex method* due to Nelder and Mead. (This use of the word “simplex” is not to be confused with the simplex method of linear programming.) This method just crawls downhill in a straightforward fashion that makes almost no special assumptions about your function. This can be extremely slow, but it can also, in some cases, be extremely robust. Not to be overlooked is the fact that the code is concise and completely self-contained: a general N -dimensional minimization program in under 100 program lines! This method is most useful when the minimization calculation is only an incidental part of your overall problem. The storage requirement is of order N^2 , and derivative calculations are not required.
- Section 10.5 deals with *direction-set methods*, of which *Powell's method* is the prototype. These are the methods of choice when you cannot easily calculate derivatives, and are not necessarily to be sneered at even if you can. Although derivatives are not needed, the method does require a one-dimensional minimization sub-algorithm such as Brent's method (see above). Storage is of order N^2 .

There are two major families of algorithms for multidimensional minimization *with* calculation of first derivatives. Both families require a one-dimensional minimization sub-algorithm, which can itself either use, or not use, the derivative information, as you see fit (depending on the relative effort of computing the function and of its gradient vector). We do not think that either family dominates the other in all applications; you should think of them as available alternatives:

- The first family goes under the name *conjugate gradient methods*, as typified by the *Fletcher-Reeves algorithm* and the closely related and probably superior *Polak-Ribiere algorithm*. Conjugate gradient methods require only of order a few times N storage, require derivative calculations and

one-dimensional sub-minimization. Turn to §10.6 for detailed discussion and implementation.

- The second family goes under the names *quasi-Newton* or *variable metric* methods, as typified by the *Davidon-Fletcher-Powell (DFP)* algorithm (sometimes referred to just as *Fletcher-Powell*) or the closely related *Broyden-Fletcher-Goldfarb-Shanno (BFGS)* algorithm. These methods require of order N^2 storage, require derivative calculations and one-dimensional sub-minimization. Details are in §10.7.

You are now ready to proceed with scaling the peaks (and/or plumbing the depths) of practical optimization.

10.1 Golden Section Search in One Dimension

Recall how the bisection method finds roots of functions in one dimension (§9.1): The root is supposed to have been bracketed in an interval (a, b) . One then evaluates the function at an intermediate point x and obtains a new, smaller bracketing interval, either (a, x) or (x, b) . The process continues until the bracketing interval is acceptably small. It is optimal to choose x to be the midpoint of (a, b) so that the decrease in the interval length is maximized when the function is as uncooperative as it can be, i.e., when the luck of the draw forces you to take the bigger bisected segment.

There is a precise, though slightly subtle, translation of these considerations to the minimization problem: What does it mean to *bracket* a minimum? A root of a function is known to be bracketed by a pair of points, a and b , when the function has opposite sign at those two points. A minimum, by contrast, is known to be bracketed only when there is a *triplet* of points, $a < b < c$ (or $c < b < a$), such that $f(b)$ is less than both $f(a)$ and $f(c)$. In this case we know that the function (if it is nonsingular) has a minimum in the interval (a, c) .

The analog of bisection is to choose a new point x , either between a and b or between b and c . Suppose, to be specific, that we make the latter choice. Then we evaluate $f(x)$. If $f(b) < f(x)$, then the new bracketing triplet of points is (a, b, x) ;

one-dimensional sub-minimization. Turn to §10.6 for detailed discussion and implementation.

- The second family goes under the names *quasi-Newton* or *variable metric* methods, as typified by the *Davidon-Fletcher-Powell (DFP)* algorithm (sometimes referred to just as *Fletcher-Powell*) or the closely related *Broyden-Fletcher-Goldfarb-Shanno (BFGS)* algorithm. These methods require of order N^2 storage, require derivative calculations and one-dimensional sub-minimization. Details are in §10.7.

You are now ready to proceed with scaling the peaks (and/or plumbing the depths) of practical optimization.

10.1 Golden Section Search in One Dimension

Recall how the bisection method finds roots of functions in one dimension (§9.1): The root is supposed to have been bracketed in an interval (a, b) . One then evaluates the function at an intermediate point x and obtains a new, smaller bracketing interval, either (a, x) or (x, b) . The process continues until the bracketing interval is acceptably small. It is optimal to choose x to be the midpoint of (a, b) so that the decrease in the interval length is maximized when the function is as uncooperative as it can be, i.e., when the luck of the draw forces you to take the bigger bisected segment.

There is a precise, though slightly subtle, translation of these considerations to the minimization problem: What does it mean to *bracket* a minimum? A root of a function is known to be bracketed by a pair of points, a and b , when the function has opposite sign at those two points. A minimum, by contrast, is known to be bracketed only when there is a *triplet* of points, $a < b < c$ (or $c < b < a$), such that $f(b)$ is less than both $f(a)$ and $f(c)$. In this case we know that the function (if it is nonsingular) has a minimum in the interval (a, c) .

The analog of bisection is to choose a new point x , either between a and b or between b and c . Suppose, to be specific, that we make the latter choice. Then we evaluate $f(x)$. If $f(b) < f(x)$, then the new bracketing triplet of points is (a, b, x) ;

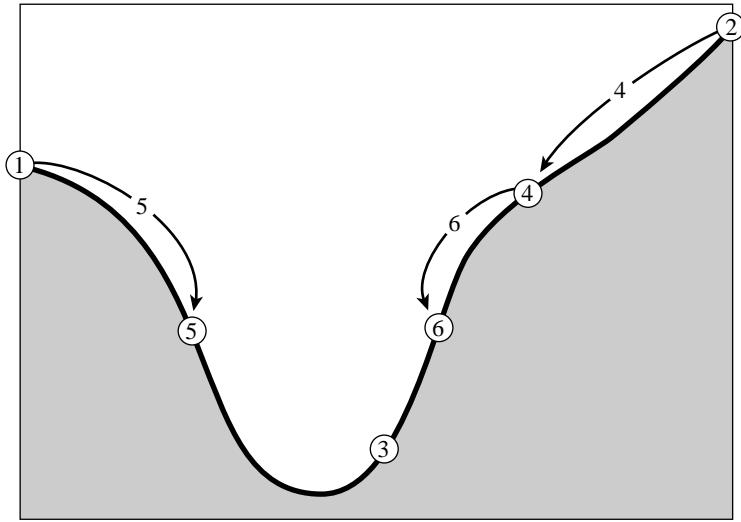

Figure 10.1.1. Successive bracketing of a minimum. The minimum is originally bracketed by points 1,3,2. The function is evaluated at 4, which replaces 2; then at 5, which replaces 1; then at 6, which replaces 4. The rule at each stage is to keep a center point that is lower than the two outside points. After the steps shown, the minimum is bracketed by points 5,3,6.

contrariwise, if $f(b) > f(x)$, then the new bracketing triplet is (b, x, c) . In all cases the middle point of the new triplet is the abscissa whose ordinate is the best minimum achieved so far; see Figure 10.1.1. We continue the process of bracketing until the distance between the two outer points of the triplet is tolerably small.

How small is “tolerably” small? For a minimum located at a value b , you might naively think that you will be able to bracket it in as small a range as $(1 - \epsilon)b < b < (1 + \epsilon)b$, where ϵ is your computer’s floating-point precision, a number like 3×10^{-8} (single precision) or 10^{-15} (double precision). Not so! In general, the shape of your function $f(x)$ near b will be given by Taylor’s theorem

$$f(x) \approx f(b) + \frac{1}{2}f''(b)(x - b)^2 \quad (10.1.1)$$

The second term will be negligible compared to the first (that is, will be a factor ϵ smaller and will act just like zero when added to it) whenever

$$|x - b| < \sqrt{\epsilon}|b| \sqrt{\frac{2|f(b)|}{b^2 f''(b)}} \quad (10.1.2)$$

The reason for writing the right-hand side in this way is that, for most functions, the final square root is a number of order unity. Therefore, as a rule of thumb, it is hopeless to ask for a bracketing interval of width less than $\sqrt{\epsilon}$ times its central value, a fractional width of only about 10^{-4} (single precision) or 3×10^{-8} (double precision). Knowing this inescapable fact will save you a lot of useless bisections!

The minimum-finding routines of this chapter will often call for a user-supplied argument `tol`, and return with an abscissa whose fractional precision is about $\pm tol$ (bracketing interval of fractional size about $2 \times tol$). Unless you have a better

estimate for the right-hand side of equation (10.1.2), you should set `tol` equal to (not much less than) the square root of your machine's floating-point precision, since smaller values will gain you nothing.

It remains to decide on a strategy for choosing the new point x , given (a, b, c) . Suppose that b is a fraction w of the way between a and c , i.e.

$$\frac{b-a}{c-a} = w \quad \frac{c-b}{c-a} = 1-w \quad (10.1.3)$$

Also suppose that our next trial point x is an additional fraction z beyond b ,

$$\frac{x-b}{c-a} = z \quad (10.1.4)$$

Then the next bracketing segment will either be of length $w+z$ relative to the current one, or else of length $1-w$. If we want to minimize the worst case possibility, then we will choose z to make these equal, namely

$$z = 1 - 2w \quad (10.1.5)$$

We see at once that the new point is the symmetric point to b in the original interval, namely with $|b-a|$ equal to $|x-c|$. This implies that the point x lies in the larger of the two segments (z is positive only if $w < 1/2$).

But where in the larger segment? Where did the value of w itself come from? Presumably from the previous stage of applying our same strategy. Therefore, if z is chosen to be optimal, then so was w before it. This *scale similarity* implies that x should be the same fraction of the way from b to c (if that is the bigger segment) as was b from a to c , in other words,

$$\frac{z}{1-w} = w \quad (10.1.6)$$

Equations (10.1.5) and (10.1.6) give the quadratic equation

$$w^2 - 3w + 1 = 0 \quad \text{yielding} \quad w = \frac{3 - \sqrt{5}}{2} \approx 0.38197 \quad (10.1.7)$$

In other words, the optimal bracketing interval (a, b, c) has its middle point b a fractional distance 0.38197 from one end (say, a), and 0.61803 from the other end (say, b). These fractions are those of the so-called *golden mean* or *golden section*, whose supposedly aesthetic properties hark back to the ancient Pythagoreans. This optimal method of function minimization, the analog of the bisection method for finding zeros, is thus called the *golden section search*, summarized as follows:

Given, at each stage, a bracketing triplet of points, the next point to be tried is that which is a fraction 0.38197 into the larger of the two intervals (measuring from the central point of the triplet). If you start out with a bracketing triplet whose segments are not in the golden ratios, the procedure of choosing successive points at the golden mean point of the larger segment will quickly converge you to the proper, self-replicating ratios.

The golden section search guarantees that each new function evaluation will (after self-replicating ratios have been achieved) bracket the minimum to an interval

just 0.61803 times the size of the preceding interval. This is comparable to, but not quite as good as, the 0.50000 that holds when finding roots by bisection. Note that the convergence is *linear* (in the language of Chapter 9), meaning that successive significant figures are won linearly with additional function evaluations. In the next section we will give a superlinear method, where the rate at which successive significant figures are liberated increases with each successive function evaluation.

Routine for Initially Bracketing a Minimum

The preceding discussion has assumed that you are able to bracket the minimum in the first place. We consider this initial bracketing to be an essential part of any one-dimensional minimization. There are some one-dimensional algorithms that do not require a rigorous initial bracketing. However, we would *never* trade the secure feeling of *knowing* that a minimum is “in there somewhere” for the dubious reduction of function evaluations that these nonbracketing routines may promise. Please bracket your minima (or, for that matter, your zeros) before isolating them!

There is not much theory as to how to do this bracketing. Obviously you want to step downhill. But how far? We like to take larger and larger steps, starting with some (wild?) initial guess and then increasing the stepsize at each step either by a constant factor, or else by the result of a parabolic extrapolation of the preceding points that is designed to take us to the extrapolated turning point. It doesn’t much matter if the steps get big. After all, we are stepping downhill, so we already have the left and middle points of the bracketing triplet. We just need to take a big enough step to stop the downhill trend and get a high third point.

Our standard routine is this:

```
SUBROUTINE mnbrak(ax,bx,cx,fa,fb,fc,func)
REAL ax,bx,cx,fa,fb,fc,func,GOLD,GLIMIT,TINY
EXTERNAL func
PARAMETER (GOLD=1.618034, GLIMIT=100., TINY=1.e-20)
Given a function func, and given distinct initial points ax and bx, this routine searches
in the downhill direction (defined by the function as evaluated at the initial points) and
returns new points ax, bx, cx that bracket a minimum of the function. Also returned are
the function values at the three points, fa, fb, and fc.
Parameters: GOLD is the default ratio by which successive intervals are magnified; GLIMIT
is the maximum magnification allowed for a parabolic-fit step.
REAL dum,fu,q,r,u,ulim
fa=func(ax)
fb=func(bx)
if(fb.gt.fa)then
  dum=ax
  ax=bx
  bx=dum
  dum=fb
  fb=fa
  fa=dum
endif
cx=bx+GOLD*(bx-ax)
fc=func(cx)
First guess for c.
1 if(fb.ge.fc)then
  r=(bx-ax)*(fb-fc)
  q=(bx-cx)*(fb-fa)
  u=bx-((bx-cx)*q-(bx-ax)*r)/(2.*sign(max(abs(q-r),TINY),q-r))
  ulim=bx+GLIMIT*(cx-bx)
  if((bx-u)*(u-cx).gt.0.)then
    fu=func(u)
    "do while": keep returning here until we bracket.
    Compute u by parabolic extrapolation from a, b, c. TINY
    is used to prevent any possible division by zero.
    We won't go farther than this. Test various possibilities:
    Parabolic u is between b and c: try it.
```

```

if(fu.lt.fc)then      Got a minimum between b and c.
    ax=bx
    fa=fb
    bx=u
    fb=fu
    return
else if(fu.gt.fb)then  Got a minimum between between a and u.
    cx=u
    fc=fu
    return
endif
u=cx+GOLD*(cx-bx)      Parabolic fit was no use. Use default magnification.
fu=func(u)
else if((cx-u)*(u-ulim).gt.0.)then      Parabolic fit is between c and its allowed
    fu=func(u)                      limit.
    if(fu.lt.fc)then
        bx=cx
        cx=u
        u=cx+GOLD*(cx-bx)
        fb=fc
        fc=fu
        fu=func(u)
    endif
else if((u-ulim)*(ulim-cx).ge.0.)then      Limit parabolic u to maximum allowed
    u=ulim                         value.
    fu=func(u)
else
    u=cx+GOLD*(cx-bx)            Reject parabolic u, use default magnification.
    fu=func(u)
endif
ax=bx                      Eliminate oldest point and continue.
bx=cx
cx=u
fa=fb
fb=fc
fc=fu
goto 1
endif
return
END

```

(Because of the housekeeping involved in moving around three or four points and their function values, the above program ends up looking deceptively formidable. That is true of several other programs in this chapter as well. The underlying ideas, however, are quite simple.)

Routine for Golden Section Search

```

FUNCTION golden(ax,bx,cx,f,tol,xmin)
REAL golden,ax,bx,cx,tol,xmin,f,R,C
EXTERNAL f
PARAMETER (R=.61803399,C=1.-R)
Given a function f, and given a bracketing triplet of abscissas ax, bx, cx (such that bx is
between ax and cx, and f(bx) is less than both f(ax) and f(cx)), this routine performs
a golden section search for the minimum, isolating it to a fractional precision of about
tol. The abscissa of the minimum is returned as xmin, and the minimum function value
is returned as golden, the returned function value.
Parameters: The golden ratios.
REAL f1,f2,x0,x1,x2,x3
x0=ax
At any given time we will keep track of four points, x0,x1,x2,x3.

```

```

x3=cx
if(abs(cx-bx).gt.abs(bx-ax))then      Make x0 to x1 the smaller segment,
    x1=bx
    x2=bx+C*(cx-bx)           and fill in the new point to be tried.
else
    x2=bx
    x1=bx-C*(bx-ax)
endif
f1=f(x1)          The initial function evaluations. Note that we never need to
f2=f(x2)          evaluate the function at the original endpoints.
1 if(abs(x3-x0).gt.tol*(abs(x1)+abs(x2)))then Do-while loop: we keep returning here.
    if(f2.lt.f1)then      One possible outcome,
        x0=x1
        x1=x2
        x2=R*x1+C*x3
        f1=f2
        f2=f(x2)           and a new function evaluation.
    else                  The other outcome,
        x3=x2
        x2=x1
        x1=R*x2+C*x0
        f2=f1
        f1=f(x1)           and its new function evaluation.
    endif
    goto 1               Back to see if we are done.
endif
if(f1.lt.f2)then      We are done. Output the best of the two current values.
    golden=f1
    xmin=x1
else
    golden=f2
    xmin=x2
endif
return
END

```

10.2 Parabolic Interpolation and Brent's Method in One Dimension

We already tipped our hand about the desirability of parabolic interpolation in the previous section's `mnbrak` routine, but it is now time to be more explicit. A golden section search is designed to handle, in effect, the worst possible case of function minimization, with the uncooperative minimum hunted down and cornered like a scared rabbit. But why assume the worst? If the function is nicely parabolic near to the minimum — surely the generic case for sufficiently smooth functions — then the parabola fitted through any three points ought to take us in a single leap to the minimum, or at least very near to it (see Figure 10.2.1). Since we want to find an abscissa rather than an ordinate, the procedure is technically called *inverse parabolic interpolation*.

The formula for the abscissa x that is the minimum of a parabola through three points $f(a)$, $f(b)$, and $f(c)$ is

$$x = b - \frac{1}{2} \frac{(b-a)^2[f(b) - f(c)] - (b-c)^2[f(b) - f(a)]}{(b-a)[f(b) - f(c)] - (b-c)[f(b) - f(a)]} \quad (10.2.1)$$

```

x3=cx
if(abs(cx-bx).gt.abs(bx-ax))then      Make x0 to x1 the smaller segment,
    x1=bx
    x2=bx+C*(cx-bx)           and fill in the new point to be tried.
else
    x2=bx
    x1=bx-C*(bx-ax)
endif
f1=f(x1)          The initial function evaluations. Note that we never need to
f2=f(x2)          evaluate the function at the original endpoints.
1 if(abs(x3-x0).gt.tol*(abs(x1)+abs(x2)))then Do-while loop: we keep returning here.
    if(f2.lt.f1)then      One possible outcome,
        x0=x1
        x1=x2
        x2=R*x1+C*x3
        f1=f2
        f2=f(x2)           and a new function evaluation.
    else                  The other outcome,
        x3=x2
        x2=x1
        x1=R*x2+C*x0
        f2=f1
        f1=f(x1)           and its new function evaluation.
    endif
    goto 1               Back to see if we are done.
endif
if(f1.lt.f2)then      We are done. Output the best of the two current values.
    golden=f1
    xmin=x1
else
    golden=f2
    xmin=x2
endif
return
END

```

10.2 Parabolic Interpolation and Brent's Method in One Dimension

We already tipped our hand about the desirability of parabolic interpolation in the previous section's `mnbrak` routine, but it is now time to be more explicit. A golden section search is designed to handle, in effect, the worst possible case of function minimization, with the uncooperative minimum hunted down and cornered like a scared rabbit. But why assume the worst? If the function is nicely parabolic near to the minimum — surely the generic case for sufficiently smooth functions — then the parabola fitted through any three points ought to take us in a single leap to the minimum, or at least very near to it (see Figure 10.2.1). Since we want to find an abscissa rather than an ordinate, the procedure is technically called *inverse parabolic interpolation*.

The formula for the abscissa x that is the minimum of a parabola through three points $f(a)$, $f(b)$, and $f(c)$ is

$$x = b - \frac{1}{2} \frac{(b-a)^2[f(b) - f(c)] - (b-c)^2[f(b) - f(a)]}{(b-a)[f(b) - f(c)] - (b-c)[f(b) - f(a)]} \quad (10.2.1)$$

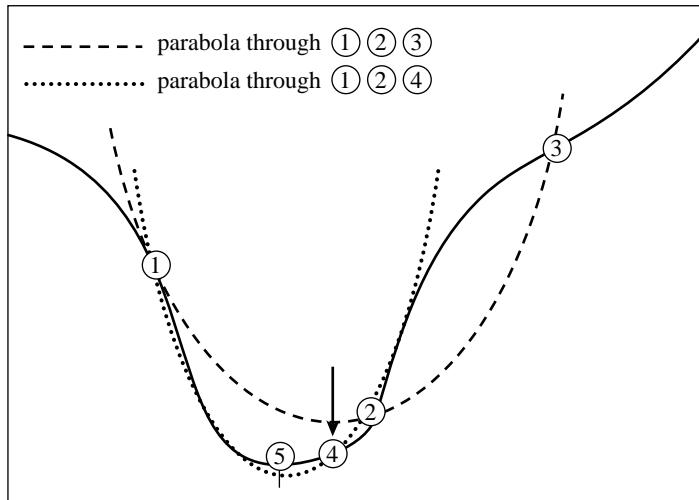

Figure 10.2.1. Convergence to a minimum by inverse parabolic interpolation. A parabola (dashed line) is drawn through the three original points 1,2,3 on the given function (solid line). The function is evaluated at the parabola's minimum, 4, which replaces point 3. A new parabola (dotted line) is drawn through points 1,4,2. The minimum of this parabola is at 5, which is close to the minimum of the function.

as you can easily derive. This formula fails only if the three points are collinear, in which case the denominator is zero (minimum of the parabola is infinitely far away). Note, however, that (10.2.1) is as happy jumping to a parabolic maximum as to a minimum. No minimization scheme that depends solely on (10.2.1) is likely to succeed in practice.

The exacting task is to invent a scheme that relies on a sure-but-slow technique, like golden section search, when the function is not cooperative, but that switches over to (10.2.1) when the function allows. The task is nontrivial for several reasons, including these: (i) The housekeeping needed to avoid unnecessary function evaluations in switching between the two methods can be complicated. (ii) Careful attention must be given to the “endgame,” where the function is being evaluated very near to the roundoff limit of equation (10.1.2). (iii) The scheme for detecting a cooperative versus noncooperative function must be very robust.

Brent's method [1] is up to the task in all particulars. At any particular stage, it is keeping track of six function points (not necessarily all distinct), a , b , u , v , w and x , defined as follows: the minimum is bracketed between a and b ; x is the point with the very least function value found so far (or the most recent one in case of a tie); w is the point with the second least function value; v is the previous value of w ; u is the point at which the function was evaluated most recently. Also appearing in the algorithm is the point x_m , the midpoint between a and b ; however, the function is not evaluated there.

You can read the code below to understand the method's logical organization. Mention of a few general principles here may, however, be helpful: Parabolic interpolation is attempted, fitting through the points x , v , and w . To be acceptable, the parabolic step must (i) fall within the bounding interval (a, b) , and (ii) imply a movement from the best current value x that is *less* than half the movement of the *step before last*. This second criterion insures that the parabolic steps are actually

converging to something, rather than, say, bouncing around in some nonconvergent limit cycle. In the worst possible case, where the parabolic steps are acceptable but useless, the method will approximately alternate between parabolic steps and golden sections, converging in due course by virtue of the latter. The reason for comparing to the step *before* last seems essentially heuristic: Experience shows that it is better not to “punish” the algorithm for a single bad step if it can make it up on the next one.

Another principle exemplified in the code is never to evaluate the function less than a distance tol from a point already evaluated (or from a known bracketing point). The reason is that, as we saw in equation (10.1.2), there is simply no information content in doing so: the function will differ from the value already evaluated only by an amount of order the roundoff error. Therefore in the code below you will find several tests and modifications of a potential new point, imposing this restriction. This restriction also interacts subtly with the test for “doneness,” which the method takes into account.

A typical ending configuration for Brent's method is that a and b are $2 \times x \times \text{tol}$ apart, with x (the best abscissa) at the midpoint of a and b , and therefore fractionally accurate to $\pm \text{tol}$.

Indulge us a final reminder that tol should generally be no smaller than the square root of your machine's floating-point precision.

```

FUNCTION brent(ax,bx,cx,f,tol,xmin)
INTEGER ITMAX
REAL brent,ax,bx,cx,tol,xmin,f,CGOLD,ZEPS
EXTERNAL f
PARAMETER (ITMAX=100,CGOLD=.3819660,ZEPS=1.0e-10)

Given a function f, and given a bracketing triplet of abscissas ax, bx, cx (such that bx is
between ax and cx, and f(bx) is less than both f(ax) and f(cx)), this routine isolates
the minimum to a fractional precision of about tol using Brent's method. The abscissa of
the minimum is returned as xmin, and the minimum function value is returned as brent,
the returned function value.

Parameters: Maximum allowed number of iterations; golden ratio; and a small number that
protects against trying to achieve fractional accuracy for a minimum that happens to be
exactly zero.

INTEGER iter
REAL a,b,d,e,etemp,fu,fv,fw,fx,p,q,r,tol1,tol2,u,v,w,x,xm
a=min(ax,cx)                                a and b must be in ascending order, though the input
b=max(ax,cx)                                abscissas need not be.
v=bx                                         Initializations...
w=v
x=v
e=0.                                         This will be the distance moved on the step before last.
fx=f(x)
fv=fx
fw=fx
do :: iter=1,ITMAX                         Main program loop.

10.3 One-Dimensional Search with First Derivatives

Here we want to accomplish precisely the same goal as in the previous section, namely to isolate a functional minimum that is bracketed by the triplet of abscissas (a, b, c) , but utilizing an additional capability to compute the function's first derivative as well as its value.

In principle, we might simply search for a zero of the derivative, ignoring the function value information, using a root finder like `rtf1sp` or `zbrent` (§§9.2–9.3). It doesn't take long to reject *that* idea: How do we distinguish maxima from minima? Where do we go from initial conditions where the derivatives on one or both of the outer bracketing points indicate that “downhill” is in the direction *out* of the bracketed interval?

We don't want to give up our strategy of maintaining a rigorous bracket on the minimum at all times. The only way to keep such a bracket is to update it using function (not derivative) information, with the central point in the bracketing triplet always that with the lowest function value. Therefore the role of the derivatives can only be to help us choose new trial points within the bracket.

One school of thought is to “use everything you've got”: Compute a polynomial of relatively high order (cubic or above) that agrees with some number of previous function and derivative evaluations. For example, there is a unique cubic that agrees with function and derivative at two points, and one can jump to the interpolated minimum of that cubic (if there is a minimum within the bracket). Suggested by Davidon and others, formulas for this tactic are given in [1].

We like to be more conservative than this. Once superlinear convergence sets in, it hardly matters whether its order is moderately lower or higher. In practical problems that we have met, most function evaluations are spent in getting globally close enough to the minimum for superlinear convergence to commence. So we are more worried about all the funny “stiff” things that high-order polynomials can do (cf. Figure 3.0.1b), and about their sensitivities to roundoff error.

This leads us to use derivative information only as follows: The sign of the derivative at the central point of the bracketing triplet (a, b, c) indicates uniquely whether the next test point should be taken in the interval (a, b) or in the interval (b, c) . The value of this derivative and of the derivative at the second-best-so-far point are extrapolated to zero by the secant method (inverse linear interpolation), which by itself is superlinear of order 1.618. (The golden mean again: see [1], p. 57.) We impose the same sort of restrictions on this new trial point as in Brent's method. If the trial point must be rejected, we *bisect* the interval under scrutiny.

Yes, we are fuddy-duddies when it comes to making flamboyant use of derivative information in one-dimensional minimization. But we have met too many functions whose computed “derivatives” *don't* integrate up to the function value and *don't* accurately point the way to the minimum, usually because of roundoff errors, sometimes because of truncation error in the method of derivative evaluation.

You will see that the following routine is closely modeled on `brent` in the previous section.

10.3 One-Dimensional Search with First Derivatives

Here we want to accomplish precisely the same goal as in the previous section, namely to isolate a functional minimum that is bracketed by the triplet of abscissas (a, b, c) , but utilizing an additional capability to compute the function's first derivative as well as its value.

In principle, we might simply search for a zero of the derivative, ignoring the function value information, using a root finder like `rtf1sp` or `zbrent` (§§9.2–9.3). It doesn't take long to reject *that* idea: How do we distinguish maxima from minima? Where do we go from initial conditions where the derivatives on one or both of the outer bracketing points indicate that “downhill” is in the direction *out* of the bracketed interval?

We don't want to give up our strategy of maintaining a rigorous bracket on the minimum at all times. The only way to keep such a bracket is to update it using function (not derivative) information, with the central point in the bracketing triplet always that with the lowest function value. Therefore the role of the derivatives can only be to help us choose new trial points within the bracket.

One school of thought is to “use everything you've got”: Compute a polynomial of relatively high order (cubic or above) that agrees with some number of previous function and derivative evaluations. For example, there is a unique cubic that agrees with function and derivative at two points, and one can jump to the interpolated minimum of that cubic (if there is a minimum within the bracket). Suggested by Davidon and others, formulas for this tactic are given in [1].

We like to be more conservative than this. Once superlinear convergence sets in, it hardly matters whether its order is moderately lower or higher. In practical problems that we have met, most function evaluations are spent in getting globally close enough to the minimum for superlinear convergence to commence. So we are more worried about all the funny “stiff” things that high-order polynomials can do (cf. Figure 3.0.1b), and about their sensitivities to roundoff error.

This leads us to use derivative information only as follows: The sign of the derivative at the central point of the bracketing triplet (a, b, c) indicates uniquely whether the next test point should be taken in the interval (a, b) or in the interval (b, c) . The value of this derivative and of the derivative at the second-best-so-far point are extrapolated to zero by the secant method (inverse linear interpolation), which by itself is superlinear of order 1.618. (The golden mean again: see [1], p. 57.) We impose the same sort of restrictions on this new trial point as in Brent's method. If the trial point must be rejected, we *bisect* the interval under scrutiny.

Yes, we are fuddy-duddies when it comes to making flamboyant use of derivative information in one-dimensional minimization. But we have met too many functions whose computed “derivatives” *don't* integrate up to the function value and *don't* accurately point the way to the minimum, usually because of roundoff errors, sometimes because of truncation error in the method of derivative evaluation.

You will see that the following routine is closely modeled on `brent` in the previous section.

```

FUNCTION dbrent(ax,bx,cx,f,df,tol,xmin)
INTEGER ITMAX
REAL dbrent,ax,bx,cx,tol,xmin,df,f,ZEPS
EXTERNAL df,f
PARAMETER (ITMAX=100,ZEPS=1.0e-10)

      Given a function f and its derivative function df, and given a bracketing triplet of abscissas
      ax, bx, cx [such that bx is between ax and cx, and f(bx) is less than both f(ax) and
      f(cx)], this routine isolates the minimum to a fractional precision of about tol using
      a modification of Brent's method that uses derivatives. The abscissa of the minimum is
      returned as xmin, and the minimum function value is returned as dbrent, the returned
      function value.

INTEGER iter

10.4 Downhill Simplex Method in Multidimensions

With this section we begin consideration of multidimensional minimization, that is, finding the minimum of a function of more than one independent variable. This section stands apart from those which follow, however: All of the algorithms after this section will make explicit use of a one-dimensional minimization algorithm as a part of their computational strategy. This section implements an entirely self-contained strategy, in which one-dimensional minimization does not figure.

The *downhill simplex method* is due to Nelder and Mead [1]. The method requires only function evaluations, not derivatives. It is not very efficient in terms of the number of function evaluations that it requires. Powell's method (§10.5) is almost surely faster in all likely applications. However, the downhill simplex method may frequently be the *best* method to use if the figure of merit is “get something working quickly” for a problem whose computational burden is small.

The method has a geometrical naturalness about it which makes it delightful to describe or work through:

A *simplex* is the geometrical figure consisting, in N dimensions, of $N + 1$ points (or vertices) and all their interconnecting line segments, polygonal faces, etc. In two dimensions, a simplex is a triangle. In three dimensions it is a tetrahedron, not necessarily the regular tetrahedron. (The *simplex method* of linear programming, described in §10.8, also makes use of the geometrical concept of a simplex. Otherwise it is completely unrelated to the algorithm that we are describing in this section.) In general we are only interested in simplexes that are nondegenerate, i.e., that enclose a finite inner N -dimensional volume. If any point of a nondegenerate simplex is taken as the origin, then the N other points define vector directions that span the N -dimensional vector space.

In one-dimensional minimization, it was possible to bracket a minimum, so that the success of a subsequent isolation was guaranteed. Alas! There is no analogous procedure in multidimensional space. For multidimensional minimization, the best we can do is give our algorithm a starting guess, that is, an N -vector of independent variables as the first point to try. The algorithm is then supposed to make its own way downhill through the unimaginable complexity of an N -dimensional topography, until it encounters a (local, at least) minimum.

The downhill simplex method must be started not just with a single point, but with $N + 1$ points, defining an initial simplex. If you think of one of these points (it matters not which) as being your initial starting point \mathbf{P}_0 , then you can take the other N points to be

$$\mathbf{P}_i = \mathbf{P}_0 + \lambda \mathbf{e}_i \quad (10.4.1)$$

where the \mathbf{e}_i 's are N unit vectors, and where λ is a constant which is your guess of the problem's characteristic length scale. (Or, you could have different λ_i 's for each vector direction.)

The downhill simplex method now takes a series of steps, most steps just moving the point of the simplex where the function is largest (“highest point”) through the opposite face of the simplex to a lower point. These steps are called reflections,

10.4 Downhill Simplex Method in Multidimensions

With this section we begin consideration of multidimensional minimization, that is, finding the minimum of a function of more than one independent variable. This section stands apart from those which follow, however: All of the algorithms after this section will make explicit use of a one-dimensional minimization algorithm as a part of their computational strategy. This section implements an entirely self-contained strategy, in which one-dimensional minimization does not figure.

The *downhill simplex method* is due to Nelder and Mead [1]. The method requires only function evaluations, not derivatives. It is not very efficient in terms of the number of function evaluations that it requires. Powell's method (§10.5) is almost surely faster in all likely applications. However, the downhill simplex method may frequently be the *best* method to use if the figure of merit is “get something working quickly” for a problem whose computational burden is small.

The method has a geometrical naturalness about it which makes it delightful to describe or work through:

A *simplex* is the geometrical figure consisting, in N dimensions, of $N + 1$ points (or vertices) and all their interconnecting line segments, polygonal faces, etc. In two dimensions, a simplex is a triangle. In three dimensions it is a tetrahedron, not necessarily the regular tetrahedron. (The *simplex method* of linear programming, described in §10.8, also makes use of the geometrical concept of a simplex. Otherwise it is completely unrelated to the algorithm that we are describing in this section.) In general we are only interested in simplexes that are nondegenerate, i.e., that enclose a finite inner N -dimensional volume. If any point of a nondegenerate simplex is taken as the origin, then the N other points define vector directions that span the N -dimensional vector space.

In one-dimensional minimization, it was possible to bracket a minimum, so that the success of a subsequent isolation was guaranteed. Alas! There is no analogous procedure in multidimensional space. For multidimensional minimization, the best we can do is give our algorithm a starting guess, that is, an N -vector of independent variables as the first point to try. The algorithm is then supposed to make its own way downhill through the unimaginable complexity of an N -dimensional topography, until it encounters a (local, at least) minimum.

The downhill simplex method must be started not just with a single point, but with $N + 1$ points, defining an initial simplex. If you think of one of these points (it matters not which) as being your initial starting point \mathbf{P}_0 , then you can take the other N points to be

$$\mathbf{P}_i = \mathbf{P}_0 + \lambda \mathbf{e}_i \quad (10.4.1)$$

where the \mathbf{e}_i 's are N unit vectors, and where λ is a constant which is your guess of the problem's characteristic length scale. (Or, you could have different λ_i 's for each vector direction.)

The downhill simplex method now takes a series of steps, most steps just moving the point of the simplex where the function is largest (“highest point”) through the opposite face of the simplex to a lower point. These steps are called reflections,

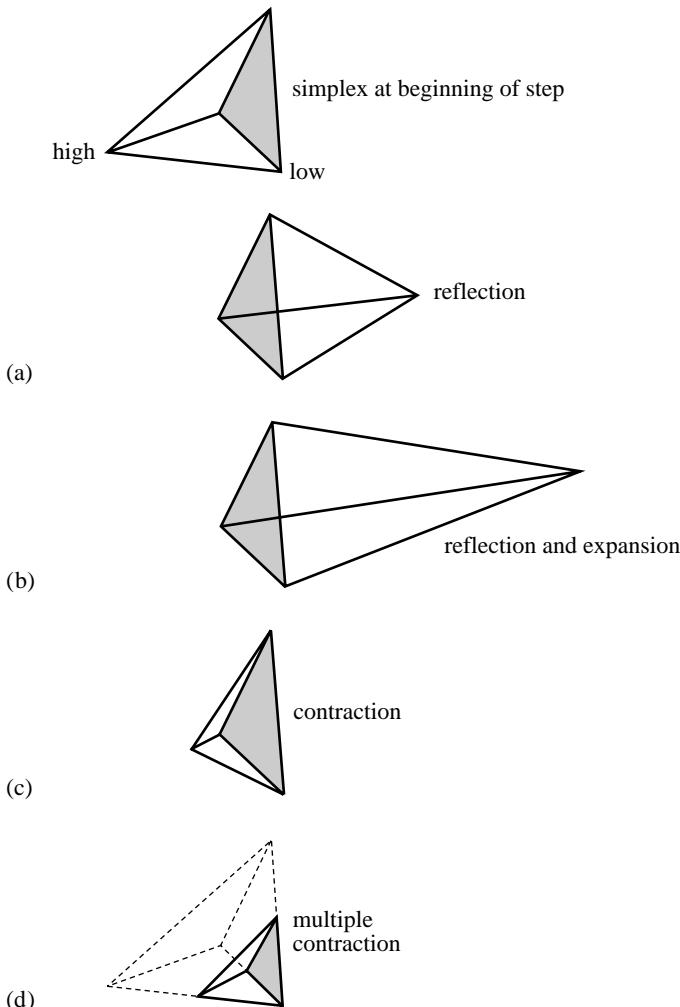

Figure 10.4.1. Possible outcomes for a step in the downhill simplex method. The simplex at the beginning of the step, here a tetrahedron, is shown, top. The simplex at the end of the step can be any one of (a) a reflection away from the high point, (b) a reflection and expansion away from the high point, (c) a contraction along one dimension from the high point, or (d) a contraction along all dimensions towards the low point. An appropriate sequence of such steps will always converge to a minimum of the function.

and they are constructed to conserve the volume of the simplex (hence maintain its nondegeneracy). When it can do so, the method expands the simplex in one or another direction to take larger steps. When it reaches a “valley floor,” the method contracts itself in the transverse direction and tries to ooze down the valley. If there is a situation where the simplex is trying to “pass through the eye of a needle,” it contracts itself in all directions, pulling itself in around its lowest (best) point. The routine name `amoeba` is intended to be descriptive of this kind of behavior; the basic moves are summarized in Figure 10.4.1.

Termination criteria can be delicate in any multidimensional minimization routine. Without bracketing, and with more than one independent variable, we no longer have the option of requiring a certain tolerance for a single independent

variable. We typically can identify one “cycle” or “step” of our multidimensional algorithm. It is then possible to terminate when the vector distance moved in that step is fractionally smaller in magnitude than some tolerance `tol`. Alternatively, we could require that the decrease in the function value in the terminating step be fractionally smaller than some tolerance `ftol`. Note that while `tol` should not usually be smaller than the square root of the machine precision, it is perfectly appropriate to let `ftol` be of order the machine precision (or perhaps slightly larger so as not to be dithered by roundoff).

Note well that either of the above criteria might be fooled by a single anomalous step that, for one reason or another, failed to get anywhere. Therefore, it is frequently a good idea to *restart* a multidimensional minimization routine at a point where it claims to have found a minimum. For this restart, you should reinitialize any ancillary input quantities. In the downhill simplex method, for example, you should reinitialize N of the $N + 1$ vertices of the simplex again by equation (10.4.1), with \mathbf{P}_0 being one of the vertices of the claimed minimum.

Restarts should never be very expensive; your algorithm did, after all, converge to the restart point once, and now you are starting the algorithm already there.

Consider, then, our N -dimensional amoeba:

```
SUBROUTINE amoeba(p,y,mp,np,ndim,ftol,funk,iter)
INTEGER iter,mp,ndim,np,NMAX,ITMAX
REAL ftol,p(mp,np),y(mp),funk,TINY
PARAMETER (NMAX=20,ITMAX=5000,TINY=1.e-10)      Maximum allowed dimensions and func-
EXTERNAL funk                                         tion evaluations, and a small number
C USES amotry,funk
Multidimensional minimization of the function funk(x) where x(1:ndim) is a vector
in ndim dimensions, by the downhill simplex method of Nelder and Mead. The matrix
p(1:ndim+1,1:ndim) is input. Its ndim+1 rows are ndim-dimensional vectors which are
the vertices of the starting simplex. Also input is the vector y(1:ndim+1), whose compo-
nents must be pre-initialized to the values of funk evaluated at the ndim+1 vertices (rows)
of p; and ftol the fractional convergence tolerance to be achieved in the function value
(n.b.!). On output, p and y will have been reset to ndim+1 new points all within ftol of
a minimum function value, and iter gives the number of function evaluations taken.
INTEGER i,ih,i,ilo,inhi,j,m,n
REAL rtol,sum,swap,ysave,ytry,psum(NMAX),amotry
iter=0
1 do 12 n=1,ndim          Enter here when starting or have just overall contracted.
    sum=0.

10.5 Direction Set (Powell's) Methods in Multidimensions

We know (§10.1–§10.3) how to minimize a function of one variable. If we start at a point \mathbf{P} in N -dimensional space, and proceed from there in some vector direction \mathbf{n} , then any function of N variables $f(\mathbf{P})$ can be minimized along the line \mathbf{n} by our one-dimensional methods. One can dream up various multidimensional minimization methods that consist of sequences of such line minimizations. Different methods will differ only by how, at each stage, they choose the next direction \mathbf{n} to try. All such methods presume the existence of a “black-box” sub-algorithm, which we might call `linmin` (given as an explicit routine at the end of this section), whose definition can be taken for now as

`linmin`: Given as input the vectors \mathbf{P} and \mathbf{n} , and the function f , find the scalar λ that minimizes $f(\mathbf{P} + \lambda\mathbf{n})$. Replace \mathbf{P} by $\mathbf{P} + \lambda\mathbf{n}$. Replace \mathbf{n} by $\lambda\mathbf{n}$. Done.

All the minimization methods in this section and in the two sections following fall under this general schema of successive line minimizations. (The algorithm in §10.7 does not need very accurate line minimizations. Accordingly, it has its own approximate line minimization routine, `lnsrch`.) In this section we consider a class of methods whose choice of successive directions does not involve explicit computation of the function’s gradient; the next two sections do require such gradient calculations. You will note that we need not specify whether `linmin` uses gradient information or not. That choice is up to you, and its optimization depends on your particular function. You would be crazy, however, to use gradients in `linmin` and *not* use them in the choice of directions, since in this latter role they can drastically reduce the total computational burden.

10.5 Direction Set (Powell's) Methods in Multidimensions

We know (§10.1–§10.3) how to minimize a function of one variable. If we start at a point \mathbf{P} in N -dimensional space, and proceed from there in some vector direction \mathbf{n} , then any function of N variables $f(\mathbf{P})$ can be minimized along the line \mathbf{n} by our one-dimensional methods. One can dream up various multidimensional minimization methods that consist of sequences of such line minimizations. Different methods will differ only by how, at each stage, they choose the next direction \mathbf{n} to try. All such methods presume the existence of a “black-box” sub-algorithm, which we might call `linmin` (given as an explicit routine at the end of this section), whose definition can be taken for now as

`linmin`: Given as input the vectors \mathbf{P} and \mathbf{n} , and the function f , find the scalar λ that minimizes $f(\mathbf{P} + \lambda\mathbf{n})$. Replace \mathbf{P} by $\mathbf{P} + \lambda\mathbf{n}$. Replace \mathbf{n} by $\lambda\mathbf{n}$. Done.

All the minimization methods in this section and in the two sections following fall under this general schema of successive line minimizations. (The algorithm in §10.7 does not need very accurate line minimizations. Accordingly, it has its own approximate line minimization routine, `lnsrch`.) In this section we consider a class of methods whose choice of successive directions does not involve explicit computation of the function’s gradient; the next two sections do require such gradient calculations. You will note that we need not specify whether `linmin` uses gradient information or not. That choice is up to you, and its optimization depends on your particular function. You would be crazy, however, to use gradients in `linmin` and *not* use them in the choice of directions, since in this latter role they can drastically reduce the total computational burden.

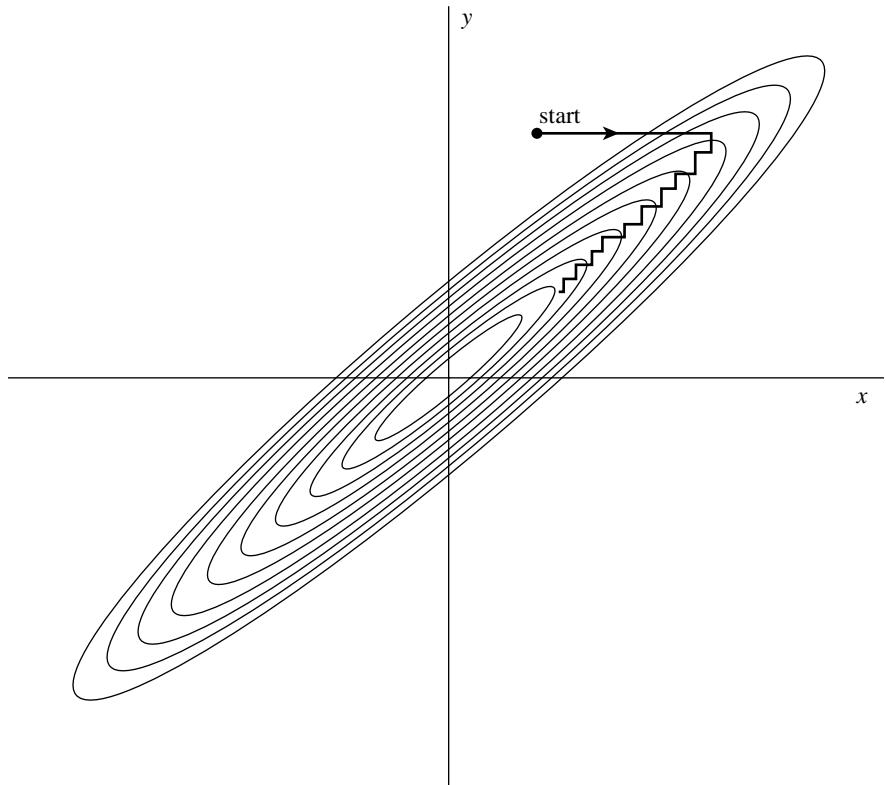

Figure 10.5.1. Successive minimizations along coordinate directions in a long, narrow “valley” (shown as contour lines). Unless the valley is optimally oriented, this method is extremely inefficient, taking many tiny steps to get to the minimum, crossing and re-crossing the principal axis.

But what if, in your application, calculation of the gradient is out of the question. You might first think of this simple method: Take the unit vectors $\mathbf{e}_1, \mathbf{e}_2, \dots, \mathbf{e}_N$ as a *set of directions*. Using `linmin`, move along the first direction to its minimum, then *from there* along the second direction to *its* minimum, and so on, cycling through the whole set of directions as many times as necessary, until the function stops decreasing.

This simple method is actually not too bad for many functions. Even more interesting is why it *is* bad, i.e. very inefficient, for some other functions. Consider a function of two dimensions whose contour map (level lines) happens to define a long, narrow valley at some angle to the coordinate basis vectors (see Figure 10.5.1). Then the only way “down the length of the valley” going along the basis vectors at each stage is by a series of many tiny steps. More generally, in N dimensions, if the function’s second derivatives are much larger in magnitude in some directions than in others, then many cycles through all N basis vectors will be required in order to get anywhere. This condition is not all that unusual; according to Murphy’s Law, you should count on it.

Obviously what we need is a better set of directions than the \mathbf{e}_i ’s. All *direction set methods* consist of prescriptions for updating the set of directions as the method proceeds, attempting to come up with a set which either (i) includes some very

good directions that will take us far along narrow valleys, or else (more subtly) (ii) includes some number of “non-interfering” directions with the special property that minimization along one is not “spoiled” by subsequent minimization along another, so that interminable cycling through the set of directions can be avoided.

Conjugate Directions

This concept of “non-interfering” directions, more conventionally called *conjugate directions*, is worth making mathematically explicit.

First, note that if we minimize a function along some direction \mathbf{u} , then the gradient of the function must be perpendicular to \mathbf{u} at the line minimum; if not, then there would still be a nonzero directional derivative along \mathbf{u} .

Next take some particular point \mathbf{P} as the origin of the coordinate system with coordinates \mathbf{x} . Then any function f can be approximated by its Taylor series

$$\begin{aligned} f(\mathbf{x}) &= f(\mathbf{P}) + \sum_i \frac{\partial f}{\partial x_i} x_i + \frac{1}{2} \sum_{i,j} \frac{\partial^2 f}{\partial x_i \partial x_j} x_i x_j + \dots \\ &\approx c - \mathbf{b} \cdot \mathbf{x} + \frac{1}{2} \mathbf{x} \cdot \mathbf{A} \cdot \mathbf{x} \end{aligned} \quad (10.5.1)$$

where

$$c \equiv f(\mathbf{P}) \quad \mathbf{b} \equiv -\nabla f|_{\mathbf{P}} \quad [\mathbf{A}]_{ij} \equiv \left. \frac{\partial^2 f}{\partial x_i \partial x_j} \right|_{\mathbf{P}} \quad (10.5.2)$$

The matrix \mathbf{A} whose components are the second partial derivative matrix of the function is called the *Hessian matrix* of the function at \mathbf{P} .

In the approximation of (10.5.1), the gradient of f is easily calculated as

$$\nabla f = \mathbf{A} \cdot \mathbf{x} - \mathbf{b} \quad (10.5.3)$$

(This implies that the gradient will vanish — the function will be at an extremum — at a value of \mathbf{x} obtained by solving $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$. This idea we will return to in §10.7!)

How does the gradient ∇f change as we move along some direction? Evidently

$$\delta(\nabla f) = \mathbf{A} \cdot (\delta \mathbf{x}) \quad (10.5.4)$$

Suppose that we have moved along some direction \mathbf{u} to a minimum and now propose to move along some new direction \mathbf{v} . The condition that motion along \mathbf{v} not spoil our minimization along \mathbf{u} is just that the gradient stay perpendicular to \mathbf{u} , i.e., that the change in the gradient be perpendicular to \mathbf{u} . By equation (10.5.4) this is just

$$0 = \mathbf{u} \cdot \delta(\nabla f) = \mathbf{u} \cdot \mathbf{A} \cdot \mathbf{v} \quad (10.5.5)$$

When (10.5.5) holds for two vectors \mathbf{u} and \mathbf{v} , they are said to be *conjugate*. When the relation holds pairwise for all members of a set of vectors, they are said to be a conjugate set. If you do successive line minimization of a function along a conjugate set of directions, then you don’t need to redo any of those directions

(unless, of course, you spoil things by minimizing along a direction that they are *not* conjugate to).

A triumph for a direction set method is to come up with a set of N linearly independent, mutually conjugate directions. Then, one pass of N line minimizations will put it exactly at the minimum of a quadratic form like (10.5.1). For functions f that are not exactly quadratic forms, it won't be exactly at the minimum; but repeated cycles of N line minimizations will in due course converge *quadratically* to the minimum.

Powell's Quadratically Convergent Method

Powell first discovered a direction set method that does produce N mutually conjugate directions. Here is how it goes: Initialize the set of directions \mathbf{u}_i to the basis vectors,

$$\mathbf{u}_i = \mathbf{e}_i \quad i = 1, \dots, N \quad (10.5.6)$$

Now repeat the following sequence of steps ("basic procedure") until your function stops decreasing:

- Save your starting position as \mathbf{P}_0 .
- For $i = 1, \dots, N$, move \mathbf{P}_{i-1} to the minimum along direction \mathbf{u}_i and call this point \mathbf{P}_i .
- For $i = 1, \dots, N - 1$, set $\mathbf{u}_i \leftarrow \mathbf{u}_{i+1}$.
- Set $\mathbf{u}_N \leftarrow \mathbf{P}_N - \mathbf{P}_0$.
- Move \mathbf{P}_N to the minimum along direction \mathbf{u}_N and call this point \mathbf{P}_0 .

Powell, in 1964, showed that, for a quadratic form like (10.5.1), k iterations of the above basic procedure produce a set of directions \mathbf{u}_i whose last k members are mutually conjugate. Therefore, N iterations of the basic procedure, amounting to $N(N + 1)$ line minimizations in all, will exactly minimize a quadratic form. Brent [1] gives proofs of these statements in accessible form.

Unfortunately, there is a problem with Powell's quadratically convergent algorithm. The procedure of throwing away, at each stage, \mathbf{u}_1 in favor of $\mathbf{P}_N - \mathbf{P}_0$ tends to produce sets of directions that "fold up on each other" and become linearly dependent. Once this happens, then the procedure finds the minimum of the function f only over a subspace of the full N -dimensional case; in other words, it gives the wrong answer. Therefore, the algorithm must not be used in the form given above.

There are a number of ways to fix up the problem of linear dependence in Powell's algorithm, among them:

1. You can reinitialize the set of directions \mathbf{u}_i to the basis vectors \mathbf{e}_i after every N or $N + 1$ iterations of the basic procedure. This produces a serviceable method, which we commend to you if quadratic convergence is important for your application (i.e., if your functions are close to quadratic forms and if you desire high accuracy).

2. Brent points out that the set of directions can equally well be reset to the columns of any orthogonal matrix. Rather than throw away the information on conjugate directions already built up, he resets the direction set to calculated principal directions of the matrix \mathbf{A} (which he gives a procedure for determining).

The calculation is essentially a singular value decomposition algorithm (see §2.6). Brent has a number of other cute tricks up his sleeve, and his modification of Powell's method is probably the best presently known. Consult [1] for a detailed description and listing of the program. Unfortunately it is rather too elaborate for us to include here.

3. You can give up the property of quadratic convergence in favor of a more heuristic scheme (due to Powell) which tries to find a few good directions along narrow valleys instead of N necessarily conjugate directions. This is the method that we now implement. (It is also the version of Powell's method given in Acton [2], from which parts of the following discussion are drawn.)

Discarding the Direction of Largest Decrease

The fox and the grapes: Now that we are going to give up the property of quadratic convergence, was it so important after all? That depends on the function that you are minimizing. Some applications produce functions with long, twisty valleys. Quadratic convergence is of no particular advantage to a program which must slalom down the length of a valley floor that twists one way and another (and another, and another, . . . – there are N dimensions!). Along the long direction, a quadratically convergent method is trying to extrapolate to the minimum of a parabola which just isn't (yet) there; while the conjugacy of the $N - 1$ transverse directions keeps getting spoiled by the twists.

Sooner or later, however, we do arrive at an approximately ellipsoidal minimum (cf. equation 10.5.1 when \mathbf{b} , the gradient, is zero). Then, depending on how much accuracy we require, a method with quadratic convergence can save us several times N^2 extra line minimizations, since quadratic convergence *doubles* the number of significant figures at each iteration.

The basic idea of our now-modified Powell's method is still to take $\mathbf{P}_N - \mathbf{P}_0$ as a new direction; it is, after all, the average direction moved after trying all N possible directions. For a valley whose long direction is twisting slowly, this direction is likely to give us a good run along the new long direction. The change is to discard the old direction along which the function f made its *largest decrease*. This seems paradoxical, since that direction was the *best* of the previous iteration. However, it is also likely to be a major component of the new direction that we are adding, so dropping it gives us the best chance of avoiding a buildup of linear dependence.

There are a couple of exceptions to this basic idea. Sometimes it is better *not* to add a new direction at all. Define

$$f_0 \equiv f(\mathbf{P}_0) \quad f_N \equiv f(\mathbf{P}_N) \quad f_E \equiv f(2\mathbf{P}_N - \mathbf{P}_0) \quad (10.5.7)$$

Here f_E is the function value at an “extrapolated” point somewhat further along the proposed new direction. Also define Δf to be the magnitude of the largest decrease along one particular direction of the present basic procedure iteration. (Δf is a positive number.) Then:

1. If $f_E \geq f_0$, then keep the old set of directions for the next basic procedure, because the average direction $\mathbf{P}_N - \mathbf{P}_0$ is all played out.
2. If $2(f_0 - 2f_N + f_E)[(f_0 - f_N) - \Delta f]^2 \geq (f_0 - f_E)^2 \Delta f$, then keep the old set of directions for the next basic procedure, because either (i) the decrease along

the average direction was not primarily due to any single direction's decrease, or (ii) there is a substantial second derivative along the average direction and we seem to be near to the bottom of its minimum.

The following routine implements Powell's method in the version just described. In the routine, \mathbf{x}_i is the matrix whose columns are the set of directions \mathbf{n}_i ; otherwise the correspondence of notation should be self-evident.

```

SUBROUTINE powell(p,xi,n,np,ftol,iter,fret)
INTEGER iter,n,np,NMAX,ITMAX
REAL fret,ftol,p(np),xi(np,np),func,TINY
EXTERNAL func
PARAMETER (NMAX=20,ITMAX=200,TINY=1.e-25)
C USES func,linmin
      Minimization of a function func of n variables. (func is not an argument, it is a fixed function name.) Input consists of an initial starting point p(1:n); an initial matrix xi(1:n,1:n) with physical dimensions np by np, and whose columns contain the initial set of directions (usually the n unit vectors); and ftol, the fractional tolerance in the function value such that failure to decrease by more than this amount on one iteration signals doneness. On output, p is set to the best point found, xi is the then-current direction set, fret is the returned function value at p, and iter is the number of iterations taken. The routine linmin is used.
      Parameters: Maximum value of n, maximum allowed iterations, and a small number.
INTEGER i,ibig,j
REAL del,fp,fptt,t,pt(NMAX),ppt(NMAX),xit(NMAX)
fret=func(p)
do 11 j=1,n
      pt(j)=p(j)
      Save the initial point.
enddo 11
iter=0
1 iter=iter+1
fp=fret
ibig=0
del=0.
do 13 i=1,n
      do 12 j=1,n
            xit(j)=xi(j,i)
      enddo 12
      fptt=fret
      call linmin(p,xit,n,fret)
      if(fptt-fret.gt.del)then
            del=fptt-fret
            ibig=i
      endif
enddo 13
if(2.*fp-fret).le.ftol*(abs(fp)+abs(fret))+TINY)return      Termination criterion.
if(iter.eq.ITMAX) pause 'powell exceeding maximum iterations'
do 14 j=1,n
      ptt(j)=2.*p(j)-pt(j)
      xit(j)=p(j)-pt(j)
      pt(j)=p(j)
      Construct the extrapolated point and the average direction moved. Save the old starting point.
enddo 14
fptt=func(ptt)
if(fptt.ge.fp)goto 1
t=2.*fp-2.*fret+fptt)*(fp-fret-del)**2-del*(fp-fptt)**2
if(t.ge.0.)goto 1
call linmin(p,xit,n,fret)
do 15 j=1,n
      xi(j,ibig)=xi(j,n)
      xi(j,n)=xit(j)
      Move to the minimum of the new direction, and save the new direction.
enddo 15
goto 1
      Back for another iteration.
END

```

Implementation of Line Minimization

In the above routine, you might have wondered why we didn't make the function name `func` an argument of the routine. The reason is buried in a slightly dirty FORTRAN practicality in our implementation of `linmin`.

Make no mistake, there is a *right* way to implement `linmin`: It is to use the *methods* of one-dimensional minimization described in §10.1–§10.3, but to rewrite the programs of those sections so that their bookkeeping is done on vector-valued points **P** (all lying along a given direction **n**) rather than scalar-valued abscissas *x*. That straightforward task produces long routines densely populated with “do *k*=1,*n*” loops.

We do not have space to include such routines in this book. Our `linmin`, which works just fine, is instead a kind of bookkeeping swindle. It constructs an “artificial” function of one variable called `f1dim`, which is the value of your function `func` along the line going through the point *p* in the direction *xi*. `linmin` communicates with `f1dim` through a common block. It then calls our familiar one-dimensional routines `mnbrak` (§10.1) and `brent` (§10.2) and instructs them to minimize `f1dim`.

Still following? Then try this: `brent` receives the function name `f1dim`, which it dutifully calls. But there is no way to signal to `f1dim` that it is supposed to use your function name, which could have been passed to `linmin` as an argument. Therefore, we have to make `f1dim` use a *fixed* function name, namely `func`. The situation is reminiscent of Henry Ford's black automobile: `powell` will minimize any function, as long as it is named `func`. Needed to remedy this situation is a way to pass a function name through a common block; this is lacking in FORTRAN.

The only thing inefficient about `linmin` is this: Its use as an interface between a multidimensional minimization strategy and a one-dimensional minimization routine results in some unnecessary copying of vectors hither and yon. That should not normally be a significant addition to the overall computational burden, but we cannot disguise its inelegance.

```
SUBROUTINE linmin(p,xi,n,fret)
INTEGER n,NMAX
REAL fret,p(n),xi(n),TOL
PARAMETER (NMAX=50,TOL=1.e-4)           Maximum anticipated n, and TOL passed to brent.
C USES brent,fldim,mnbrak
      Given an n-dimensional point p(1:n) and an n-dimensional direction xi(1:n), moves and
      resets p to where the function func(p) takes on a minimum along the direction xi from
      p, and replaces xi by the actual vector displacement that p was moved. Also returns as
      fret the value of func at the returned location p. This is actually all accomplished by
      calling the routines mnbrak and brent.
      INTEGER j,ncom
      REAL ax,bx,fa,fb,fx,xmin,xx,pcom(NMAX),xicom(NMAX),brent
      COMMON /ficom/ pcom,xicom,ncom
      EXTERNAL fidim
      ncom=n                           Set up the common block.
      do 11 j=1,n
         pcom(j)=p(j)
         xicom(j)=xi(j)
      enddo 11
      ax=0.                            Initial guess for brackets.
      xx=1.
      call mnbrak(ax,xx,bx,fa,fx,fb,fidim)
      fret=brent(ax,xx,bx,fidim,TOL,xmin)
      do 12 j=1,n
         Construct the vector results to return.
```

```

xi(j)=xmin*xi(j)
p(j)=p(j)+xi(j)
enddo 12
return
END

FUNCTION fidim(x)
INTEGER NMAX
REAL fidim,func,x
PARAMETER (NMAX=50)
C USES func
      Used by linmin as the function passed to mnbrak and brent.
INTEGER j,ncom
REAL pcom(NMAX),xicom(NMAX),xt(NMAX)
COMMON /ficom/ pcom,xicom,ncom
do 11 j=1,ncom
      xt(j)=pcom(j)+x*xicom(j)
enddo 11
fidim=func(xt)
return
END

```

10.6 Conjugate Gradient Methods in Multidimensions

We consider now the case where you are able to calculate, at a given N -dimensional point \mathbf{P} , not just the value of a function $f(\mathbf{P})$ but also the gradient (vector of first partial derivatives) $\nabla f(\mathbf{P})$.

A rough counting argument will show how advantageous it is to use the gradient information: Suppose that the function f is roughly approximated as a quadratic form, as above in equation (10.5.1),

$$f(\mathbf{x}) \approx c - \mathbf{b} \cdot \mathbf{x} + \frac{1}{2} \mathbf{x} \cdot \mathbf{A} \cdot \mathbf{x} \quad (10.6.1)$$

Then the number of unknown parameters in f is equal to the number of free parameters in \mathbf{A} and \mathbf{b} , which is $\frac{1}{2}N(N+1)$, which we see to be of order N^2 . Changing any one of these parameters can move the location of the minimum. Therefore, we should not expect to be able to *find* the minimum until we have collected an equivalent information content, of order N^2 numbers.

```

10.6 Conjugate Gradient Methods in Multidimensions

We consider now the case where you are able to calculate, at a given N -dimensional point \mathbf{P} , not just the value of a function $f(\mathbf{P})$ but also the gradient (vector of first partial derivatives) $\nabla f(\mathbf{P})$.

A rough counting argument will show how advantageous it is to use the gradient information: Suppose that the function f is roughly approximated as a quadratic form, as above in equation (10.5.1),

$$f(\mathbf{x}) \approx c - \mathbf{b} \cdot \mathbf{x} + \frac{1}{2} \mathbf{x} \cdot \mathbf{A} \cdot \mathbf{x} \quad (10.6.1)$$

Then the number of unknown parameters in f is equal to the number of free parameters in \mathbf{A} and \mathbf{b} , which is $\frac{1}{2}N(N+1)$, which we see to be of order N^2 . Changing any one of these parameters can move the location of the minimum. Therefore, we should not expect to be able to *find* the minimum until we have collected an equivalent information content, of order N^2 numbers.

In the direction set methods of §10.5, we collected the necessary information by making on the order of N^2 separate line minimizations, each requiring “a few” (but sometimes a *big* few!) function evaluations. Now, each evaluation of the gradient will bring us N new components of information. If we use them wisely, we should need to make only of order N separate line minimizations. That is in fact the case for the algorithms in this section and the next.

A factor of N improvement in computational speed is not necessarily implied. As a rough estimate, we might imagine that the calculation of *each component* of the gradient takes about as long as evaluating the function itself. In that case there will be of order N^2 equivalent function evaluations both with and without gradient information. Even if the advantage is not of order N , however, it is nevertheless quite substantial: (i) Each calculated component of the gradient will typically save not just one function evaluation, but a number of them, equivalent to, say, a whole line minimization. (ii) There is often a high degree of redundancy in the formulas for the various components of a function’s gradient; when this is so, especially when there is also redundancy with the calculation of the function, then the calculation of the gradient may cost significantly less than N function evaluations.

A common beginner’s error is to assume that any reasonable way of incorporating gradient information should be about as good as any other. This line of thought leads to the following *not very good* algorithm, the *steepest descent method*:

Steepest Descent: Start at a point \mathbf{P}_0 . As many times as needed, move from point \mathbf{P}_i to the point \mathbf{P}_{i+1} by minimizing along the line from \mathbf{P}_i in the direction of the local downhill gradient $-\nabla f(\mathbf{P}_i)$.

The problem with the steepest descent method (which, incidentally, goes back to Cauchy), is similar to the problem that was shown in Figure 10.5.1. The method will perform many small steps in going down a long, narrow valley, even if the valley is a perfect quadratic form. You might have hoped that, say in two dimensions, your first step would take you to the valley floor, the second step directly down the long axis; but remember that the new gradient at the minimum point of any line minimization is perpendicular to the direction just traversed. Therefore, with the steepest descent method, you *must* make a right angle turn, which does *not*, in general, take you to the minimum. (See Figure 10.6.1.)

Just as in the discussion that led up to equation (10.5.5), we really want a way of proceeding not down the new gradient, but rather in a direction that is somehow constructed to be *conjugate* to the old gradient, and, insofar as possible, to all previous directions traversed. Methods that accomplish this construction are called *conjugate gradient* methods.

In §2.7 we discussed the conjugate gradient method as a technique for solving linear algebraic equations by minimizing a quadratic form. That formalism can also be applied to the problem of minimizing a function *approximated* by the quadratic form (10.6.1). Recall that, starting with an arbitrary initial vector \mathbf{g}_0 and letting $\mathbf{h}_0 = \mathbf{g}_0$, the conjugate gradient method constructs two sequences of vectors from the recurrence

$$\mathbf{g}_{i+1} = \mathbf{g}_i - \lambda_i \mathbf{A} \cdot \mathbf{h}_i \quad \mathbf{h}_{i+1} = \mathbf{g}_{i+1} + \gamma_i \mathbf{h}_i \quad i = 0, 1, 2, \dots \quad (10.6.2)$$

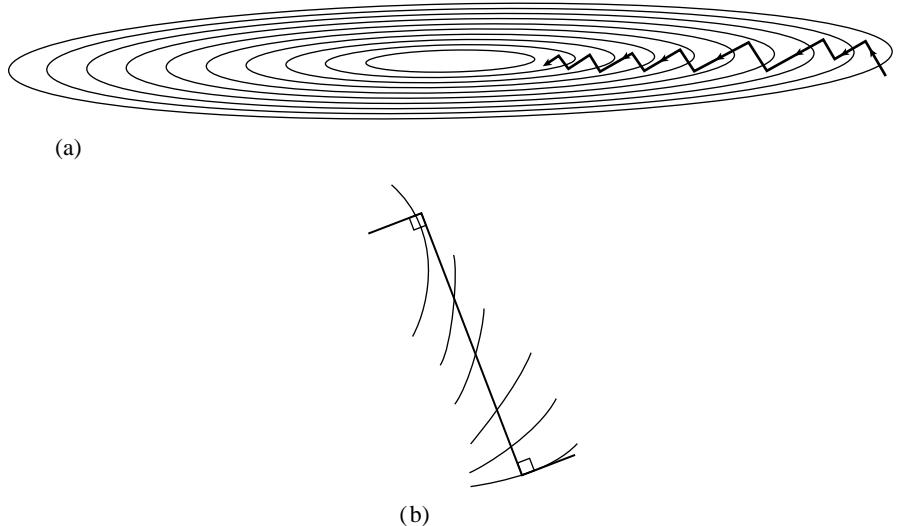

Figure 10.6.1. (a) Steepest descent method in a long, narrow “valley.” While more efficient than the strategy of Figure 10.5.1, steepest descent is nonetheless an inefficient strategy, taking many steps to reach the valley floor. (b) Magnified view of one step: A step starts off in the local gradient direction, perpendicular to the contour lines, and traverses a straight line until a local minimum is reached, where the traverse is parallel to the local contour lines.

The vectors satisfy the orthogonality and conjugacy conditions

$$\mathbf{g}_i \cdot \mathbf{g}_j = 0 \quad \mathbf{h}_i \cdot \mathbf{A} \cdot \mathbf{h}_j = 0 \quad \mathbf{g}_i \cdot \mathbf{h}_j = 0 \quad j < i \quad (10.6.3)$$

The scalars λ_i and γ_i are given by

$$\lambda_i = \frac{\mathbf{g}_i \cdot \mathbf{g}_i}{\mathbf{h}_i \cdot \mathbf{A} \cdot \mathbf{h}_i} = \frac{\mathbf{g}_i \cdot \mathbf{h}_i}{\mathbf{h}_i \cdot \mathbf{A} \cdot \mathbf{h}_i} \quad (10.6.4)$$

$$\gamma_i = \frac{\mathbf{g}_{i+1} \cdot \mathbf{g}_{i+1}}{\mathbf{g}_i \cdot \mathbf{g}_i} \quad (10.6.5)$$

Equations (10.6.2)–(10.6.5) are simply equations (2.7.32)–(2.7.35) for a symmetric \mathbf{A} in a new notation. (A self-contained derivation of these results in the context of function minimization is given by Polak [1].)

Now suppose that we knew the Hessian matrix \mathbf{A} in equation (10.6.1). Then we could use the construction (10.6.2) to find successively conjugate directions \mathbf{h}_i along which to line-minimize. After N such, we would efficiently have arrived at the minimum of the quadratic form. But we don’t know \mathbf{A} .

Here is a remarkable theorem to save the day: Suppose we happen to have $\mathbf{g}_i = -\nabla f(\mathbf{P}_i)$, for some point \mathbf{P}_i , where f is of the form (10.6.1). Suppose that we proceed from \mathbf{P}_i along the direction \mathbf{h}_i to the local minimum of f located at some point \mathbf{P}_{i+1} and then set $\mathbf{g}_{i+1} = -\nabla f(\mathbf{P}_{i+1})$. Then, this \mathbf{g}_{i+1} is the same vector as would have been constructed by equation (10.6.2). (And we have constructed it without knowledge of \mathbf{A} !)

Proof: By equation (10.5.3), $\mathbf{g}_i = -\mathbf{A} \cdot \mathbf{P}_i + \mathbf{b}$, and

$$\mathbf{g}_{i+1} = -\mathbf{A} \cdot (\mathbf{P}_i + \lambda \mathbf{h}_i) + \mathbf{b} = \mathbf{g}_i - \lambda \mathbf{A} \cdot \mathbf{h}_i \quad (10.6.6)$$

with λ chosen to take us to the line minimum. But at the line minimum $\mathbf{h}_i \cdot \nabla f = -\mathbf{h}_i \cdot \mathbf{g}_{i+1} = 0$. This latter condition is easily combined with (10.6.6) to solve for λ . The result is exactly the expression (10.6.4). But with this value of λ , (10.6.6) is the same as (10.6.2), q.e.d.

We have, then, the basis of an algorithm that requires neither knowledge of the Hessian matrix \mathbf{A} , nor even the storage necessary to store such a matrix. A sequence of directions \mathbf{h}_i is constructed, using only line minimizations, evaluations of the gradient vector, and an auxiliary vector to store the latest in the sequence of \mathbf{g} 's.

The algorithm described so far is the original Fletcher-Reeves version of the conjugate gradient algorithm. Later, Polak and Ribiere introduced one tiny, but sometimes significant, change. They proposed using the form

$$\gamma_i = \frac{(\mathbf{g}_{i+1} - \mathbf{g}_i) \cdot \mathbf{g}_{i+1}}{\mathbf{g}_i \cdot \mathbf{g}_i} \quad (10.6.7)$$

instead of equation (10.6.5). “Wait,” you say, “aren’t they equal by the orthogonality conditions (10.6.3)?” They are equal for exact quadratic forms. In the real world, however, your function is not exactly a quadratic form. Arriving at the supposed minimum of the quadratic form, you may still need to proceed for another set of iterations. There is some evidence [2] that the Polak-Ribiere formula accomplishes the transition to further iterations more gracefully: When it runs out of steam, it tends to reset \mathbf{h} to be down the local gradient, which is equivalent to beginning the conjugate-gradient procedure anew.

The following routine implements the Polak-Ribiere variant, which we recommend; but changing one program line, as shown, will give you Fletcher-Reeves. The routine presumes the existence of a function `func(p)`, where `p(1:n)` is a vector of length `n`, and also presumes the existence of a subroutine `dfunc(p,df)` that returns the vector gradient `df(1:n)` evaluated at the input point `p`.

The routine calls `linmin` to do the line minimizations. As already discussed, you may wish to use a modified version of `linmin` that uses `dbrent` instead of `brent`, i.e., that uses the gradient in doing the line minimizations. See note below.

```
SUBROUTINE frprmn(p,n,ftol,iter,fret)
INTEGER iter,n,NMAX,ITMAX
REAL fret,ftol,p(n),EPS,func
EXTERNAL func
PARAMETER (NMAX=50,ITMAX=200,EPS=1.e-10)
C USES dfunc,func,linmin
```

Given a starting point `p` that is a vector of length `n`, Fletcher-Reeves-Polak-Ribiere minimization is performed on a function `func`, using its gradient as calculated by a routine `dfunc`. The convergence tolerance on the function value is input as `ftol`. Returned quantities are `p` (the location of the minimum), `iter` (the number of iterations that were performed), and `fret` (the minimum value of the function). The routine `linmin` is called to perform line minimizations.

Parameters: `NMAX` is the maximum anticipated value of `n`; `ITMAX` is the maximum allowed number of iterations; `EPS` is a small number to rectify special case of converging to exactly zero function value.

```
INTEGER its,j
REAL dgg,fp,gam,gg,g(NMAX),h(NMAX),xi(NMAX)
fp=func(p)                                Initializations.
call dfunc(p,xi)
do ii j=1,n
  g(j)=-xi(j)
  h(j)=g(j)
```

```

xi(j)=h(j)
enddo 11
do 14 its=1,ITMAX           Loop over iterations.
  iter=its
  call linmin(p,xi,n,fret)   Next statement is the normal return:
  if(2.*abs(fret-fp).le.ftol*(abs(fret)+abs(fp)+EPS))return
  fp=fret
  call dfunc(p,xi)
  gg=0.
  dgg=0.
  do 12 j=1,n
    gg=gg+g(j)**2
    dgg=dgg+xi(j)*2          This statement for Fletcher-Reeves.
    dgg=dgg+(xi(j)+g(j))*xi(j) This statement for Polak-Ribiere.
  enddo 12
  if(gg.eq.0.)return         Unlikely. If gradient is exactly zero then we are al-
  gam=dgg/gg               ready done.
  do 13 j=1,n
    g(j)=-xi(j)
    h(j)=g(j)+gam*h(j)
    xi(j)=h(j)
  enddo 13
enddo 14
pause 'frprmn maximum iterations exceeded'
return
END

```

Note on Line Minimization Using Derivatives

Kindly reread the last part of §10.5. We here want to do the same thing, but using derivative information in performing the line minimization.

Rather than reprint the whole routine `linmin` just to show one modified statement, let us just tell you what the change is: The statement

```
fret=brent(ax,xx,bx,f1dim,tol,xmin)
```

should be replaced by

```
fret=dbrent(ax,xx,bx,f1dim,df1dim,tol,xmin)
```

You must also include the following function, which is analogous to `f1dim` as discussed in §10.5. And remember, your function must be named `func`, and its gradient calculation must be named `dfunc`.

```

FUNCTION df1dim(x)
INTEGER NMAX
REAL df1dim,x
PARAMETER (NMAX=50)
C USES dfunc
INTEGER j,ncom
REAL df(NMAX),pcom(NMAX),xicom(NMAX),xt(NMAX)
COMMON /ficom/ pcom,xicom,ncom
do 11 j=1,ncom
  xt(j)=pcom(j)+x*xicom(j)
enddo 11
call dfunc(xt,df)
df1dim=0.

```

```

do 12 j=1,ncom
    df1dim=df1dim+df(j)*xicom(j)
12      enddo
      return
END

```

10.7 Variable Metric Methods in Multidimensions

The goal of *variable metric* methods, which are sometimes called *quasi-Newton* methods, is not different from the goal of conjugate gradient methods: to accumulate information from successive line minimizations so that N such line minimizations lead to the exact minimum of a quadratic form in N dimensions. In that case, the method will also be quadratically convergent for more general smooth functions.

Both variable metric and conjugate gradient methods require that you are able to compute your function's gradient, or first partial derivatives, at arbitrary points. The variable metric approach differs from the conjugate gradient in the way that it stores and updates the information that is accumulated. Instead of requiring intermediate storage on the order of N , the number of dimensions, it requires a matrix of size $N \times N$. Generally, for any moderate N , this is an entirely trivial disadvantage.

On the other hand, there is not, as far as we know, any overwhelming advantage that the variable metric methods hold over the conjugate gradient techniques, except perhaps a historical one. Developed somewhat earlier, and more widely propagated, the variable metric methods have by now developed a wider constituency of satisfied users. Likewise, some fancier implementations of variable metric methods (going beyond the scope of this book, see below) have been developed to a greater level of sophistication on issues like the minimization of roundoff error, handling of special conditions, and so on. We tend to use variable metric rather than conjugate gradient, but we have no reason to urge this habit on you.

Variable metric methods come in two main flavors. One is the *Davidon-Fletcher-Powell (DFP)* algorithm (sometimes referred to as simply *Fletcher-Powell*). The other goes by the name *Broyden-Fletcher-Goldfarb-Shanno (BFGS)*. The BFGS and DFP schemes differ only in details of their roundoff error, convergence tolerances, and similar “dirty” issues which are outside of our scope [1,2]. However, it has become generally recognized that, empirically, the BFGS scheme is superior in these details. We will implement BFGS in this section.

As before, we imagine that our arbitrary function $f(\mathbf{x})$ can be locally approximated by the quadratic form of equation (10.6.1). We don't, however, have any

```

do 12 j=1,ncom
    df1dim=df1dim+df(j)*xicom(j)
12      enddo
      return
END

```

10.7 Variable Metric Methods in Multidimensions

The goal of *variable metric* methods, which are sometimes called *quasi-Newton* methods, is not different from the goal of conjugate gradient methods: to accumulate information from successive line minimizations so that N such line minimizations lead to the exact minimum of a quadratic form in N dimensions. In that case, the method will also be quadratically convergent for more general smooth functions.

Both variable metric and conjugate gradient methods require that you are able to compute your function's gradient, or first partial derivatives, at arbitrary points. The variable metric approach differs from the conjugate gradient in the way that it stores and updates the information that is accumulated. Instead of requiring intermediate storage on the order of N , the number of dimensions, it requires a matrix of size $N \times N$. Generally, for any moderate N , this is an entirely trivial disadvantage.

On the other hand, there is not, as far as we know, any overwhelming advantage that the variable metric methods hold over the conjugate gradient techniques, except perhaps a historical one. Developed somewhat earlier, and more widely propagated, the variable metric methods have by now developed a wider constituency of satisfied users. Likewise, some fancier implementations of variable metric methods (going beyond the scope of this book, see below) have been developed to a greater level of sophistication on issues like the minimization of roundoff error, handling of special conditions, and so on. We tend to use variable metric rather than conjugate gradient, but we have no reason to urge this habit on you.

Variable metric methods come in two main flavors. One is the *Davidon-Fletcher-Powell (DFP)* algorithm (sometimes referred to as simply *Fletcher-Powell*). The other goes by the name *Broyden-Fletcher-Goldfarb-Shanno (BFGS)*. The BFGS and DFP schemes differ only in details of their roundoff error, convergence tolerances, and similar “dirty” issues which are outside of our scope [1,2]. However, it has become generally recognized that, empirically, the BFGS scheme is superior in these details. We will implement BFGS in this section.

As before, we imagine that our arbitrary function $f(\mathbf{x})$ can be locally approximated by the quadratic form of equation (10.6.1). We don't, however, have any

information about the values of the quadratic form's parameters \mathbf{A} and \mathbf{b} , except insofar as we can glean such information from our function evaluations and line minimizations.

The basic idea of the variable metric method is to build up, iteratively, a good approximation to the inverse Hessian matrix \mathbf{A}^{-1} , that is, to construct a sequence of matrices \mathbf{H}_i with the property,

$$\lim_{i \rightarrow \infty} \mathbf{H}_i = \mathbf{A}^{-1} \quad (10.7.1)$$

Even better if the limit is achieved after N iterations instead of ∞ .

The reason that variable metric methods are sometimes called quasi-Newton methods can now be explained. Consider finding a minimum by using Newton's method to search for a zero of the gradient of the function. Near the current point \mathbf{x}_i , we have to second order

$$f(\mathbf{x}) = f(\mathbf{x}_i) + (\mathbf{x} - \mathbf{x}_i) \cdot \nabla f(\mathbf{x}_i) + \frac{1}{2}(\mathbf{x} - \mathbf{x}_i) \cdot \mathbf{A} \cdot (\mathbf{x} - \mathbf{x}_i) \quad (10.7.2)$$

so

$$\nabla f(\mathbf{x}) = \nabla f(\mathbf{x}_i) + \mathbf{A} \cdot (\mathbf{x} - \mathbf{x}_i) \quad (10.7.3)$$

In Newton's method we set $\nabla f(\mathbf{x}) = 0$ to determine the next iteration point:

$$\mathbf{x} - \mathbf{x}_i = -\mathbf{A}^{-1} \cdot \nabla f(\mathbf{x}_i) \quad (10.7.4)$$

The left-hand side is the finite step we need take to get to the exact minimum; the right-hand side is known once we have accumulated an accurate $\mathbf{H} \approx \mathbf{A}^{-1}$.

The “quasi” in quasi-Newton is because we don't use the actual Hessian matrix of f , but instead use our current approximation of it. This is often *better* than using the true Hessian. We can understand this paradoxical result by considering the *descent directions* of f at \mathbf{x}_i . These are the directions \mathbf{p} along which f decreases: $\nabla f \cdot \mathbf{p} < 0$. For the Newton direction (10.7.4) to be a descent direction, we must have

$$\nabla f(\mathbf{x}_i) \cdot (\mathbf{x} - \mathbf{x}_i) = -(\mathbf{x} - \mathbf{x}_i) \cdot \mathbf{A} \cdot (\mathbf{x} - \mathbf{x}_i) < 0 \quad (10.7.5)$$

which is true if \mathbf{A} is positive definite. In general, far from a minimum, we have no guarantee that the Hessian is positive definite. Taking the actual Newton step with the real Hessian can move us to points where the function is *increasing* in value. The idea behind quasi-Newton methods is to start with a positive definite, symmetric approximation to \mathbf{A} (usually the unit matrix) and build up the approximating \mathbf{H}_i 's in such a way that the matrix \mathbf{H}_i remains positive definite and symmetric. Far from the minimum, this guarantees that we always move in a downhill direction. Close to the minimum, the updating formula approaches the true Hessian and we enjoy the quadratic convergence of Newton's method.

When we are not close enough to the minimum, taking the full Newton step \mathbf{p} even with a positive definite \mathbf{A} need not decrease the function; we may move too far for the quadratic approximation to be valid. All we are guaranteed is that *initially* f decreases as we move in the Newton direction. Once again we can use the backtracking strategy described in §9.7 to choose a step along the *direction* of the Newton step \mathbf{p} , but not necessarily all the way.

We won't rigorously derive the DFP algorithm for taking \mathbf{H}_i into \mathbf{H}_{i+1} ; you can consult [3] for clear derivations. Following Brodlie (in [2]), we will give the following heuristic motivation of the procedure.

Subtracting equation (10.7.4) at \mathbf{x}_{i+1} from that same equation at \mathbf{x}_i gives

$$\mathbf{x}_{i+1} - \mathbf{x}_i = \mathbf{A}^{-1} \cdot (\nabla f_{i+1} - \nabla f_i) \quad (10.7.6)$$

where $\nabla f_j \equiv \nabla f(\mathbf{x}_j)$. Having made the step from \mathbf{x}_i to \mathbf{x}_{i+1} , we might reasonably want to require that the new approximation \mathbf{H}_{i+1} satisfy (10.7.6) as if it were actually \mathbf{A}^{-1} , that is,

$$\mathbf{x}_{i+1} - \mathbf{x}_i = \mathbf{H}_{i+1} \cdot (\nabla f_{i+1} - \nabla f_i) \quad (10.7.7)$$

We might also imagine that the updating formula should be of the form $\mathbf{H}_{i+1} = \mathbf{H}_i + \text{correction}$.

What “objects” are around out of which to construct a correction term? Most notable are the two vectors $\mathbf{x}_{i+1} - \mathbf{x}_i$ and $\nabla f_{i+1} - \nabla f_i$; and there is also \mathbf{H}_i . There are not infinitely many natural ways of making a matrix out of these objects, especially if (10.7.7) must hold! One such way, the *DFP updating formula*, is

$$\begin{aligned} \mathbf{H}_{i+1} &= \mathbf{H}_i + \frac{(\mathbf{x}_{i+1} - \mathbf{x}_i) \otimes (\mathbf{x}_{i+1} - \mathbf{x}_i)}{(\mathbf{x}_{i+1} - \mathbf{x}_i) \cdot (\nabla f_{i+1} - \nabla f_i)} \\ &\quad - \frac{[\mathbf{H}_i \cdot (\nabla f_{i+1} - \nabla f_i)] \otimes [\mathbf{H}_i \cdot (\nabla f_{i+1} - \nabla f_i)]}{(\nabla f_{i+1} - \nabla f_i) \cdot \mathbf{H}_i \cdot (\nabla f_{i+1} - \nabla f_i)} \end{aligned} \quad (10.7.8)$$

where \otimes denotes the “outer” or “direct” product of two vectors, a matrix: The ij component of $\mathbf{u} \otimes \mathbf{v}$ is $u_i v_j$. (You might want to verify that 10.7.8 does satisfy 10.7.7.)

The *BFGS updating formula* is exactly the same, but with one additional term,

$$\dots + [(\nabla f_{i+1} - \nabla f_i) \cdot \mathbf{H}_i \cdot (\nabla f_{i+1} - \nabla f_i)] \mathbf{u} \otimes \mathbf{u} \quad (10.7.9)$$

where \mathbf{u} is defined as the vector

$$\begin{aligned} \mathbf{u} &\equiv \frac{(\mathbf{x}_{i+1} - \mathbf{x}_i)}{(\mathbf{x}_{i+1} - \mathbf{x}_i) \cdot (\nabla f_{i+1} - \nabla f_i)} \\ &\quad - \frac{\mathbf{H}_i \cdot (\nabla f_{i+1} - \nabla f_i)}{(\nabla f_{i+1} - \nabla f_i) \cdot \mathbf{H}_i \cdot (\nabla f_{i+1} - \nabla f_i)} \end{aligned} \quad (10.7.10)$$

(You might also verify that this satisfies 10.7.7.)

You will have to take on faith — or else consult [3] for details of — the “deep” result that equation (10.7.8), with or without (10.7.9), does in fact converge to \mathbf{A}^{-1} in N steps, if f is a quadratic form.

Here now is the routine `dfpmin` that implements the quasi-Newton method, and uses `lnsrch` from §9.7. As mentioned at the end of `newt` in §9.7, this algorithm can fail if your variables are badly scaled.

```

SUBROUTINE dfpmin(p,n,gtol,iter,fret,func,dfunc)
INTEGER iter,n,NMAX,ITMAX
REAL fret,gtol,p(n),func,EPS,STPMX,TOLX
PARAMETER (NMAX=50,ITMAX=200,STPMX=100.,EPS=3.e-8,TOLX=4.*EPS)
EXTERNAL dfunc,func
C USES dfunc,func,lnsrch
      Given a starting point p(1:n) that is a vector of length n, the Broyden-Fletcher-Goldfarb-
      Shanno variant of Davidon-Fletcher-Powell minimization is performed on a function func,
      using its gradient as calculated by a routine dfunc. The convergence requirement on zeroing
      the gradient is input as gtol. Returned quantities are p(1:n) (the location of the mini-
      mum), iter (the number of iterations that were performed), and fret (the minimum value
      of the function). The routine lnsrch is called to perform approximate line minimizations.
      Parameters: NMAX is the maximum anticipated value of n; ITMAX is the maximum allowed
      number of iterations; STPMX is the scaled maximum step length allowed in line searches;
      TOLX is the convergence criterion on x values.
      INTEGER i,its,j
      LOGICAL check
      REAL den,fac,fad,fae,fp,stpmx,sum,sumdg,sumxi,temp,test,
*          dg(NMAX),g(NMAX),hdg(NMAX),hessin(NMAX,NMAX),
*          pnew(NMAX),xi(NMAX)
      fp=func(p)                                Calculate starting function value and gradient,
      call dfunc(p,g)
      sum=0.
      do 12 i=1,n                               and initialize the inverse Hessian to the unit matrix.
      do 11 j=1,n
          hessin(i,j)=0.
      enddo 11
      hessin(i,i)=1.
      xi(i)=-g(i)                                Initial line direction.
      sum=sum+p(i)**2
  enddo 12
  stpmx=STPMX*max(sqrt(sum),float(n))
  do 27 its=1,ITMAX                          Main loop over the iterations.
      iter=its
      call lnsrch(n,p,fp,g,xi,pnew,fret,stpmx,check,func)
      The new function evaluation occurs in lnsrch; save the function value in fp for the next
      line search. It is usually safe to ignore the value of check.
      fp=fret
      do 13 i=1,n
          xi(i)=pnew(i)-p(i)                  Update the line direction,
          p(i)=pnew(i)                        and the current point.
      enddo 13
      test=0.                                    Test for convergence on  $\Delta x$ .
      do 14 i=1,n
          temp=abs(xi(i))/max(abs(p(i)),1.)
          if(temp.gt.test)test=temp
      enddo 14
      if(test.lt.TOLX)return
      do 15 i=1,n                               Save the old gradient,
          dg(i)=g(i)
      enddo 15
      call dfunc(p,g)                            and get the new gradient.
      test=0.                                    Test for convergence on zero gradient.
      den=max(fret,1.)
      do 16 i=1,n
          temp=abs(g(i))*max(abs(p(i)),1.)/den
          if(temp.gt.test)test=temp
      enddo 16
      if(test.lt.gtol)return
      do 17 i=1,n                               Compute difference of gradients,
          dg(i)=g(i)-dg(i)
      enddo 17
      do 19 i=1,n                               and difference times current matrix.
          hdg(i)=0.

```

```

        do 18 j=1,n
            hdg(i)=hdg(i)+hessin(i,j)*dg(j)
        enddo 18
    enddo 19
    fac=0.                                Calculate dot products for the denominators.
    fae=0.
    sumdg=0.
    sumxi=0.
    do 21 i=1,n
        fac=fac+dg(i)*xi(i)
        fae=fae+dg(i)*hdg(i)
        sumdg=sumdg+dg(i)**2
        sumxi=sumxi+xi(i)**2
    enddo 21
    if(fac.gt.sqrt(EPS*sumdg*sumxi))then Skip update if fac not sufficiently positive.
        fac=1./fac
        fad=1./fae
        do 22 i=1,n                          The vector that makes BFGS different from DFP:
            dg(i)=fac*xi(i)-fad*hdg(i)
        enddo 22
        do 24 i=1,n                          The BFGS updating formula:
            do 23 j=i,n
                hessin(i,j)=hessin(i,j)+fac*xi(i)*xi(j)
                -fad*hdg(i)*hdg(j)+fae*dg(i)*dg(j)
                hessin(j,i)=hessin(i,j)
            enddo 23
        enddo 24
    endif
    do 26 i=1,n                            Now calculate the next direction to go,
        xi(i)=0.
        do 25 j=1,n
            xi(i)=xi(i)-hessin(i,j)*g(j)
        enddo 25
    enddo 26
    enddo 27                                and go back for another iteration.
pause 'too many iterations in dfpmin'
return
END

```

Quasi-Newton methods like `dfpmin` work well with the approximate line minimization done by `lnsrch`. The routines `powell` (§10.5) and `frprmn` (§10.6), however, need more accurate line minimization, which is carried out by the routine `linmin`.

Advanced Implementations of Variable Metric Methods

Although rare, it can conceivably happen that roundoff errors cause the matrix \mathbf{H}_i to become nearly singular or non-positive-definite. This can be serious, because the supposed search directions might then not lead downhill, and because nearly singular \mathbf{H}_i 's tend to give subsequent \mathbf{H}_i 's that are also nearly singular.

There is a simple fix for this rare problem, the same as was mentioned in §10.4: In case of any doubt, you should *restart* the algorithm at the claimed minimum point, and see if it goes anywhere. Simple, but not very elegant. Modern implementations of variable metric methods deal with the problem in a more sophisticated way.

Instead of building up an approximation to \mathbf{A}^{-1} , it is possible to build up an approximation of \mathbf{A} itself. Then, instead of calculating the left-hand side of (10.7.4) directly, one solves the set of linear equations

$$\mathbf{A} \cdot (\mathbf{x} - \mathbf{x}_i) = -\nabla f(\mathbf{x}_i) \quad (10.7.11)$$

At first glance this seems like a bad idea, since solving (10.7.11) is a process of order N^3 — and anyway, how does this help the roundoff problem? The trick is not to store \mathbf{A} but

rather a triangular decomposition of \mathbf{A} , its *Cholesky decomposition* (cf. §2.9). The updating formula used for the Cholesky decomposition of \mathbf{A} is of order N^2 and can be arranged to guarantee that the matrix remains positive definite and nonsingular, even in the presence of finite roundoff. This method is due to Gill and Murray [1,2].

10.8 Linear Programming and the Simplex Method

The subject of *linear programming*, sometimes called *linear optimization*, concerns itself with the following problem: For N independent variables x_1, \dots, x_N , maximize the function

$$z = a_{01}x_1 + a_{02}x_2 + \dots + a_{0N}x_N \quad (10.8.1)$$

subject to the primary constraints

$$x_1 \geq 0, \quad x_2 \geq 0, \quad \dots \quad x_N \geq 0 \quad (10.8.2)$$

and simultaneously subject to $M = m_1 + m_2 + m_3$ additional constraints, m_1 of them of the form

$$a_{i1}x_1 + a_{i2}x_2 + \dots + a_{iN}x_N \leq b_i \quad (b_i \geq 0) \quad i = 1, \dots, m_1 \quad (10.8.3)$$

m_2 of them of the form

$$a_{j1}x_1 + a_{j2}x_2 + \dots + a_{jN}x_N \geq b_j \geq 0 \quad j = m_1 + 1, \dots, m_1 + m_2 \quad (10.8.4)$$

and m_3 of them of the form

$$\begin{aligned} a_{k1}x_1 + a_{k2}x_2 + \dots + a_{kN}x_N &= b_k \geq 0 \\ k &= m_1 + m_2 + 1, \dots, m_1 + m_2 + m_3 \end{aligned} \quad (10.8.5)$$

The various a_{ij} 's can have either sign, or be zero. The fact that the b 's must all be nonnegative (as indicated by the final inequality in the above three equations) is a matter of convention only, since you can multiply any contrary inequality by -1 . There is no particular significance in the number of constraints M being less than, equal to, or greater than the number of unknowns N .

rather a triangular decomposition of \mathbf{A} , its *Cholesky decomposition* (cf. §2.9). The updating formula used for the Cholesky decomposition of \mathbf{A} is of order N^2 and can be arranged to guarantee that the matrix remains positive definite and nonsingular, even in the presence of finite roundoff. This method is due to Gill and Murray [1,2].

10.8 Linear Programming and the Simplex Method

The subject of *linear programming*, sometimes called *linear optimization*, concerns itself with the following problem: For N independent variables x_1, \dots, x_N , maximize the function

$$z = a_{01}x_1 + a_{02}x_2 + \dots + a_{0N}x_N \quad (10.8.1)$$

subject to the primary constraints

$$x_1 \geq 0, \quad x_2 \geq 0, \quad \dots \quad x_N \geq 0 \quad (10.8.2)$$

and simultaneously subject to $M = m_1 + m_2 + m_3$ additional constraints, m_1 of them of the form

$$a_{i1}x_1 + a_{i2}x_2 + \dots + a_{iN}x_N \leq b_i \quad (b_i \geq 0) \quad i = 1, \dots, m_1 \quad (10.8.3)$$

m_2 of them of the form

$$a_{j1}x_1 + a_{j2}x_2 + \dots + a_{jN}x_N \geq b_j \geq 0 \quad j = m_1 + 1, \dots, m_1 + m_2 \quad (10.8.4)$$

and m_3 of them of the form

$$\begin{aligned} a_{k1}x_1 + a_{k2}x_2 + \dots + a_{kN}x_N &= b_k \geq 0 \\ k &= m_1 + m_2 + 1, \dots, m_1 + m_2 + m_3 \end{aligned} \quad (10.8.5)$$

The various a_{ij} 's can have either sign, or be zero. The fact that the b 's must all be nonnegative (as indicated by the final inequality in the above three equations) is a matter of convention only, since you can multiply any contrary inequality by -1 . There is no particular significance in the number of constraints M being less than, equal to, or greater than the number of unknowns N .

A set of values $x_1 \dots x_N$ that satisfies the constraints (10.8.2)–(10.8.5) is called a *feasible vector*. The function that we are trying to maximize is called the *objective function*. The feasible vector that maximizes the objective function is called the *optimal feasible vector*. An optimal feasible vector can fail to exist for two distinct reasons: (i) there are *no* feasible vectors, i.e., the given constraints are incompatible, or (ii) there is no maximum, i.e., there is a direction in N space where one or more of the variables can be taken to infinity while still satisfying the constraints, giving an unbounded value for the objective function.

As you see, the subject of linear programming is surrounded by notational and terminological thickets. Both of these thorny defenses are lovingly cultivated by a coterie of stern acolytes who have devoted themselves to the field. Actually, the basic ideas of linear programming are quite simple. Avoiding the shrubbery, we want to teach you the basics by means of a couple of specific examples; it should then be quite obvious how to generalize.

Why is linear programming so important? (i) Because “nonnegativity” is the usual constraint on any variable x_i that represents the tangible amount of some physical commodity, like guns, butter, dollars, units of vitamin E, food calories, kilowatt hours, mass, etc. Hence equation (10.8.2). (ii) Because one is often interested in additive (linear) limitations or bounds imposed by man or nature: minimum nutritional requirement, maximum affordable cost, maximum on available labor or capital, minimum tolerable level of voter approval, etc. Hence equations (10.8.3)–(10.8.5). (iii) Because the function that one wants to optimize may be linear, or else may at least be approximated by a linear function — since that is the problem that linear programming *can* solve. Hence equation (10.8.1). For a short, semipopular survey of linear programming applications, see Bland [1].

Here is a specific example of a problem in linear programming, which has $N = 4$, $m_1 = 2$, $m_2 = m_3 = 1$, hence $M = 4$:

$$\text{Maximize } z = x_1 + x_2 + 3x_3 - \frac{1}{2}x_4 \quad (10.8.6)$$

with all the x 's nonnegative and also with

$$\begin{aligned} x_1 + 2x_3 &\leq 740 \\ 2x_2 - 7x_4 &\leq 0 \\ x_2 - x_3 + 2x_4 &\geq \frac{1}{2} \\ x_1 + x_2 + x_3 + x_4 &= 9 \end{aligned} \quad (10.8.7)$$

The answer turns out to be (to 2 decimals) $x_1 = 0$, $x_2 = 3.33$, $x_3 = 4.73$, $x_4 = 0.95$. In the rest of this section we will learn how this answer is obtained. Figure 10.8.1 summarizes some of the terminology thus far.

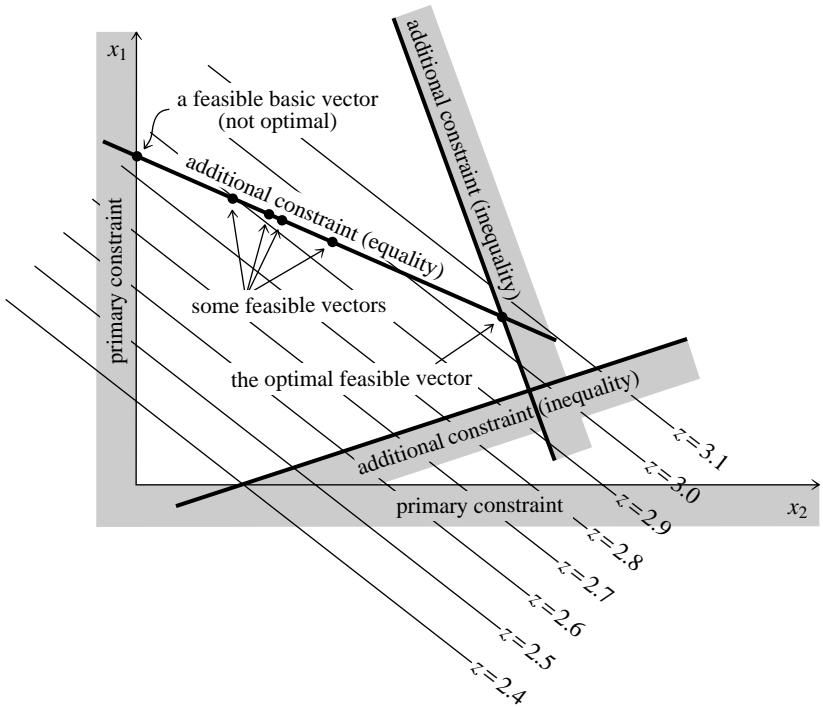

Figure 10.8.1. Basic concepts of linear programming. The case of only two independent variables, x_1, x_2 , is shown. The linear function z , to be maximized, is represented by its contour lines. Primary constraints require x_1 and x_2 to be positive. Additional constraints may restrict the solution to regions (inequality constraints) or to surfaces of lower dimensionality (equality constraints). Feasible vectors satisfy all constraints. Feasible basic vectors also lie on the boundary of the allowed region. The simplex method steps among feasible basic vectors until the optimal feasible vector is found.

Fundamental Theorem of Linear Optimization

Imagine that we start with a full N -dimensional space of candidate vectors. Then (in mind's eye, at least) we carve away the regions that are eliminated in turn by each imposed constraint. Since the constraints are linear, every boundary introduced by this process is a plane, or rather hyperplane. Equality constraints of the form (10.8.5) force the feasible region onto hyperplanes of smaller dimension, while inequalities simply divide the then-feasible region into allowed and nonallowed pieces.

When all the constraints are imposed, either we are left with some feasible region or else there are no feasible vectors. Since the feasible region is bounded by hyperplanes, it is geometrically a kind of convex polyhedron or simplex (cf. §10.4). If there is a feasible region, can the optimal feasible vector be somewhere in its interior, away from the boundaries? No, because the objective function is linear. This means that it always has a nonzero vector gradient. This, in turn, means that we could always increase the objective function by running up the gradient until we hit a boundary wall.

The boundary of any geometrical region has one less dimension than its interior. Therefore, we can now run up the gradient projected into the boundary wall until we

reach an edge of that wall. We can then run up that edge, and so on, down through whatever number of dimensions, until we finally arrive at a point, a *vertex* of the original simplex. Since this point has all N of its coordinates defined, it must be the solution of N simultaneous *equalsities* drawn from the original set of equalities and inequalities (10.8.2)–(10.8.5).

Points that are feasible vectors and that satisfy N of the original constraints as equalities, are termed *feasible basic vectors*. If $N > M$, then a feasible basic vector has *at least* $N - M$ of its components equal to zero, since at least that many of the constraints (10.8.2) will be needed to make up the total of N . Put the other way, *at most* M components of a feasible basic vector are nonzero. In the example (10.8.6)–(10.8.7), you can check that the solution as given satisfies as equalities the last three constraints of (10.8.7) and the constraint $x_1 \geq 0$, for the required total of 4.

Put together the two preceding paragraphs and you have the *Fundamental Theorem of Linear Optimization*: If an optimal feasible vector exists, then there is a feasible basic vector that is optimal. (Didn't we warn you about the terminological thicket?)

The importance of the fundamental theorem is that it reduces the optimization problem to a “combinatorial” problem, that of determining which N constraints (out of the $M + N$ constraints in 10.8.2–10.8.5) should be satisfied by the optimal feasible vector. We have only to keep trying different combinations, and computing the objective function for each trial, until we find the best.

Doing this blindly would take halfway to forever. The *simplex method*, first published by Dantzig in 1948 (see [2]), is a way of organizing the procedure so that (i) a series of combinations is tried for which the objective function increases at each step, and (ii) the optimal feasible vector is reached after a number of iterations that is almost always no larger than of order M or N , whichever is larger. An interesting mathematical sidelight is that this second property, although known empirically ever since the simplex method was devised, was not proved to be true until the 1982 work of Stephen Smale. (For a contemporary account, see [3].)

Simplex Method for a Restricted Normal Form

A linear programming problem is said to be in *normal form* if it has no constraints in the form (10.8.3) or (10.8.4), but rather only equality constraints of the form (10.8.5) and nonnegativity constraints of the form (10.8.2).

For our purposes it will be useful to consider an even more restricted set of cases, with this additional property: Each equality constraint of the form (10.8.5) must have at least one variable that has a positive coefficient and *that appears uniquely in that one constraint only*. We can then choose one such variable in each constraint equation, and solve that constraint equation for it. The variables thus chosen are called *left-hand variables* or *basic variables*, and there are exactly M ($= m_3$) of them. The remaining $N - M$ variables are called *right-hand variables* or *nonbasic variables*. Obviously this *restricted normal form* can be achieved only in the case $M \leq N$, so that is the case that we will consider.

You may be thinking that our restricted normal form is so specialized that it is unlikely to include the linear programming problem that you wish to solve. Not at all! We will presently show how *any* linear programming problem can be

transformed into restricted normal form. Therefore bear with us and learn how to apply the simplex method to a restricted normal form.

Here is an example of a problem in restricted normal form:

$$\text{Maximize } z = 2x_2 - 4x_3 \quad (10.8.8)$$

with x_1, x_2, x_3 , and x_4 all nonnegative and also with

$$\begin{aligned} x_1 &= 2 - 6x_2 + x_3 \\ x_4 &= 8 + 3x_2 - 4x_3 \end{aligned} \quad (10.8.9)$$

This example has $N = 4$, $M = 2$; the left-hand variables are x_1 and x_4 ; the right-hand variables are x_2 and x_3 . The objective function (10.8.8) is written so as to depend only on right-hand variables; note, however, that this is not an actual restriction on objective functions in restricted normal form, since any left-hand variables appearing in the objective function could be eliminated algebraically by use of (10.8.9) or its analogs.

For any problem in restricted normal form, we can instantly read off a feasible basic vector (although not necessarily the *optimal* feasible basic vector). Simply set all right-hand variables equal to zero, and equation (10.8.9) then gives the values of the left-hand variables for which the constraints are satisfied. The idea of the simplex method is to proceed by a series of exchanges. In each exchange, a right-hand variable and a left-hand variable change places. At each stage we maintain a problem in restricted normal form that is equivalent to the original problem.

It is notationally convenient to record the information content of equations (10.8.8) and (10.8.9) in a so-called *tableau*, as follows:

		x_2	x_3
z	0	2	-4
x_1	2	-6	1
x_4	8	3	-4

(10.8.10)

You should study (10.8.10) to be sure that you understand where each entry comes from, and how to translate back and forth between the tableau and equation formats of a problem in restricted normal form.

The first step in the simplex method is to examine the top row of the tableau, which we will call the “z-row.” Look at the entries in columns labeled by right-hand variables (we will call these “right-columns”). We want to imagine in turn the effect of increasing each right-hand variable from its present value of zero, while leaving all the other right-hand variables at zero. Will the objective function increase or decrease? The answer is given by the sign of the entry in the z-row. Since we want to increase the objective function, only right columns having positive z-row entries are of interest. In (10.8.10) there is only one such column, whose z-row entry is 2.

The second step is to examine the column entries below each z-row entry that was selected by step one. We want to ask how much we can increase the right-hand variable before one of the left-hand variables is driven negative, which is not allowed. If the tableau element at the intersection of the right-hand column and the left-hand

variable's row is positive, then it poses no restriction: the corresponding left-hand variable will just be driven more and more positive. If *all* the entries in any right-hand column are positive, then there is no bound on the objective function and (having said so) we are done with the problem.

If one or more entries below a positive z-row entry are negative, then we have to figure out which such entry first limits the increase of that column's right-hand variable. Evidently the limiting increase is given by dividing the element in the right-hand column (which is called the *pivot element*) into the element in the "constant column" (leftmost column) of the pivot element's row. A value that is small in magnitude is most restrictive. The increase in the objective function for this choice of pivot element is then that value multiplied by the z-row entry of that column. We repeat this procedure on all possible right-hand columns to find the pivot element with the largest such increase. That completes our "choice of a pivot element."

In the above example, the only positive z-row entry is 2. There is only one negative entry below it, namely -6 , so this is the pivot element. Its constant-column entry is 2. This pivot will therefore allow x_2 to be increased by $2 \div |6|$, which results in an increase of the objective function by an amount $(2 \times 2) \div |6|$.

The third step is to *do* the increase of the selected right-hand variable, thus making it a left-hand variable; and simultaneously to modify the left-hand variables, reducing the pivot-row element to zero and thus making it a right-hand variable. For our above example let's do this first by hand: We begin by solving the pivot-row equation for the new left-hand variable x_2 in favor of the old one x_1 , namely

$$x_1 = 2 - 6x_2 + x_3 \quad \rightarrow \quad x_2 = \frac{1}{3} - \frac{1}{6}x_1 + \frac{1}{6}x_3 \quad (10.8.11)$$

We then substitute this into the old z-row,

$$z = 2x_2 - 4x_3 = 2 \left[\frac{1}{3} - \frac{1}{6}x_1 + \frac{1}{6}x_3 \right] - 4x_3 = \frac{2}{3} - \frac{1}{3}x_1 - \frac{11}{3}x_3 \quad (10.8.12)$$

and into all other left-variable rows, in this case only x_4 ,

$$x_4 = 8 + 3 \left[\frac{1}{3} - \frac{1}{6}x_1 + \frac{1}{6}x_3 \right] - 4x_3 = 9 - \frac{1}{2}x_1 - \frac{7}{2}x_3 \quad (10.8.13)$$

Equations (10.8.11)–(10.8.13) form the new tableau

		x_1	x_3
z	$\frac{2}{3}$	$-\frac{1}{3}$	$-\frac{11}{3}$
x_2	$\frac{1}{3}$	$-\frac{1}{6}$	$\frac{1}{6}$
x_4	9	$-\frac{1}{2}$	$-\frac{7}{2}$

(10.8.14)

The fourth step is to go back and repeat the first step, looking for another possible increase of the objective function. We do this as many times as possible, that is, until all the right-hand entries in the z-row are negative, signaling that no further increase is possible. In the present example, this already occurs in (10.8.14), so we are done.

The answer can now be read from the constant column of the final tableau. In (10.8.14) we see that the objective function is maximized to a value of $2/3$ for the solution vector $x_2 = 1/3$, $x_4 = 9$, $x_1 = x_3 = 0$.

Now look back over the procedure that led from (10.8.10) to (10.8.14). You will find that it could be summarized entirely in tableau format as a series of prescribed elementary matrix operations:

- Locate the pivot element and save it.
- Save the whole pivot column.
- Replace each row, except the pivot row, by that linear combination of itself and the pivot row which makes its pivot-column entry zero.
- Divide the pivot row by the negative of the pivot.
- Replace the pivot element by the reciprocal of its saved value.
- Replace the rest of the pivot column by its saved values divided by the saved pivot element.

This is the sequence of operations actually performed by a linear programming routine, such as the one that we will presently give.

You should now be able to solve almost any linear programming problem that starts in restricted normal form. The only special case that might stump you is if an entry in the constant column turns out to be zero at some stage, so that a left-hand variable is zero at the same time as all the right-hand variables are zero. This is called a *degenerate feasible vector*. To proceed, you may need to exchange the degenerate left-hand variable for one of the right-hand variables, perhaps even making several such exchanges.

Writing the General Problem in Restricted Normal Form

Here is a pleasant surprise. There exist a couple of clever tricks that render trivial the task of translating a general linear programming problem into restricted normal form!

First, we need to get rid of the inequalities of the form (10.8.3) or (10.8.4), for example, the first three constraints in (10.8.7). We do this by adding to the problem so-called *slack variables* which, when their nonnegativity is required, convert the inequalities to equalities. We will denote slack variables as y_i . There will be $m_1 + m_2$ of them. Once they are introduced, you treat them on an equal footing with the original variables x_i ; then, at the very end, you simply ignore them.

For example, introducing slack variables leaves (10.8.6) unchanged but turns (10.8.7) into

$$\begin{aligned} x_1 + 2x_3 + y_1 &= 740 \\ 2x_2 - 7x_4 + y_2 &= 0 \\ x_2 - x_3 + 2x_4 - y_3 &= \frac{1}{2} \\ x_1 + x_2 + x_3 + x_4 &= 9 \end{aligned} \tag{10.8.15}$$

(Notice how the sign of the coefficient of the slack variable is determined by which sense of inequality it is replacing.)

Second, we need to insure that there is a set of M left-hand vectors, so that we can set up a starting tableau in restricted normal form. (In other words, we need to find a “feasible basic starting vector.”) The trick is again to invent new variables! There are M of these, and they are called *artificial variables*; we denote them by z_i . You put exactly one artificial variable into each constraint equation on the following

model for the example (10.8.15):

$$\begin{aligned} z_1 &= 740 - x_1 - 2x_3 - y_1 \\ z_2 &= -2x_2 + 7x_4 - y_2 \\ z_3 &= \frac{1}{2} - x_2 + x_3 - 2x_4 + y_3 \\ z_4 &= 9 - x_1 - x_2 - x_3 - x_4 \end{aligned} \tag{10.8.16}$$

Our example is now in restricted normal form.

Now you may object that (10.8.16) is not the same problem as (10.8.15) or (10.8.7) *unless all the z_i 's are zero*. Right you are! There is some subtlety here! We must proceed to solve our problem in two phases. First phase: We replace our objective function (10.8.6) by a so-called *auxiliary objective function*

$$z' \equiv -z_1 - z_2 - z_3 - z_4 = -(749\frac{1}{2} - 2x_1 - 4x_2 - 2x_3 + 4x_4 - y_1 - y_2 + y_3) \tag{10.8.17}$$

(where the last equality follows from using 10.8.16). We now perform the simplex method on the auxiliary objective function (10.8.17) with the constraints (10.8.16). Obviously the auxiliary objective function will be maximized for nonnegative z_i 's if all the z_i 's are zero. We therefore expect the simplex method in this first phase to produce a set of left-hand variables drawn from the x_i 's and y_i 's only, with all the z_i 's being right-hand variables. Aha! We then cross out the z_i 's, leaving a problem involving only x_i 's and y_i 's in restricted normal form. In other words, the first phase produces an initial feasible basic vector. Second phase: Solve the problem produced by the first phase, using the original objective function, not the auxiliary.

And what if the first phase *doesn't* produce zero values for all the z_i 's? That signals that there is *no* initial feasible basic vector, i.e., that the constraints given to us are inconsistent among themselves. Report that fact, and you are done.

Here is how to translate into tableau format the information needed for both the first and second phases of the overall method. As before, the underlying problem to be solved is as posed in equations (10.8.6)–(10.8.7).

	x_1	x_2	x_3	x_4		y_1	y_2	y_3
z	0	1	1	3	$-\frac{1}{2}$	0	0	0
z_1	740	-1	0	-2	0	-1	0	0
z_2	0	0	-2	0	7	0	-1	0
z_3	$\frac{1}{2}$	0	-1	1	-2	0	0	1
z_4	9	-1	-1	-1	-1	0	0	0
z'	$-749\frac{1}{2}$	2	4	2	-4	1	1	-1

(10.8.18)

This is not as daunting as it may, at first sight, appear. The table entries inside the box of double lines are no more than the coefficients of the original problem (10.8.6)–(10.8.7) organized into a tabular form. In fact, these entries, along with

the values of N , M , m_1 , m_2 , and m_3 , are the only input that is needed by the simplex method routine below. The columns under the slack variables y_i simply record whether each of the M constraints is of the form \leq , \geq , or $=$; this is redundant information with the values m_1, m_2, m_3 , as long as we are sure to enter the rows of the tableau in the correct respective order. The coefficients of the auxiliary objective function (bottom row) are just the negatives of the column sums of the rows above, so these are easily calculated automatically.

The output from a simplex routine will be (i) a flag telling whether a finite solution, no solution, or an unbounded solution was found, and (ii) an updated tableau. The output tableau that derives from (10.8.18), given to two significant figures, is

	x_1	y_2	y_3	\dots
z	17.03	-.95	-.05	-1.05
x_2	3.33	-.35	-.15	.35
x_3	4.73	-.55	.05	-.45
x_4	.95	-.10	.10	.10
y_1	730.55	.10	-.10	.90

(10.8.19)

A little counting of the x_i 's and y_i 's will convince you that there are $M + 1$ rows (including the z -row) in both the input and the output tableaux, but that only $N + 1 - m_3$ columns of the output tableau (including the constant column) contain any useful information, the other columns belonging to now-discarded artificial variables. In the output, the first numerical column contains the solution vector, along with the maximum value of the objective function. Where a slack variable (y_i) appears on the left, the corresponding value is the amount by which its inequality is safely satisfied. Variables that are not left-hand variables in the output tableau have zero values. Slack variables with zero values represent constraints that are satisfied as equalities.

Routine Implementing the Simplex Method

The following routine is based algorithmically on the implementation of Kuenzi, Tzsachach, and Zehnder [4]. Aside from input values of M , N , m_1 , m_2 , m_3 , the principal input to the routine is a two-dimensional array a containing the portion of the tableau (10.8.18) that is contained between the double lines. This input occupies the first $M + 1$ rows and $N + 1$ columns of a . Note, however, that reference is made internally to row $M + 2$ of a (used for the auxiliary objective function, just as in 10.8.18). Therefore the physical dimensions of a ,

REAL $a(MP, NP)$ (10.8.20)

must have $NP \geq N + 1$ and $MP \geq M + 2$. You will suffer endless agonies if you fail to understand this simple point. Also do not neglect to order the rows of a in the same order as equations (10.8.1), (10.8.3), (10.8.4), and (10.8.5), that is, objective function, \leq -constraints, \geq -constraints, $=$ -constraints.

On output, the tableau a is indexed by two returned arrays of integers. $\text{iposv}(j)$ contains, for $j = 1 \dots M$, the number i whose original variable x_i is now represented by row $j+1$ of a . These are thus the left-hand variables in the solution. (The first row of a is of course the z-row.) A value $i > N$ indicates that the variable is a y_i rather than an x_i , $x_{N+j} \equiv y_j$. Likewise, $\text{izrov}(j)$ contains, for $j = 1 \dots N$, the number i whose original variable x_i is now a right-hand variable, represented by column $j+1$ of a . These variables are all zero in the solution. The meaning of $i > N$ is the same as above, except that $i > N + m_1 + m_2$ denotes an artificial or slack variable which was used only internally and should now be entirely ignored.

The flag icase is returned as zero if a finite solution is found, $+1$ if the objective function is unbounded, -1 if no solution satisfies the given constraints.

The routine treats the case of degenerate feasible vectors, so don't worry about them. You may also wish to admire the fact that the routine does not require storage for the columns of the tableau (10.8.18) that are to the right of the double line; it keeps track of slack variables by more efficient bookkeeping.

Please note that, as given, the routine is only "semi-sophisticated" in its tests for convergence. While the routine properly implements tests for inequality with zero as tests against some small parameter EPS, it does not adjust this parameter to reflect the scale of the input data. This is adequate for many problems, where the input data do not differ from unity by too many orders of magnitude. If, however, you encounter endless cycling, then you should modify EPS in the routines `simplx` and `simpl2`. Permuting your variables can also help. Finally, consult [5].

Other Topics Briefly Mentioned

Every linear programming problem in normal form with N variables and M constraints has a corresponding *dual* problem with M variables and N constraints. The tableau of the dual problem is, in essence, the transpose of the tableau of the original (sometimes called *primal*) problem. It is possible to go from a solution of the dual to a solution of the primal. This can occasionally be computationally useful, but generally it is no big deal.

The *revised simplex method* is exactly equivalent to the simplex method in its choice of which left-hand and right-hand variables are exchanged. Its computational effort is not significantly less than that of the simplex method. It does differ in the organization of its storage, requiring only a matrix of size $M \times M$, rather than $M \times N$, in its intermediate stages. If you have a lot of constraints, and memory size is one of them, then you should look into it.

The *primal-dual algorithm* and the *composite simplex algorithm* are two different methods for avoiding the two phases of the usual simplex method: Progress is made simultaneously towards finding a feasible solution and finding an optimal solution. There seems to be no clearcut evidence that these methods are superior

to the usual method by any factor substantially larger than the “tender-loving-care factor” (which reflects the programming effort of the proponents).

Problems where the objective function and/or one or more of the constraints are replaced by expressions nonlinear in the variables are called *nonlinear programming problems*. The literature on such problems is vast, but outside our scope. The special case of quadratic expressions is called *quadratic programming*. Optimization problems where the variables take on only integer values are called *integer programming* problems, a special case of *discrete optimization* generally. The next section looks at a particular kind of discrete optimization problem.

10.9 Simulated Annealing Methods

The *method of simulated annealing* [1,2] is a technique that has attracted significant attention as suitable for optimization problems of large scale, especially ones where a desired global extremum is hidden among many, poorer, local extrema. For practical purposes, simulated annealing has effectively “solved” the famous *traveling salesman problem* of finding the shortest cyclical itinerary for a traveling salesman who must visit each of N cities in turn. (Other practical methods have also been found.) The method has also been used successfully for designing complex integrated circuits: The arrangement of several hundred thousand circuit elements on a tiny silicon substrate is optimized so as to minimize interference among their connecting wires [3,4]. Surprisingly, the implementation of the algorithm is relatively simple.

Notice that the two applications cited are both examples of *combinatorial minimization*. There is an objective function to be minimized, as usual; but the space over which function is defined is not simply the N -dimensional space of N

to the usual method by any factor substantially larger than the “tender-loving-care factor” (which reflects the programming effort of the proponents).

10.9 Simulated Annealing Methods

The *method of simulated annealing* [1,2] is a technique that has attracted significant attention as suitable for optimization problems of large scale, especially ones where a desired global extremum is hidden among many, poorer, local extrema. For practical purposes, simulated annealing has effectively “solved” the famous *traveling salesman problem* of finding the shortest cyclical itinerary for a traveling salesman who must visit each of N cities in turn. (Other practical methods have also been found.) The method has also been used successfully for designing complex integrated circuits: The arrangement of several hundred thousand circuit elements on a tiny silicon substrate is optimized so as to minimize interference among their connecting wires [3,4]. Surprisingly, the implementation of the algorithm is relatively simple.

Notice that the two applications cited are both examples of *combinatorial minimization*. There is an objective function to be minimized, as usual; but the space over which function is defined is not simply the N -dimensional space of N

continuously variable parameters. Rather, it is a discrete, but very large, configuration space, like the set of possible orders of cities, or the set of possible allocations of silicon “real estate” blocks to circuit elements. The number of elements in the configuration space is factorially large, so that they cannot be explored exhaustively. Furthermore, since the set is discrete, we are deprived of any notion of “continuing downhill in a favorable direction.” The concept of “direction” may not have any meaning in the configuration space.

Below, we will also discuss how to use simulated annealing methods for spaces with continuous control parameters, like those of §§10.4–10.7. This application is actually more complicated than the combinatorial one, since the familiar problem of “long, narrow valleys” again asserts itself. Simulated annealing, as we will see, tries “random” steps; but in a long, narrow valley, almost all random steps are uphill! Some additional finesse is therefore required.

At the heart of the method of simulated annealing is an analogy with thermodynamics, specifically with the way that liquids freeze and crystallize, or metals cool and anneal. At high temperatures, the molecules of a liquid move freely with respect to one another. If the liquid is cooled slowly, thermal mobility is lost. The atoms are often able to line themselves up and form a pure crystal that is completely ordered over a distance up to billions of times the size of an individual atom in all directions. This crystal is the state of minimum energy for this system. The amazing fact is that, for slowly cooled systems, nature is able to find this minimum energy state. In fact, if a liquid metal is cooled quickly or “quenched,” it does not reach this state but rather ends up in a polycrystalline or amorphous state having somewhat higher energy.

So the essence of the process is *slow* cooling, allowing ample time for redistribution of the atoms as they lose mobility. This is the technical definition of *annealing*, and it is essential for ensuring that a low energy state will be achieved.

Although the analogy is not perfect, there is a sense in which all of the minimization algorithms thus far in this chapter correspond to rapid cooling or quenching. In all cases, we have gone greedily for the quick, nearby solution: From the starting point, go immediately downhill as far as you can go. This, as often remarked above, leads to a local, but not necessarily a global, minimum. Nature’s own minimization algorithm is based on quite a different procedure. The so-called Boltzmann probability distribution,

$$\text{Prob}(E) \sim \exp(-E/kT) \quad (10.9.1)$$

expresses the idea that a system in thermal equilibrium at temperature T has its energy probabilistically distributed among all different energy states E . Even at low temperature, there is a chance, albeit very small, of a system being in a high energy state. Therefore, there is a corresponding chance for the system to get out of a local energy minimum in favor of finding a better, more global, one. The quantity k (Boltzmann’s constant) is a constant of nature that relates temperature to energy. In other words, the system sometimes goes *uphill* as well as downhill; but the lower the temperature, the less likely is any significant uphill excursion.

In 1953, Metropolis and coworkers [5] first incorporated these kinds of principles into numerical calculations. Offered a succession of options, a simulated thermodynamic system was assumed to change its configuration from energy E_1 to energy E_2 with probability $p = \exp[-(E_2 - E_1)/kT]$. Notice that if $E_2 < E_1$, this probability is greater than unity; in such cases the change is arbitrarily assigned a

probability $p = 1$, i.e., the system *always* took such an option. This general scheme, of always taking a downhill step while *sometimes* taking an uphill step, has come to be known as the Metropolis algorithm.

To make use of the Metropolis algorithm for other than thermodynamic systems, one must provide the following elements:

1. A description of possible system configurations.
2. A generator of random changes in the configuration; these changes are the “options” presented to the system.
3. An objective function E (analog of energy) whose minimization is the goal of the procedure.
4. A control parameter T (analog of temperature) and an *annealing schedule* which tells how it is lowered from high to low values, e.g., after how many random changes in configuration is each downward step in T taken, and how large is that step. The meaning of “high” and “low” in this context, and the assignment of a schedule, may require physical insight and/or trial-and-error experiments.

Combinatorial Minimization: The Traveling Salesman

A concrete illustration is provided by the traveling salesman problem. The proverbial seller visits N cities with given positions (x_i, y_i) , returning finally to his or her city of origin. Each city is to be visited only once, and the route is to be made as short as possible. This problem belongs to a class known as *NP-complete* problems, whose computation time for an *exact* solution increases with N as $\exp(\text{const.} \times N)$, becoming rapidly prohibitive in cost as N increases. The traveling salesman problem also belongs to a class of minimization problems for which the objective function E has many local minima. In practical cases, it is often enough to be able to choose from these a minimum which, even if not absolute, cannot be significantly improved upon. The annealing method manages to achieve this, while limiting its calculations to scale as a small power of N .

As a problem in simulated annealing, the traveling salesman problem is handled as follows:

1. *Configuration.* The cities are numbered $i = 1 \dots N$ and each has coordinates (x_i, y_i) . A configuration is a permutation of the number $1 \dots N$, interpreted as the order in which the cities are visited.
2. *Rearrangements.* An efficient set of moves has been suggested by Lin [6]. The moves consist of two types: (a) A section of path is removed and then replaced with the same cities running in the opposite order; or (b) a section of path is removed and then replaced in between two cities on another, randomly chosen, part of the path.
3. *Objective Function.* In the simplest form of the problem, E is taken just as the total length of journey,

$$E = L \equiv \sum_{i=1}^N \sqrt{(x_i - x_{i+1})^2 + (y_i - y_{i+1})^2} \quad (10.9.2)$$

with the convention that point $N + 1$ is identified with point 1. To illustrate the flexibility of the method, however, we can add the following additional wrinkle: Suppose that the salesman has an irrational fear of flying over the Mississippi River.

In that case, we would assign each city a parameter μ_i , equal to +1 if it is east of the Mississippi, -1 if it is west, and take the objective function to be

$$E = \sum_{i=1}^N \left[\sqrt{(x_i - x_{i+1})^2 + (y_i - y_{i+1})^2} + \lambda(\mu_i - \mu_{i+1})^2 \right] \quad (10.9.3)$$

A penalty 4λ is thereby assigned to any river crossing. The algorithm now finds the shortest path that avoids crossings. The relative importance that it assigns to length of path versus river crossings is determined by our choice of λ . Figure 10.9.1 shows the results obtained. Clearly, this technique can be generalized to include many conflicting goals in the minimization.

4. *Annealing schedule.* This requires experimentation. We first generate some random rearrangements, and use them to determine the range of values of ΔE that will be encountered from move to move. Choosing a starting value for the parameter T which is considerably larger than the largest ΔE normally encountered, we proceed downward in multiplicative steps each amounting to a 10 percent decrease in T . We hold each new value of T constant for, say, $100N$ reconfigurations, or for $10N$ successful reconfigurations, whichever comes first. When efforts to reduce E further become sufficiently discouraging, we stop.

The following traveling salesman program, using the Metropolis algorithm, illustrates the main aspects of the simulated annealing technique for combinatorial problems.

```
SUBROUTINE anneal(x,y,iorder,ncity)
INTEGER ncity,iorder(ncity)
REAL x(ncity),y(ncity)
C USES irbit1,metrop,ran3,revcst,trncst,trnspt

SUBROUTINE revcst(x,y,iorder,ncity,n,de)
INTEGER ncity,iorder(ncity),n(6)
REAL de,x(ncity),y(ncity)
This subroutine returns the value of the cost function for a proposed path reversal. ncity
is the number of cities, and arrays x(1:ncity),y(1:ncity) give the coordinates of these
cities. iorder(1:ncity) holds the present itinerary. The first two values n(1) and n(2)
of array n give the starting and ending cities along the path segment which is to be reversed.
On output, de is the cost of making the reversal. The actual reversal is not performed by
this routine.
INTEGER ii,j
REAL alen,xx(4),yy(4),x1,x2,y1,y2
alen(x1,x2,y1,y2)=sqrt((x2-x1)**2+(y2-y1)**2)
n(3)=1+mod((n(1)+ncity-2),ncity)           Find the city before n(1) ..
n(4)=1+mod(n(2),ncity)                      .. and the city after n(2).
do 11 j=1,4
  ii=iorder(n(j))                          Find coordinates for the four cities involved.
  xx(j)=x(ii)
  yy(j)=y(ii)
enddo 11
de=alen(xx(1),xx(3),yy(1),yy(3))
*     -alen(xx(2),xx(4),yy(2),yy(4))          Calculate cost of disconnecting the segment
*     +alen(xx(1),xx(4),yy(1),yy(4))            at both ends and reconnecting in the op-
*     +alen(xx(2),xx(3),yy(2),yy(3))            posite order.
return
END

```

```
SUBROUTINE revers(iorder,ncity,n)
INTEGER ncity,iorder(ncity),n(6)
```

This routine performs a path segment reversal. *iorder*(1:ncity) is an input array giving the present itinerary. The vector *n* has as its first four elements the first and last cities *n*(1),*n*(2) of the path segment to be reversed, and the two cities *n*(3) and *n*(4) that immediately precede and follow this segment. *n*(3) and *n*(4) are found by subroutine *revcst*. On output, *iorder*(1:ncity) contains the segment from *n*(1) to *n*(2) in reversed order.

```
INTEGER itmp,j,k,l,nn
nn=(1+mod(n(2)-n(1)+ncity,ncity))/2
do 11 j=1,nn
  k=1+mod((n(1)+j-2),ncity)
  l=1+mod((n(2)-j+ncity),ncity)
  itmp=iorder(k)
  iorder(k)=iorder(l)
  iorder(l)=itmp
11 enddo 11
return
END
```

This many cities must be swapped to effect the reversal.

Start at the ends of the segment and swap pairs of cities, moving toward the center.

```
SUBROUTINE trncst(x,y,iorder, ncity,n,de)
INTEGER ncity,iorder(ncity),n(6)
REAL de,x(ncity),y(ncity)
```

This subroutine returns the value of the cost function for a proposed path segment transport. *ncity* is the number of cities, and arrays *x*(1:ncity) and *y*(1:ncity) give the city coordinates. *iorder* is an array giving the present itinerary. The first three elements of array *n* give the starting and ending cities of the path to be transported, and the point among the remaining cities after which it is to be inserted. On output, *de* is the cost of the change. The actual transport is not performed by this routine.

```

Continuous Minimization by Simulated Annealing

The basic ideas of simulated annealing are also applicable to optimization problems with continuous N -dimensional control spaces, e.g., finding the (ideally, global) minimum of some function $f(\mathbf{x})$, in the presence of many local minima, where \mathbf{x} is an N -dimensional vector. The four elements required by the Metropolis procedure are now as follows: The value of f is the objective function. The system state is the point \mathbf{x} . The control parameter T is, as before, something like a temperature, with an annealing schedule by which it is gradually reduced. And there must be a generator of random changes in the configuration, that is, a procedure for taking a random step from \mathbf{x} to $\mathbf{x} + \Delta\mathbf{x}$.

The last of these elements is the most problematical. The literature to date [7-10] describes several different schemes for choosing $\Delta\mathbf{x}$, none of which, in our view, inspire complete confidence. The problem is one of efficiency: A generator of random changes is inefficient if, *when local downhill moves exist*, it nevertheless almost always proposes an uphill move. A good generator, we think, should not become inefficient in narrow valleys; nor should it become more and more inefficient as convergence to a minimum is approached. Except possibly for [7], all of the schemes that we have seen are inefficient in one or both of these situations.

Our own way of doing simulated annealing minimization on continuous control spaces is to use a modification of the downhill simplex method (§10.4). This amounts to replacing the single point \mathbf{x} as a description of the system state by a simplex of $N + 1$ points. The “moves” are the same as described in §10.4, namely reflections, expansions, and contractions of the simplex. The implementation of the Metropolis procedure is slightly subtle: We *add* a positive, logarithmically distributed random variable, proportional to the temperature T , to the stored function value associated with every vertex of the simplex, and we *subtract* a similar random variable from the function value of every new point that is tried as a replacement point. Like the ordinary Metropolis procedure, this method always accepts a true downhill step, but sometimes accepts an uphill one. In the limit $T \rightarrow 0$, this algorithm reduces exactly to the downhill simplex method and converges to a local minimum.

At a finite value of T , the simplex expands to a scale that approximates the size of the region that can be reached at this temperature, and then executes a stochastic, tumbling Brownian motion within that region, sampling new, approximately random, points as it does so. The efficiency with which a region is explored is independent of its narrowness (for an ellipsoidal valley, the ratio of its principal axes) and orientation. If the temperature is reduced sufficiently slowly, it becomes highly likely that the simplex will shrink into that region containing the lowest relative minimum encountered.

As in all applications of simulated annealing, there can be quite a lot of problem-dependent subtlety in the phrase “sufficiently slowly”; success or failure is quite often determined by the choice of annealing schedule. Here are some possibilities worth trying:

- Reduce T to $(1 - \epsilon)T$ after every m moves, where ϵ/m is determined by experiment.
- Budget a total of K moves, and reduce T after every m moves to a value $T = T_0(1 - k/K)^\alpha$, where k is the cumulative number of moves thus far, and α is a constant, say 1, 2, or 4. The optimal value for α depends on the statistical distribution of relative minima of various depths. Larger values of α spend more iterations at lower temperature.
- After every m moves, set T to β times $f_1 - f_b$, where β is an experimentally determined constant of order 1, f_1 is the smallest function value currently represented in the simplex, and f_b is the best function ever encountered. However, never reduce T by more than some fraction γ at a time.

Another strategic question is whether to do an occasional *restart*, where a vertex of the simplex is discarded in favor of the “best-ever” point. (You must be sure that the best-ever point is not currently in the simplex when you do this!) We have found problems for which restarts — every time the temperature has decreased by a factor of 3, say — are highly beneficial; we have found other problems for which restarts

have no positive, or a somewhat negative, effect.

You should compare the following routine, amebsa, with its counterpart amoeba in §10.4. Note that the argument *iter* is used in a somewhat different manner.

```
SUBROUTINE amebsa(p,y,np,ndim,pb,yb,ftol,funk,iter,temptr)
INTEGER iter,mp,ndim,np,NMAX
REAL ftol,temptr,yb,p(mp,np),pb(np),y(mp),funk
PARAMETER (NMAX=200)
EXTERNAL funk
C USES amotsa,funk,rani
      Multidimensional minimization of the function funk(x) where x(1:ndim) is a vector in
      ndim dimensions, by simulated annealing combined with the downhill simplex method of
      Nelder and Mead. The input matrix p(1..ndim+1,1..ndim) has ndim+1 rows, each an
      ndim-dimensional vector which is a vertex of the starting simplex. Also input is the vector
      y(1:ndim+1), whose components must be pre-initialized to the values of funk evaluated at
      the ndim+1 vertices (rows) of p; ftol, the fractional convergence tolerance to be achieved
      in the function value for an early return; iter, and temptr. The routine makes iter
      function evaluations at an annealing temperature temptr, then returns. You should then
      decrease temptr according to your annealing schedule, reset iter, and call the routine
      again (leaving other arguments unaltered between calls). If iter is returned with a positive
      value, then early convergence and return occurred. If you initialize yb to a very large value
      on the first call, then yb and pb(1:ndim) will subsequently return the best function value
      and point ever encountered (even if it is no longer a point in the simplex).
      INTEGER i,idum,ihi,ilo,j,m,n
      REAL rtol,sum,swap,tt,yhi,ylo,ynhi,ysave,yt,ytry,psum(NMAX),
*           amotsa,rani
      COMMON /ambsa/ tt,idum
      tt=temptr
      1 do 12 n=1,ndim          Enter here when starting or after overall contraction.
           sum=0.                  Recompute psum.
           do 11 m=1,ndim+1
               sum=sum+p(m,n)
           enddo 11
           psum(n)=sum
      enddo 12
      2 ilo=1                   Enter here after changing a single point. Find which point
      ihi=2                     is the highest (worst), next-highest, and lowest (best).
      ylo=y(1)+tt*log(ran1(idum))  Whenever we "look at" a vertex, it gets a random thermal
      ynhi=ylo                  fluctuation.
      yhi=y(2)+tt*log(ran1(idum))
      if (ylo.gt.yhi) then
          ihi=1

```

There is not yet enough practical experience with the method of simulated annealing to say definitively what its future place among optimization methods will be. The method has several extremely attractive features, rather unique when compared with other optimization techniques.

First, it is not “greedy,” in the sense that it is not easily fooled by the quick payoff achieved by falling into unfavorable local minima. Provided that sufficiently general reconfigurations are given, it wanders freely among local minima of depth less than about T . As T is lowered, the number of such minima qualifying for frequent visits is gradually reduced.

Second, configuration decisions tend to proceed in a logical order. Changes that cause the greatest energy differences are sifted over when the control parameter T is large. These decisions become more permanent as T is lowered, and attention then shifts more to smaller refinements in the solution. For example, in the traveling salesman problem with the Mississippi River twist, if λ is large, a decision to cross the Mississippi only twice is made at high T , while the specific routes on each side of the river are determined only at later stages.

The analogies to thermodynamics may be pursued to a greater extent than we have done here. Quantities analogous to specific heat and entropy may be defined, and these can be useful in monitoring the progress of the algorithm towards an acceptable solution. Information on this subject is found in [1].

Chapter 11. Eigensystems

11.0 Introduction

An $N \times N$ matrix \mathbf{A} is said to have an *eigenvector* \mathbf{x} and corresponding *eigenvalue* λ if

$$\mathbf{A} \cdot \mathbf{x} = \lambda \mathbf{x} \quad (11.0.1)$$

Obviously any multiple of an eigenvector \mathbf{x} will also be an eigenvector, but we won't consider such multiples as being distinct eigenvectors. (The zero vector is not considered to be an eigenvector at all.) Evidently (11.0.1) can hold only if

$$\det |\mathbf{A} - \lambda \mathbf{1}| = 0 \quad (11.0.2)$$

which, if expanded out, is an N th degree polynomial in λ whose roots are the eigenvalues. This proves that there are always N (not necessarily distinct) eigenvalues. Equal eigenvalues coming from multiple roots are called *degenerate*. Root-searching in the characteristic equation (11.0.2) is usually a very poor computational method for finding eigenvalues. We will learn much better ways in this chapter, as well as efficient ways for finding corresponding eigenvectors.

The above two equations also prove that every one of the N eigenvalues has a (not necessarily distinct) corresponding eigenvector: If λ is set to an eigenvalue, then the matrix $\mathbf{A} - \lambda \mathbf{1}$ is singular, and we know that every singular matrix has at least one nonzero vector in its nullspace (see §2.6 on singular value decomposition).

If you add $\tau \mathbf{x}$ to both sides of (11.0.1), you will easily see that the eigenvalues of any matrix can be changed or *shifted* by an additive constant τ by adding to the matrix that constant times the identity matrix. The eigenvectors are unchanged by this shift. Shifting, as we will see, is an important part of many algorithms for computing eigenvalues. We see also that there is no special significance to a zero eigenvalue. Any eigenvalue can be shifted to zero, or any zero eigenvalue can be shifted away from zero.

Definitions and Basic Facts

A matrix is called *symmetric* if it is equal to its transpose,

$$\mathbf{A} = \mathbf{A}^T \quad \text{or} \quad a_{ij} = a_{ji} \quad (11.0.3)$$

It is called *Hermitian* or *self-adjoint* if it equals the complex-conjugate of its transpose (its *Hermitian conjugate*, denoted by “ \dagger ”)

$$\mathbf{A} = \mathbf{A}^\dagger \quad \text{or} \quad a_{ij} = a_{ji}^* \quad (11.0.4)$$

It is termed *orthogonal* if its transpose equals its inverse,

$$\mathbf{A}^T \cdot \mathbf{A} = \mathbf{A} \cdot \mathbf{A}^T = \mathbf{1} \quad (11.0.5)$$

and *unitary* if its Hermitian conjugate equals its inverse. Finally, a matrix is called *normal* if it *commutes* with its Hermitian conjugate,

$$\mathbf{A} \cdot \mathbf{A}^\dagger = \mathbf{A}^\dagger \cdot \mathbf{A} \quad (11.0.6)$$

For real matrices, Hermitian means the same as symmetric, unitary means the same as orthogonal, and *both* of these distinct classes are normal.

The reason that “Hermitian” is an important concept has to do with eigenvalues. The eigenvalues of a Hermitian matrix are all real. In particular, the eigenvalues of a real symmetric matrix are all real. Contrariwise, the eigenvalues of a real nonsymmetric matrix may include real values, but may also include pairs of complex conjugate values; and the eigenvalues of a complex matrix that is not Hermitian will in general be complex.

The reason that “normal” is an important concept has to do with the eigenvectors. The eigenvectors of a normal matrix with nondegenerate (i.e., distinct) eigenvalues are complete and orthogonal, spanning the N -dimensional vector space. For a normal matrix with degenerate eigenvalues, we have the additional freedom of replacing the eigenvectors corresponding to a degenerate eigenvalue by linear combinations of themselves. Using this freedom, we can always perform Gram-Schmidt orthogonalization (consult any linear algebra text) and *find* a set of eigenvectors that are complete and orthogonal, just as in the nondegenerate case. The matrix whose columns are an orthonormal set of eigenvectors is evidently unitary. A special case is that the matrix of eigenvectors of a real, symmetric matrix is orthogonal, since the eigenvectors of that matrix are all real.

When a matrix is not normal, as typified by any random, nonsymmetric, real matrix, then in general we cannot find *any* orthonormal set of eigenvectors, nor even any pairs of eigenvectors that are orthogonal (except perhaps by rare chance). While the N non-orthonormal eigenvectors will “usually” span the N -dimensional vector space, they do not always do so; that is, the eigenvectors are not always complete. Such a matrix is said to be *defective*.

Left and Right Eigenvectors

While the eigenvectors of a non-normal matrix are not particularly orthogonal among themselves, they *do* have an orthogonality relation with a different set of vectors, which we must now define. Up to now our eigenvectors have been column vectors that are multiplied to the right of a matrix \mathbf{A} , as in (11.0.1). These, more explicitly, are termed *right eigenvectors*. We could also, however, try to find row vectors, which multiply \mathbf{A} to the left and satisfy

$$\mathbf{x} \cdot \mathbf{A} = \lambda \mathbf{x} \quad (11.0.7)$$

These are called *left eigenvectors*. By taking the transpose of equation (11.0.7), we see that every left eigenvector is the transpose of a right eigenvector of *the transpose* of \mathbf{A} . Now by comparing to (11.0.2), and using the fact that the determinant of a matrix equals the determinant of its transpose, we also see that the left and right eigenvalues of \mathbf{A} are identical.

If the matrix \mathbf{A} is symmetric, then the left and right eigenvectors are just transposes of each other, that is, have the same numerical values as components. Likewise, if the matrix is self-adjoint, the left and right eigenvectors are Hermitian conjugates of each other. For the general nonnormal case, however, we have the following calculation: Let \mathbf{X}_R be the matrix formed by columns from the right eigenvectors, and \mathbf{X}_L be the matrix formed by rows from the left eigenvectors. Then (11.0.1) and (11.0.7) can be rewritten as

$$\mathbf{A} \cdot \mathbf{X}_R = \mathbf{X}_R \cdot \text{diag}(\lambda_1 \dots \lambda_N) \quad \mathbf{X}_L \cdot \mathbf{A} = \text{diag}(\lambda_1 \dots \lambda_N) \cdot \mathbf{X}_L \quad (11.0.8)$$

Multiplying the first of these equations on the left by \mathbf{X}_L , the second on the right by \mathbf{X}_R , and subtracting the two, gives

$$(\mathbf{X}_L \cdot \mathbf{X}_R) \cdot \text{diag}(\lambda_1 \dots \lambda_N) = \text{diag}(\lambda_1 \dots \lambda_N) \cdot (\mathbf{X}_L \cdot \mathbf{X}_R) \quad (11.0.9)$$

This says that the matrix of dot products of the left and right eigenvectors commutes with the diagonal matrix of eigenvalues. But the only matrices that commute with a diagonal matrix of *distinct elements* are themselves diagonal. Thus, if the eigenvalues are nondegenerate, each left eigenvector is orthogonal to all right eigenvectors except its corresponding one, and vice versa. By choice of normalization, the dot products of corresponding left and right eigenvectors can always be made unity for any matrix with nondegenerate eigenvalues.

If some eigenvalues are degenerate, then either the left or the right eigenvectors corresponding to a degenerate eigenvalue must be linearly combined among themselves to achieve orthogonality with the right or left ones, respectively. This can always be done by a procedure akin to Gram-Schmidt orthogonalization. The normalization can then be adjusted to give unity for the nonzero dot products between corresponding left and right eigenvectors. If the dot product of corresponding left and right eigenvectors is zero at this stage, then you have a case where the eigenvectors are incomplete! Note that incomplete eigenvectors can occur only where there are degenerate eigenvalues, but do not always occur in such cases (in fact, never occur for the class of “normal” matrices). See [1] for a clear discussion.

In both the degenerate and nondegenerate cases, the final normalization to unity of all nonzero dot products produces the result: The matrix whose rows are left eigenvectors is the inverse matrix of the matrix whose columns are right eigenvectors, *if the inverse exists*.

Diagonalization of a Matrix

Multiplying the first equation in (11.0.8) by \mathbf{X}_L , and using the fact that \mathbf{X}_L and \mathbf{X}_R are matrix inverses, we get

$$\mathbf{X}_R^{-1} \cdot \mathbf{A} \cdot \mathbf{X}_R = \text{diag}(\lambda_1 \dots \lambda_N) \quad (11.0.10)$$

This is a particular case of a *similarity transform* of the matrix \mathbf{A} ,

$$\mathbf{A} \rightarrow \mathbf{Z}^{-1} \cdot \mathbf{A} \cdot \mathbf{Z} \quad (11.0.11)$$

for some transformation matrix \mathbf{Z} . Similarity transformations play a crucial role in the computation of eigenvalues, because they leave the eigenvalues of a matrix unchanged. This is easily seen from

$$\begin{aligned} \det |\mathbf{Z}^{-1} \cdot \mathbf{A} \cdot \mathbf{Z} - \lambda \mathbf{1}| &= \det |\mathbf{Z}^{-1} \cdot (\mathbf{A} - \lambda \mathbf{1}) \cdot \mathbf{Z}| \\ &= \det |\mathbf{Z}| \det |\mathbf{A} - \lambda \mathbf{1}| \det |\mathbf{Z}^{-1}| \\ &= \det |\mathbf{A} - \lambda \mathbf{1}| \end{aligned} \quad (11.0.12)$$

Equation (11.0.10) shows that any matrix with complete eigenvectors (which includes all normal matrices and “most” random nonnormal ones) can be diagonalized by a similarity transformation, that the columns of the transformation matrix that effects the diagonalization are the right eigenvectors, and that the rows of its inverse are the left eigenvectors.

For real, symmetric matrices, the eigenvectors are real and orthonormal, so the transformation matrix is orthogonal. The similarity transformation is then also an *orthogonal transformation* of the form

$$\mathbf{A} \rightarrow \mathbf{Z}^T \cdot \mathbf{A} \cdot \mathbf{Z} \quad (11.0.13)$$

While real nonsymmetric matrices can be diagonalized in their usual case of complete eigenvectors, the transformation matrix is not necessarily real. It turns out, however, that a real similarity transformation can “almost” do the job. It can reduce the matrix down to a form with little two-by-two blocks along the diagonal, all other elements zero. Each two-by-two block corresponds to a complex-conjugate pair of complex eigenvalues. We will see this idea exploited in some routines given later in the chapter.

The “grand strategy” of virtually all modern eigensystem routines is to nudge the matrix \mathbf{A} towards diagonal form by a sequence of similarity transformations,

$$\begin{aligned} \mathbf{A} \rightarrow \mathbf{P}_1^{-1} \cdot \mathbf{A} \cdot \mathbf{P}_1 &\rightarrow \mathbf{P}_2^{-1} \cdot \mathbf{P}_1^{-1} \cdot \mathbf{A} \cdot \mathbf{P}_1 \cdot \mathbf{P}_2 \\ \rightarrow \mathbf{P}_3^{-1} \cdot \mathbf{P}_2^{-1} \cdot \mathbf{P}_1^{-1} \cdot \mathbf{A} \cdot \mathbf{P}_1 \cdot \mathbf{P}_2 \cdot \mathbf{P}_3 &\rightarrow \text{etc.} \end{aligned} \quad (11.0.14)$$

If we get all the way to diagonal form, then the eigenvectors are the columns of the accumulated transformation

$$\mathbf{X}_R = \mathbf{P}_1 \cdot \mathbf{P}_2 \cdot \mathbf{P}_3 \cdot \dots \quad (11.0.15)$$

Sometimes we do not want to go all the way to diagonal form. For example, if we are interested only in eigenvalues, not eigenvectors, it is enough to transform the matrix \mathbf{A} to be triangular, with all elements below (or above) the diagonal zero. In this case the diagonal elements are already the eigenvalues, as you can see by mentally evaluating (11.0.2) using expansion by minors.

There are two rather different sets of techniques for implementing the grand strategy (11.0.14). It turns out that they work rather well in combination, so most modern eigensystem routines use both. The first set of techniques constructs individual \mathbf{P}_i 's as explicit “atomic” transformations designed to perform specific tasks, for example zeroing a particular off-diagonal element (Jacobi transformation, §11.1), or a whole particular row or column (Householder transformation, §11.2; elimination method, §11.5). In general, a finite sequence of these simple transformations cannot completely diagonalize a matrix. There are then two choices: either use the finite sequence of transformations to go most of the way (e.g., to some special form like *tridiagonal* or *Hessenberg*, see §11.2 and §11.5 below) and follow up with the second set of techniques about to be mentioned; or else iterate the finite sequence of simple transformations over and over until the deviation of the matrix from diagonal is negligibly small. This latter approach is conceptually simplest, so we will discuss it in the next section; however, for N greater than ~ 10 , it is computationally inefficient by a roughly constant factor ~ 5 .

The second set of techniques, called *factorization methods*, is more subtle. Suppose that the matrix \mathbf{A} can be factored into a left factor \mathbf{F}_L and a right factor \mathbf{F}_R . Then

$$\mathbf{A} = \mathbf{F}_L \cdot \mathbf{F}_R \quad \text{or equivalently} \quad \mathbf{F}_L^{-1} \cdot \mathbf{A} = \mathbf{F}_R \quad (11.0.16)$$

If we now multiply back together the factors in the reverse order, and use the second equation in (11.0.16) we get

$$\mathbf{F}_R \cdot \mathbf{F}_L = \mathbf{F}_L^{-1} \cdot \mathbf{A} \cdot \mathbf{F}_L \quad (11.0.17)$$

which we recognize as having effected a similarity transformation on \mathbf{A} with the transformation matrix being \mathbf{F}_L ! In §11.3 and §11.6 we will discuss the *QR method* which exploits this idea.

Factorization methods also do not converge exactly in a finite number of transformations. But the better ones do converge rapidly and reliably, and, when following an appropriate initial reduction by simple similarity transformations, they are the methods of choice.

“Eigenpackages of Canned Eigenroutines”

You have probably gathered by now that the solution of eigensystems is a fairly complicated business. It is. It is one of the few subjects covered in this book for which we do *not* recommend that you avoid canned routines. On the contrary, the purpose of this chapter is precisely to give you some appreciation of what is going on inside such canned routines, so that you can make intelligent choices about using them, and intelligent diagnoses when something goes wrong.

You will find that almost all canned routines in use nowadays trace their ancestry back to routines published in Wilkinson and Reinsch's *Handbook for Automatic Computation, Vol. II, Linear Algebra* [2]. This excellent reference, containing papers by a number of authors, is the Bible of the field. A public-domain implementation of the *Handbook* routines in FORTRAN is the EISPACK set of programs [3]. The routines in this chapter are translations of either the *Handbook* or EISPACK routines, so understanding these will take you a lot of the way towards understanding those canonical packages.

IMSL [4] and NAG [5] each provide proprietary implementations, in FORTRAN, of what are essentially the *Handbook* routines.

A good “eigenpackage” will provide separate routines, or separate paths through sequences of routines, for the following desired calculations:

- all eigenvalues and no eigenvectors
- all eigenvalues and some corresponding eigenvectors
- all eigenvalues and all corresponding eigenvectors

The purpose of these distinctions is to save compute time and storage; it is wasteful to calculate eigenvectors that you don't need. Often one is interested only in the eigenvectors corresponding to the largest few eigenvalues, or largest few in magnitude, or few that are negative. The method usually used to calculate “some” eigenvectors is typically more efficient than calculating all eigenvectors if you desire fewer than about a quarter of the eigenvectors.

A good eigenpackage also provides separate paths for each of the above calculations for each of the following special forms of the matrix:

- real, symmetric, tridiagonal
- real, symmetric, banded (only a small number of sub- and superdiagonals are nonzero)
- real, symmetric
- real, nonsymmetric
- complex, Hermitian
- complex, non-Hermitian

Again, the purpose of these distinctions is to save time and storage by using the *least* general routine that will serve in any particular application.

In this chapter, as a bare introduction, we give good routines for the following paths:

- all eigenvalues and eigenvectors of a real, symmetric, tridiagonal matrix (§11.3)
- all eigenvalues and eigenvectors of a real, symmetric, matrix (§11.1–§11.3)
- all eigenvalues and eigenvectors of a complex, Hermitian matrix (§11.4)
- all eigenvalues and no eigenvectors of a real, nonsymmetric matrix (§11.5–

§11.6)

We also discuss, in §11.7, how to obtain some eigenvectors of nonsymmetric matrices by the method of inverse iteration.

Generalized and Nonlinear Eigenvalue Problems

Many eigenpackages also deal with the so-called *generalized eigenproblem*, [6]

$$\mathbf{A} \cdot \mathbf{x} = \lambda \mathbf{B} \cdot \mathbf{x} \quad (11.0.18)$$

where \mathbf{A} and \mathbf{B} are both matrices. Most such problems, where \mathbf{B} is nonsingular, can be handled by the equivalent

$$(\mathbf{B}^{-1} \cdot \mathbf{A}) \cdot \mathbf{x} = \lambda \mathbf{x} \quad (11.0.19)$$

Often \mathbf{A} and \mathbf{B} are symmetric and \mathbf{B} is positive definite. The matrix $\mathbf{B}^{-1} \cdot \mathbf{A}$ in (11.0.19) is not symmetric, but we can recover a symmetric eigenvalue problem by using the Cholesky decomposition $\mathbf{B} = \mathbf{L} \cdot \mathbf{L}^T$ of §2.9. Multiplying equation (11.0.18) by \mathbf{L}^{-1} , we get

$$\mathbf{C} \cdot (\mathbf{L}^T \cdot \mathbf{x}) = \lambda (\mathbf{L}^T \cdot \mathbf{x}) \quad (11.0.20)$$

where

$$\mathbf{C} = \mathbf{L}^{-1} \cdot \mathbf{A} \cdot (\mathbf{L}^{-1})^T \quad (11.0.21)$$

The matrix \mathbf{C} is symmetric and its eigenvalues are the same as those of the original problem (11.0.18); its eigenfunctions are $\mathbf{L}^T \cdot \mathbf{x}$. The efficient way to form \mathbf{C} is first to solve the equation

$$\mathbf{Y} \cdot \mathbf{L}^T = \mathbf{A} \quad (11.0.22)$$

for the lower triangle of the matrix \mathbf{Y} . Then solve

$$\mathbf{L} \cdot \mathbf{C} = \mathbf{Y} \quad (11.0.23)$$

for the lower triangle of the symmetric matrix \mathbf{C} .

Another generalization of the standard eigenvalue problem is to problems nonlinear in the eigenvalue λ , for example,

$$(\mathbf{A}\lambda^2 + \mathbf{B}\lambda + \mathbf{C}) \cdot \mathbf{x} = 0 \quad (11.0.24)$$

This can be turned into a linear problem by introducing an additional unknown eigenvector \mathbf{y} and solving the $2N \times 2N$ eigensystem,

$$\begin{pmatrix} 0 & \mathbf{1} \\ -\mathbf{A}^{-1} \cdot \mathbf{C} & -\mathbf{A}^{-1} \cdot \mathbf{B} \end{pmatrix} \cdot \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} = \lambda \begin{pmatrix} \mathbf{x} \\ \mathbf{y} \end{pmatrix} \quad (11.0.25)$$

This technique generalizes to higher-order polynomials in λ . A polynomial of degree M produces a linear $MN \times MN$ eigensystem (see [7]).

11.1 Jacobi Transformations of a Symmetric Matrix

The Jacobi method consists of a sequence of orthogonal similarity transformations of the form of equation (11.0.14). Each transformation (a *Jacobi rotation*) is just a plane rotation designed to annihilate one of the off-diagonal matrix elements. Successive transformations undo previously set zeros, but the off-diagonal elements nevertheless get smaller and smaller, until the matrix is diagonal to machine precision. Accumulating the product of the transformations as you go gives the matrix of eigenvectors, equation (11.0.15), while the elements of the final diagonal matrix are the eigenvalues.

The Jacobi method is absolutely foolproof for all real symmetric matrices. For matrices of order greater than about 10, say, the algorithm is slower, by a significant constant factor, than the *QR* method we shall give in §11.3. However, the Jacobi algorithm is much simpler than the more efficient methods. We thus recommend it for matrices of moderate order, where expense is not a major consideration.

The basic Jacobi rotation \mathbf{P}_{pq} is a matrix of the form

$$\mathbf{P}_{pq} = \begin{bmatrix} 1 & & & & \\ & \ddots & & & \\ & & c & \cdots & s \\ & & \vdots & 1 & \vdots \\ & & -s & \cdots & c \\ & & & & \ddots \\ & & & & 1 \end{bmatrix} \quad (11.1.1)$$

Here all the diagonal elements are unity except for the two elements c in rows (and columns) p and q . All off-diagonal elements are zero except the two elements s and $-s$. The numbers c and s are the cosine and sine of a rotation angle ϕ , so $c^2 + s^2 = 1$.

11.1 Jacobi Transformations of a Symmetric Matrix

The Jacobi method consists of a sequence of orthogonal similarity transformations of the form of equation (11.0.14). Each transformation (a *Jacobi rotation*) is just a plane rotation designed to annihilate one of the off-diagonal matrix elements. Successive transformations undo previously set zeros, but the off-diagonal elements nevertheless get smaller and smaller, until the matrix is diagonal to machine precision. Accumulating the product of the transformations as you go gives the matrix of eigenvectors, equation (11.0.15), while the elements of the final diagonal matrix are the eigenvalues.

The Jacobi method is absolutely foolproof for all real symmetric matrices. For matrices of order greater than about 10, say, the algorithm is slower, by a significant constant factor, than the *QR* method we shall give in §11.3. However, the Jacobi algorithm is much simpler than the more efficient methods. We thus recommend it for matrices of moderate order, where expense is not a major consideration.

The basic Jacobi rotation \mathbf{P}_{pq} is a matrix of the form

$$\mathbf{P}_{pq} = \begin{bmatrix} 1 & & & & \\ & \ddots & & & \\ & & c & \cdots & s \\ & & \vdots & 1 & \vdots \\ & & -s & \cdots & c \\ & & & & \ddots \\ & & & & & 1 \end{bmatrix} \quad (11.1.1)$$

Here all the diagonal elements are unity except for the two elements c in rows (and columns) p and q . All off-diagonal elements are zero except the two elements s and $-s$. The numbers c and s are the cosine and sine of a rotation angle ϕ , so $c^2 + s^2 = 1$.

A plane rotation such as (11.1.1) is used to transform the matrix \mathbf{A} according to

$$\mathbf{A}' = \mathbf{P}_{pq}^T \cdot \mathbf{A} \cdot \mathbf{P}_{pq} \quad (11.1.2)$$

Now, $\mathbf{P}_{pq}^T \cdot \mathbf{A}$ changes only rows p and q of \mathbf{A} , while $\mathbf{A} \cdot \mathbf{P}_{pq}$ changes only columns p and q . Notice that the subscripts p and q do not denote components of \mathbf{P}_{pq} , but rather label which kind of rotation the matrix is, i.e., which rows and columns it affects. Thus the changed elements of \mathbf{A} in (11.1.2) are only in the p and q rows and columns indicated below:

$$\mathbf{A}' = \begin{bmatrix} & \cdots & a'_{1p} & \cdots & a'_{1q} & \cdots & \\ \vdots & & \vdots & & \vdots & & \vdots \\ a'_{p1} & \cdots & a'_{pp} & \cdots & a'_{pq} & \cdots & a'_{pn} \\ \vdots & & \vdots & & \vdots & & \vdots \\ a'_{q1} & \cdots & a'_{qp} & \cdots & a'_{qq} & \cdots & a'_{qn} \\ \vdots & & \vdots & & \vdots & & \vdots \\ & \cdots & a'_{np} & \cdots & a'_{nq} & \cdots & \end{bmatrix} \quad (11.1.3)$$

Multiplying out equation (11.1.2) and using the symmetry of \mathbf{A} , we get the explicit formulas

$$\begin{aligned} a'_{rp} &= ca_{rp} - sa_{rq} & r \neq p, r \neq q \\ a'_{rq} &= ca_{rq} + sa_{rp} \end{aligned} \quad (11.1.4)$$

$$a'_{pp} = c^2 a_{pp} + s^2 a_{qq} - 2sc a_{pq} \quad (11.1.5)$$

$$a'_{qq} = s^2 a_{pp} + c^2 a_{qq} + 2sc a_{pq} \quad (11.1.6)$$

$$a'_{pq} = (c^2 - s^2)a_{pq} + sc(a_{pp} - a_{qq}) \quad (11.1.7)$$

The idea of the Jacobi method is to try to zero the off-diagonal elements by a series of plane rotations. Accordingly, to set $a'_{pq} = 0$, equation (11.1.7) gives the following expression for the rotation angle ϕ

$$\theta \equiv \cot 2\phi \equiv \frac{c^2 - s^2}{2sc} = \frac{a_{qq} - a_{pp}}{2a_{pq}} \quad (11.1.8)$$

If we let $t \equiv s/c$, the definition of θ can be rewritten

$$t^2 + 2t\theta - 1 = 0 \quad (11.1.9)$$

The smaller root of this equation corresponds to a rotation angle less than $\pi/4$ in magnitude; this choice at each stage gives the most stable reduction. Using the form of the quadratic formula with the discriminant in the denominator, we can write this smaller root as

$$t = \frac{\operatorname{sgn}(\theta)}{|\theta| + \sqrt{\theta^2 + 1}} \quad (11.1.10)$$

If θ is so large that θ^2 would overflow on the computer, we set $t = 1/(2\theta)$. It now follows that

$$c = \frac{1}{\sqrt{t^2 + 1}} \quad (11.1.11)$$

$$s = tc \quad (11.1.12)$$

When we actually use equations (11.1.4)–(11.1.7) numerically, we rewrite them to minimize roundoff error. Equation (11.1.7) is replaced by

$$a'_{pq} = 0 \quad (11.1.13)$$

The idea in the remaining equations is to set the new quantity equal to the old quantity plus a small correction. Thus we can use (11.1.7) and (11.1.13) to eliminate a_{qq} from (11.1.5), giving

$$a'_{pp} = a_{pp} - ta_{pq} \quad (11.1.14)$$

Similarly,

$$a'_{qq} = a_{qq} + ta_{pq} \quad (11.1.15)$$

$$a'_{rp} = a_{rp} - s(a_{rq} + \tau a_{rp}) \quad (11.1.16)$$

$$a'_{rq} = a_{rq} + s(a_{rp} - \tau a_{rq}) \quad (11.1.17)$$

where τ ($= \tan \phi/2$) is defined by

$$\tau \equiv \frac{s}{1 + c} \quad (11.1.18)$$

One can see the convergence of the Jacobi method by considering the sum of the squares of the off-diagonal elements

$$S = \sum_{r \neq s} |a_{rs}|^2 \quad (11.1.19)$$

Equations (11.1.4)–(11.1.7) imply that

$$S' = S - 2|a_{pq}|^2 \quad (11.1.20)$$

(Since the transformation is orthogonal, the sum of the squares of the diagonal elements increases correspondingly by $2|a_{pq}|^2$.) The sequence of S 's thus decreases monotonically. Since the sequence is bounded below by zero, and since we can choose a_{pq} to be whatever element we want, the sequence can be made to converge to zero.

Eventually one obtains a matrix \mathbf{D} that is diagonal to machine precision. The diagonal elements give the eigenvalues of the original matrix \mathbf{A} , since

$$\mathbf{D} = \mathbf{V}^T \cdot \mathbf{A} \cdot \mathbf{V} \quad (11.1.21)$$

where

$$\mathbf{V} = \mathbf{P}_1 \cdot \mathbf{P}_2 \cdot \mathbf{P}_3 \cdots \quad (11.1.22)$$

the \mathbf{P}_i 's being the successive Jacobi rotation matrices. The columns of \mathbf{V} are the eigenvectors (since $\mathbf{A} \cdot \mathbf{V} = \mathbf{V} \cdot \mathbf{D}$). They can be computed by applying

$$\mathbf{V}' = \mathbf{V} \cdot \mathbf{P}_i \quad (11.1.23)$$

at each stage of calculation, where initially \mathbf{V} is the identity matrix. In detail, equation (11.1.23) is

$$\begin{aligned} v'_{rs} &= v_{rs} \quad (s \neq p, s \neq q) \\ v'_{rp} &= cv_{rp} - sv_{rq} \\ v'_{rq} &= sv_{rp} + cv_{rq} \end{aligned} \quad (11.1.24)$$

We rewrite these equations in terms of τ as in equations (11.1.16) and (11.1.17) to minimize roundoff.

The only remaining question is the strategy one should adopt for the order in which the elements are to be annihilated. Jacobi's original algorithm of 1846 searched the whole upper triangle at each stage and set the largest off-diagonal element to zero. This is a reasonable strategy for hand calculation, but it is prohibitive on a computer since the search alone makes each Jacobi rotation a process of order N^2 instead of N .

A better strategy for our purposes is the *cyclic Jacobi method*, where one annihilates elements in strict order. For example, one can simply proceed down the rows: $\mathbf{P}_{12}, \mathbf{P}_{13}, \dots, \mathbf{P}_{1n}$; then $\mathbf{P}_{23}, \mathbf{P}_{24}, \dots$, etc. One can show that convergence is generally quadratic for both the original or the cyclic Jacobi methods, for nondegenerate eigenvalues. One such set of $n(n - 1)/2$ Jacobi rotations is called a *sweep*.

The program below, based on the implementations in [1,2], uses two further refinements:

- In the first three sweeps, we carry out the pq rotation only if $|a_{pq}| > \epsilon$ for some threshold value

$$\epsilon = \frac{1}{5} \frac{S_0}{n^2} \quad (11.1.25)$$

where S_0 is the sum of the off-diagonal moduli,

$$S_0 = \sum_{r < s} |a_{rs}| \quad (11.1.26)$$

- After four sweeps, if $|a_{pq}| \ll |a_{pp}|$ and $|a_{pq}| \ll |a_{qq}|$, we set $|a_{pq}| = 0$ and skip the rotation. The criterion used in the comparison is $|a_{pq}| < 10^{-(D+2)}|a_{pp}|$, where D is the number of significant decimal digits on the machine, and similarly for $|a_{qq}|$.

In the following routine the $n \times n$ symmetric matrix $a(1:n, 1:n)$ is stored in an $np \times np$ array. On output, the superdiagonal elements of a are destroyed, but the diagonal and subdiagonal are unchanged and give full information on the original symmetric matrix a . The parameter d is a vector of length np . On output, it returns the eigenvalues of a in its first n elements. During the computation, it contains the current diagonal of a . The matrix v outputs the normalized eigenvector belonging to $d(k)$ in its k th column. The parameter $nrot$ is the number of Jacobi rotations that were needed to achieve convergence.

Typical matrices require 6 to 10 sweeps to achieve convergence, or $3n^2$ to $5n^2$ Jacobi rotations. Each rotation requires of order $4n$ operations, each consisting of a multiply and an add, so the total labor is of order $12n^3$ to $20n^3$ operations. Calculation of the eigenvectors as well as the eigenvalues changes the operation count from $4n$ to $6n$ per rotation, which is only a 50 percent overhead.

```
SUBROUTINE jacobi(a,n,np,d,v,nrot)
INTEGER n,np,nrot,NMAX
REAL a(np,np),d(np),v(np,np)
PARAMETER (NMAX=500)

Computes all eigenvalues and eigenvectors of a real symmetric matrix a, which is of size n by n, stored in a physical np by np array. On output, elements of a above the diagonal are destroyed. d returns the eigenvalues of a in its first n elements. v is a matrix with the same logical and physical dimensions as a, whose columns contain, on output, the normalized eigenvectors of a. nrot returns the number of Jacobi rotations that were required.

```

Note that the above routine assumes that underflows are set to zero. On machines where this is not true, the program must be modified.

The eigenvalues are not ordered on output. If sorting is desired, the following routine can be invoked to reorder the output of `jacobi` or of later routines in this chapter. (The method, straight insertion, is N^2 rather than $N \log N$; but since you have just done an N^3 procedure to get the eigenvalues, you can afford yourself this little indulgence.)

```

SUBROUTINE eigsrt(d,v,n,np)
INTEGER n,np

11.2 Reduction of a Symmetric Matrix to Tridiagonal Form: Givens and Householder Reductions

As already mentioned, the optimum strategy for finding eigenvalues and eigenvectors is, first, to reduce the matrix to a simple form, only then beginning an iterative procedure. For symmetric matrices, the preferred simple form is tridiagonal. The *Givens reduction* is a modification of the Jacobi method. Instead of trying to reduce the matrix all the way to diagonal form, we are content to stop when the matrix is tridiagonal. This allows the procedure to be carried out *in a finite number of steps*, unlike the Jacobi method, which requires iteration to convergence.

11.2 Reduction of a Symmetric Matrix to Tridiagonal Form: Givens and Householder Reductions

As already mentioned, the optimum strategy for finding eigenvalues and eigenvectors is, first, to reduce the matrix to a simple form, only then beginning an iterative procedure. For symmetric matrices, the preferred simple form is tridiagonal. The *Givens reduction* is a modification of the Jacobi method. Instead of trying to reduce the matrix all the way to diagonal form, we are content to stop when the matrix is tridiagonal. This allows the procedure to be carried out *in a finite number of steps*, unlike the Jacobi method, which requires iteration to convergence.

Givens Method

For the Givens method, we choose the rotation angle in equation (11.1.1) so as to zero an element that is *not* at one of the four “corners,” i.e., not a_{pp} , a_{pq} , or a_{qq} in equation (11.1.3). Specifically, we first choose \mathbf{P}_{23} to annihilate a_{31} (and, by symmetry, a_{13}). Then we choose \mathbf{P}_{24} to annihilate a_{41} . In general, we choose the sequence

$$\mathbf{P}_{23}, \mathbf{P}_{24}, \dots, \mathbf{P}_{2n}, \mathbf{P}_{34}, \dots, \mathbf{P}_{3n}; \dots; \mathbf{P}_{n-1,n}$$

where \mathbf{P}_{jk} annihilates $a_{k,j-1}$. The method works because elements such as a'_{rp} and a'_{rq} , with $r \neq p$ $r \neq q$, are linear combinations of the old quantities a_{rp} and a_{rq} , by equation (11.1.4). Thus, if a_{rp} and a_{rq} have already been set to zero, they remain zero as the reduction proceeds. Evidently, of order $n^2/2$ rotations are required, and the number of multiplications in a straightforward implementation is of order $4n^3/3$, not counting those for keeping track of the product of the transformation matrices, required for the eigenvectors.

The Householder method, to be discussed next, is just as stable as the Givens reduction and it is a factor of 2 more efficient, so the Givens method is not generally used. Recent work (see [1]) has shown that the Givens reduction can be reformulated to reduce the number of operations by a factor of 2, and also avoid the necessity of taking square roots. This appears to make the algorithm competitive with the Householder reduction. However, this “fast Givens” reduction has to be monitored to avoid overflows, and the variables have to be periodically rescaled. There does not seem to be any compelling reason to prefer the Givens reduction over the Householder method.

Householder Method

The Householder algorithm reduces an $n \times n$ symmetric matrix \mathbf{A} to tridiagonal form by $n - 2$ orthogonal transformations. Each transformation annihilates the required part of a whole column and whole corresponding row. The basic ingredient is a Householder matrix \mathbf{P} , which has the form

$$\mathbf{P} = \mathbf{1} - 2\mathbf{w} \cdot \mathbf{w}^T \tag{11.2.1}$$

where \mathbf{w} is a real vector with $|\mathbf{w}|^2 = 1$. (In the present notation, the *outer* or matrix product of two vectors, \mathbf{a} and \mathbf{b} is written $\mathbf{a} \cdot \mathbf{b}^T$, while the *inner* or scalar product of the vectors is written as $\mathbf{a}^T \cdot \mathbf{b}$.) The matrix \mathbf{P} is orthogonal, because

$$\begin{aligned} \mathbf{P}^2 &= (\mathbf{1} - 2\mathbf{w} \cdot \mathbf{w}^T) \cdot (\mathbf{1} - 2\mathbf{w} \cdot \mathbf{w}^T) \\ &= \mathbf{1} - 4\mathbf{w} \cdot \mathbf{w}^T + 4\mathbf{w} \cdot (\mathbf{w}^T \cdot \mathbf{w}) \cdot \mathbf{w}^T \\ &= \mathbf{1} \end{aligned} \tag{11.2.2}$$

Therefore $\mathbf{P} = \mathbf{P}^{-1}$. But $\mathbf{P}^T = \mathbf{P}$, and so $\mathbf{P}^T = \mathbf{P}^{-1}$, proving orthogonality.

Rewrite \mathbf{P} as

$$\mathbf{P} = \mathbf{1} - \frac{\mathbf{u} \cdot \mathbf{u}^T}{H} \quad (11.2.3)$$

where the scalar H is

$$H \equiv \frac{1}{2} |\mathbf{u}|^2 \quad (11.2.4)$$

and \mathbf{u} can now be any vector. Suppose \mathbf{x} is the vector composed of the first column of \mathbf{A} . Choose

$$\mathbf{u} = \mathbf{x} \mp |\mathbf{x}| \mathbf{e}_1 \quad (11.2.5)$$

where \mathbf{e}_1 is the unit vector $[1, 0, \dots, 0]^T$, and the choice of signs will be made later. Then

$$\begin{aligned} \mathbf{P} \cdot \mathbf{x} &= \mathbf{x} - \frac{\mathbf{u}}{H} \cdot (\mathbf{x} \mp |\mathbf{x}| \mathbf{e}_1)^T \cdot \mathbf{x} \\ &= \mathbf{x} - \frac{2\mathbf{u} \cdot (|\mathbf{x}|^2 \mp |\mathbf{x}|x_1)}{2|\mathbf{x}|^2 \mp 2|\mathbf{x}|x_1} \\ &= \mathbf{x} - \mathbf{u} \\ &= \pm |\mathbf{x}| \mathbf{e}_1 \end{aligned} \quad (11.2.6)$$

This shows that the Householder matrix \mathbf{P} acts on a given vector \mathbf{x} to zero all its elements except the first one.

To reduce a symmetric matrix \mathbf{A} to tridiagonal form, we choose the vector \mathbf{x} for the first Householder matrix to be the lower $n - 1$ elements of the first column. Then the lower $n - 2$ elements will be zeroed:

$$\begin{aligned} \mathbf{P}_1 \cdot \mathbf{A} &= \left[\begin{array}{c|cccc} 1 & 0 & 0 & \cdots & 0 \\ 0 & & & & \\ 0 & & & & \\ \vdots & & (n-1)\mathbf{P}_1 & & \\ 0 & & & & \end{array} \right] \cdot \left[\begin{array}{c|ccccc} a_{11} & a_{12} & a_{13} & \cdots & a_{1n} \\ a_{21} & & & & \\ a_{31} & & & & \\ \vdots & & & & \\ a_{n1} & & & & \text{irrelevant} \end{array} \right] \\ &= \left[\begin{array}{c|ccccc} a_{11} & a_{12} & a_{13} & \cdots & a_{1n} \\ k & & & & \\ 0 & & & & \\ \vdots & & & & \text{irrelevant} \\ 0 & & & & \end{array} \right] \end{aligned} \quad (11.2.7)$$

Here we have written the matrices in partitioned form, with $(n-1)\mathbf{P}$ denoting a Householder matrix with dimensions $(n - 1) \times (n - 1)$. The quantity k is simply plus or minus the magnitude of the vector $[a_{21}, \dots, a_{n1}]^T$.

The complete orthogonal transformation is now

$$\mathbf{A}' = \mathbf{P} \cdot \mathbf{A} \cdot \mathbf{P} = \left[\begin{array}{c|cccc} a_{11} & k & 0 & \cdots & 0 \\ \hline k & & & & \\ 0 & & & & \\ \vdots & & & & \text{irrelevant} \\ 0 & & & & \end{array} \right] \quad (11.2.8)$$

We have used the fact that $\mathbf{P}^T = \mathbf{P}$.

Now choose the vector \mathbf{x} for the second Householder matrix to be the bottom $n - 2$ elements of the second column, and from it construct

$$\mathbf{P}_2 \equiv \left[\begin{array}{cc|ccc} 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & 0 & \cdots & 0 \\ \hline 0 & 0 & & & \\ \vdots & \vdots & & (n-2)\mathbf{P}_2 & \\ 0 & 0 & & & \end{array} \right] \quad (11.2.9)$$

The identity block in the upper left corner insures that the tridiagonalization achieved in the first step will not be spoiled by this one, while the $(n - 2)$ -dimensional Householder matrix $(n-2)\mathbf{P}_2$ creates one additional row and column of the tridiagonal output. Clearly, a sequence of $n - 2$ such transformations will reduce the matrix \mathbf{A} to tridiagonal form.

Instead of actually carrying out the matrix multiplications in $\mathbf{P} \cdot \mathbf{A} \cdot \mathbf{P}$, we compute a vector

$$\mathbf{p} \equiv \frac{\mathbf{A} \cdot \mathbf{u}}{H} \quad (11.2.10)$$

Then

$$\begin{aligned} \mathbf{A} \cdot \mathbf{P} &= \mathbf{A} \cdot \left(1 - \frac{\mathbf{u} \cdot \mathbf{u}^T}{H}\right) = \mathbf{A} - \mathbf{p} \cdot \mathbf{u}^T \\ \mathbf{A}' &= \mathbf{P} \cdot \mathbf{A} \cdot \mathbf{P} = \mathbf{A} - \mathbf{p} \cdot \mathbf{u}^T - \mathbf{u} \cdot \mathbf{p}^T + 2K\mathbf{u} \cdot \mathbf{u}^T \end{aligned}$$

where the scalar K is defined by

$$K = \frac{\mathbf{u}^T \cdot \mathbf{p}}{2H} \quad (11.2.11)$$

If we write

$$\mathbf{q} \equiv \mathbf{p} - K\mathbf{u} \quad (11.2.12)$$

then we have

$$\mathbf{A}' = \mathbf{A} - \mathbf{q} \cdot \mathbf{u}^T - \mathbf{u} \cdot \mathbf{q}^T \quad (11.2.13)$$

This is the computationally useful formula.

Following [2], the routine for Householder reduction given below actually starts in the n th column of \mathbf{A} , not the first as in the explanation above. In detail, the equations are as follows: At stage m ($m = 1, 2, \dots, n - 2$) the vector \mathbf{u} has the form

$$\mathbf{u}^T = [a_{i1}, a_{i2}, \dots, a_{i,i-2}, a_{i,i-1} \pm \sqrt{\sigma}, 0, \dots, 0] \quad (11.2.14)$$

Here

$$i \equiv n - m + 1 = n, n - 1, \dots, 3 \quad (11.2.15)$$

and the quantity σ ($|x|^2$ in our earlier notation) is

$$\sigma = (a_{i1})^2 + \dots + (a_{i,i-1})^2 \quad (11.2.16)$$

We choose the sign of σ in (11.2.14) to be the same as the sign of $a_{i,i-1}$ to lessen roundoff error.

Variables are thus computed in the following order: $\sigma, \mathbf{u}, H, \mathbf{p}, K, \mathbf{q}, \mathbf{A}'$. At any stage m , \mathbf{A} is tridiagonal in its last $m - 1$ rows and columns.

If the eigenvectors of the final tridiagonal matrix are found (for example, by the routine in the next section), then the eigenvectors of \mathbf{A} can be obtained by applying the accumulated transformation

$$\mathbf{Q} = \mathbf{P}_1 \cdot \mathbf{P}_2 \cdots \mathbf{P}_{n-2} \quad (11.2.17)$$

to those eigenvectors. We therefore form \mathbf{Q} by recursion after all the \mathbf{P} 's have been determined:

$$\begin{aligned} \mathbf{Q}_{n-2} &= \mathbf{P}_{n-2} \\ \mathbf{Q}_j &= \mathbf{P}_j \cdot \mathbf{Q}_{j+1}, \quad j = n - 3, \dots, 1 \\ \mathbf{Q} &= \mathbf{Q}_1 \end{aligned} \quad (11.2.18)$$

The input parameters for the routine below are the $n \times n$ real, symmetric matrix \mathbf{a} , stored in an $np \times np$ array. On output, \mathbf{a} contains the elements of the orthogonal matrix \mathbf{q} . The vector \mathbf{d} returns the diagonal elements of the tridiagonal matrix \mathbf{A}' , while the vector \mathbf{e} returns the off-diagonal elements in its components 2 through n , with $\mathbf{e}(1)=0$. Note that since \mathbf{a} is overwritten, you should copy it before calling the routine, if it is required for subsequent computations.

No extra storage arrays are needed for the intermediate results. At stage m , the vectors \mathbf{p} and \mathbf{q} are nonzero only in elements $1, \dots, i$ (recall that $i = n - m + 1$), while \mathbf{u} is nonzero only in elements $1, \dots, i - 1$. The elements of the vector \mathbf{e} are being determined in the order $n, n - 1, \dots$, so we can store \mathbf{p} in the elements of \mathbf{e} not already determined. The vector \mathbf{q} can overwrite \mathbf{p} once \mathbf{p} is no longer needed. We store \mathbf{u} in the i th row of \mathbf{a} and \mathbf{u}/H in the i th column of \mathbf{a} . Once the reduction is complete, we compute the matrices \mathbf{Q}_j using the quantities \mathbf{u} and \mathbf{u}/H that have been stored in \mathbf{a} . Since \mathbf{Q}_j is an identity matrix in the last $n - j + 1$ rows and columns, we only need compute its elements up to row and column $n - j$. These can overwrite the \mathbf{u} 's and \mathbf{u}/H 's in the corresponding rows and columns of \mathbf{a} , which are no longer required for subsequent \mathbf{Q} 's.

The routine `trd2`, given below, includes one further refinement. If the quantity σ is zero or “small” at any stage, one can skip the corresponding transformation. A simple criterion, such as

$$\sigma < \frac{\text{smallest positive number representable on machine}}{\text{machine precision}}$$

would be fine most of the time. A more careful criterion is actually used. Define the quantity

$$\epsilon = \sum_{k=1}^{i-1} |a_{ik}| \quad (11.2.19)$$

If $\epsilon = 0$ to machine precision, we skip the transformation. Otherwise we redefine

$$a_{ik} \text{ becomes } a_{ik}/\epsilon \quad (11.2.20)$$

and use the scaled variables for the transformation. (A Householder transformation depends only on the ratios of the elements.)

Note that when dealing with a matrix whose elements vary over many orders of magnitude, it is important that the matrix be permuted, insofar as possible, so that the smaller elements are in the top left-hand corner. This is because the reduction is performed starting from the bottom right-hand corner, and a mixture of small and large elements there can lead to considerable rounding errors.

The routine `tred2` is designed for use with the routine `tqli` of the next section. `tqli` finds the eigenvalues and eigenvectors of a symmetric, tridiagonal matrix. The combination of `tred2` and `tqli` is the most efficient known technique for finding all the eigenvalues and eigenvectors (or just all the eigenvalues) of a real, symmetric matrix.

In the listing below, the statements indicated by comments are required only for subsequent computation of eigenvectors. If only eigenvalues are required, omission of the commented statements speeds up the execution time of `tred2` by a factor of 2 for large n . In the limit of large n , the operation count of the Householder reduction is $2n^3/3$ for eigenvalues only, and $4n^3/3$ for both eigenvalues and eigenvectors.

```
SUBROUTINE tred2(a,n,np,d,e)
INTEGER n,np
REAL a(np,np),d(np),e(np)
Householder reduction of a real, symmetric, n by n matrix a, stored in an np by np physical
array. On output, a is replaced by the orthogonal matrix Q effecting the transformation. d
returns the diagonal elements of the tridiagonal matrix, and e the off-diagonal elements,
with e(1)=0. Several statements, as noted in comments, can be omitted if only eigenvalues
are to be found, in which case a contains no useful information on output. Otherwise they
are to be included.

11.3 Eigenvalues and Eigenvectors of a Tridiagonal Matrix

Evaluation of the Characteristic Polynomial

Once our original, real, symmetric matrix has been reduced to tridiagonal form, one possible way to determine its eigenvalues is to find the roots of the characteristic polynomial $p_n(\lambda)$ directly. The characteristic polynomial of a tridiagonal matrix can be evaluated for any trial value of λ by an efficient recursion relation (see [1], for example). The polynomials of lower degree produced during the recurrence form a Sturmian sequence that can be used to localize the eigenvalues to intervals on the real axis. A root-finding method such as bisection or Newton's method can then be employed to refine the intervals. The corresponding eigenvectors can then be found by inverse iteration (see §11.7).

Procedures based on these ideas can be found in [2,3]. If, however, more than a small fraction of all the eigenvalues and eigenvectors are required, then the factorization method next considered is much more efficient.

The QR and QL Algorithms

The basic idea behind the *QR* algorithm is that any real matrix can be decomposed in the form

$$\mathbf{A} = \mathbf{Q} \cdot \mathbf{R} \quad (11.3.1)$$

where \mathbf{Q} is orthogonal and \mathbf{R} is upper triangular. For a general matrix, the decomposition is constructed by applying Householder transformations to annihilate successive columns of \mathbf{A} below the diagonal (see §2.10).

Now consider the matrix formed by writing the factors in (11.3.1) in the opposite order:

$$\mathbf{A}' = \mathbf{R} \cdot \mathbf{Q} \quad (11.3.2)$$

Since \mathbf{Q} is orthogonal, equation (11.3.1) gives $\mathbf{R} = \mathbf{Q}^T \cdot \mathbf{A}$. Thus equation (11.3.2) becomes

$$\mathbf{A}' = \mathbf{Q}^T \cdot \mathbf{A} \cdot \mathbf{Q} \quad (11.3.3)$$

11.3 Eigenvalues and Eigenvectors of a Tridiagonal Matrix

Evaluation of the Characteristic Polynomial

Once our original, real, symmetric matrix has been reduced to tridiagonal form, one possible way to determine its eigenvalues is to find the roots of the characteristic polynomial $p_n(\lambda)$ directly. The characteristic polynomial of a tridiagonal matrix can be evaluated for any trial value of λ by an efficient recursion relation (see [1], for example). The polynomials of lower degree produced during the recurrence form a Sturmian sequence that can be used to localize the eigenvalues to intervals on the real axis. A root-finding method such as bisection or Newton's method can then be employed to refine the intervals. The corresponding eigenvectors can then be found by inverse iteration (see §11.7).

Procedures based on these ideas can be found in [2,3]. If, however, more than a small fraction of all the eigenvalues and eigenvectors are required, then the factorization method next considered is much more efficient.

The QR and QL Algorithms

The basic idea behind the *QR* algorithm is that any real matrix can be decomposed in the form

$$\mathbf{A} = \mathbf{Q} \cdot \mathbf{R} \quad (11.3.1)$$

where \mathbf{Q} is orthogonal and \mathbf{R} is upper triangular. For a general matrix, the decomposition is constructed by applying Householder transformations to annihilate successive columns of \mathbf{A} below the diagonal (see §2.10).

Now consider the matrix formed by writing the factors in (11.3.1) in the opposite order:

$$\mathbf{A}' = \mathbf{R} \cdot \mathbf{Q} \quad (11.3.2)$$

Since \mathbf{Q} is orthogonal, equation (11.3.1) gives $\mathbf{R} = \mathbf{Q}^T \cdot \mathbf{A}$. Thus equation (11.3.2) becomes

$$\mathbf{A}' = \mathbf{Q}^T \cdot \mathbf{A} \cdot \mathbf{Q} \quad (11.3.3)$$

We see that \mathbf{A}' is an orthogonal transformation of \mathbf{A} .

You can verify that a QR transformation preserves the following properties of a matrix: symmetry, tridiagonal form, and Hessenberg form (to be defined in §11.5).

There is nothing special about choosing one of the factors of \mathbf{A} to be upper triangular; one could equally well make it lower triangular. This is called the QL algorithm, since

$$\mathbf{A} = \mathbf{Q} \cdot \mathbf{L} \quad (11.3.4)$$

where \mathbf{L} is lower triangular. (The standard, but confusing, nomenclature R and L stands for whether the *right* or *left* of the matrix is nonzero.)

Recall that in the Householder reduction to tridiagonal form in §11.2, we started in the n th (last) column of the original matrix. To minimize roundoff, we then exhorted you to put the biggest elements of the matrix in the lower right-hand corner, if you can. If we now wish to diagonalize the resulting tridiagonal matrix, the QL algorithm will have smaller roundoff than the QR algorithm, so we shall use QL henceforth.

The QL algorithm consists of a *sequence* of orthogonal transformations:

$$\begin{aligned} \mathbf{A}_s &= \mathbf{Q}_s \cdot \mathbf{L}_s \\ \mathbf{A}_{s+1} &= \mathbf{L}_s \cdot \mathbf{Q}_s \quad (= \mathbf{Q}_s^T \cdot \mathbf{A}_s \cdot \mathbf{Q}_s) \end{aligned} \quad (11.3.5)$$

The following (nonobvious!) theorem is the basis of the algorithm for a general matrix \mathbf{A} : (i) If \mathbf{A} has eigenvalues of different absolute value $|\lambda_i|$, then $\mathbf{A}_s \rightarrow$ [lower triangular form] as $s \rightarrow \infty$. The eigenvalues appear on the diagonal in increasing order of absolute magnitude. (ii) If \mathbf{A} has an eigenvalue $|\lambda_i|$ of multiplicity p , $\mathbf{A}_s \rightarrow$ [lower triangular form] as $s \rightarrow \infty$, except for a diagonal block matrix of order p , whose eigenvalues $\rightarrow \lambda_i$. The proof of this theorem is fairly lengthy; see, for example, [4].

The workload in the QL algorithm is $O(n^3)$ per iteration for a general matrix, which is prohibitive. However, the workload is only $O(n)$ per iteration for a tridiagonal matrix and $O(n^2)$ for a Hessenberg matrix, which makes it highly efficient on these forms.

In this section we are concerned only with the case where \mathbf{A} is a real, symmetric, tridiagonal matrix. All the eigenvalues λ_i are thus real. According to the theorem, if any λ_i has a multiplicity p , then there must be at least $p - 1$ zeros on the sub- and superdiagonal. Thus the matrix can be split into submatrices that can be diagonalized separately, and the complication of diagonal blocks that can arise in the general case is irrelevant.

In the proof of the theorem quoted above, one finds that in general a super-diagonal element converges to zero like

$$a_{ij}^{(s)} \sim \left(\frac{\lambda_i}{\lambda_j} \right)^s \quad (11.3.6)$$

Although $\lambda_i < \lambda_j$, convergence can be slow if λ_i is close to λ_j . Convergence can be accelerated by the technique of *shifting*: If k is any constant, then $\mathbf{A} - k\mathbf{1}$ has

eigenvalues $\lambda_i - k$. If we decompose

$$\mathbf{A}_s - k_s \mathbf{1} = \mathbf{Q}_s \cdot \mathbf{L}_s \quad (11.3.7)$$

so that

$$\begin{aligned} \mathbf{A}_{s+1} &= \mathbf{L}_s \cdot \mathbf{Q}_s + k_s \mathbf{1} \\ &= \mathbf{Q}_s^T \cdot \mathbf{A}_s \cdot \mathbf{Q}_s \end{aligned} \quad (11.3.8)$$

then the convergence is determined by the ratio

$$\frac{\lambda_i - k_s}{\lambda_j - k_s} \quad (11.3.9)$$

The idea is to choose the shift k_s at each stage to maximize the rate of convergence. A good choice for the shift initially would be k_s close to λ_1 , the smallest eigenvalue. Then the first row of off-diagonal elements would tend rapidly to zero. However, λ_1 is not usually known *a priori*. A very effective strategy in practice (although there is no proof that it is optimal) is to compute the eigenvalues of the leading 2×2 diagonal submatrix of \mathbf{A} . Then set k_s equal to the eigenvalue closer to a_{11} .

More generally, suppose you have already found $r - 1$ eigenvalues of \mathbf{A} . Then you can *deflate* the matrix by crossing out the first $r - 1$ rows and columns, leaving

$$\mathbf{A} = \begin{bmatrix} 0 & & \cdots & \cdots & & 0 \\ & \ddots & & & & \\ & & 0 & & & \\ \vdots & & d_r & e_r & & \vdots \\ \vdots & & e_r & d_{r+1} & & \\ & & & & \cdots & 0 \\ 0 & & \cdots & & 0 & e_{n-1} \\ & & & & e_{n-1} & d_n \end{bmatrix} \quad (11.3.10)$$

Choose k_s equal to the eigenvalue of the leading 2×2 submatrix that is closer to d_r . One can show that the convergence of the algorithm with this strategy is generally cubic (and at worst quadratic for degenerate eigenvalues). This rapid convergence is what makes the algorithm so attractive.

Note that with shifting, the eigenvalues no longer necessarily appear on the diagonal in order of increasing absolute magnitude. The routine `eigsrt` (§11.1) can be used if required.

As we mentioned earlier, the QL decomposition of a general matrix is effected by a sequence of Householder transformations. For a tridiagonal matrix, however, it is more efficient to use plane rotations \mathbf{P}_{pq} . One uses the sequence $\mathbf{P}_{12}, \mathbf{P}_{23}, \dots, \mathbf{P}_{n-1,n}$ to annihilate the elements $a_{12}, a_{23}, \dots, a_{n-1,n}$. By symmetry, the subdiagonal elements $a_{21}, a_{32}, \dots, a_{n,n-1}$ will be annihilated too. Thus each \mathbf{Q}_s is a product of plane rotations:

$$\mathbf{Q}_s^T = \mathbf{P}_1^{(s)} \cdot \mathbf{P}_2^{(s)} \cdots \mathbf{P}_{n-1}^{(s)} \quad (11.3.11)$$

where \mathbf{P}_i annihilates $a_{i,i+1}$. Note that it is \mathbf{Q}^T in equation (11.3.11), not \mathbf{Q} , because we defined $\mathbf{L} = \mathbf{Q}^T \cdot \mathbf{A}$.

QL Algorithm with Implicit Shifts

The algorithm as described so far can be very successful. However, when the elements of \mathbf{A} differ widely in order of magnitude, subtracting a large k_s from the diagonal elements can lead to loss of accuracy for the small eigenvalues. This difficulty is avoided by the *QL* algorithm with *implicit shifts*. The implicit *QL* algorithm is mathematically equivalent to the original *QL* algorithm, but the computation does not require $k_s \mathbf{1}$ to be actually subtracted from \mathbf{A} .

The algorithm is based on the following lemma: If \mathbf{A} is a symmetric nonsingular matrix and $\mathbf{B} = \mathbf{Q}^T \cdot \mathbf{A} \cdot \mathbf{Q}$, where \mathbf{Q} is orthogonal and \mathbf{B} is tridiagonal with positive off-diagonal elements, then \mathbf{Q} and \mathbf{B} are fully determined when the last row of \mathbf{Q}^T is specified. Proof: Let \mathbf{q}_i^T denote the i th row vector of the matrix \mathbf{Q}^T . Then \mathbf{q}_i is the i th column vector of the matrix \mathbf{Q} . The relation $\mathbf{B} \cdot \mathbf{Q}^T = \mathbf{Q}^T \cdot \mathbf{A}$ can be written

$$\begin{bmatrix} \beta_1 & \gamma_1 & & \\ \alpha_2 & \beta_2 & \gamma_2 & \\ & \vdots & & \\ & & \alpha_{n-1} & \beta_{n-1} & \gamma_{n-1} \\ & & & \alpha_n & \beta_n \end{bmatrix} \cdot \begin{bmatrix} \mathbf{q}_1^T \\ \mathbf{q}_2^T \\ \vdots \\ \mathbf{q}_{n-1}^T \\ \mathbf{q}_n^T \end{bmatrix} = \begin{bmatrix} \mathbf{q}_1^T \\ \mathbf{q}_2^T \\ \vdots \\ \mathbf{q}_{n-1}^T \\ \mathbf{q}_n^T \end{bmatrix} \cdot \mathbf{A} \quad (11.3.12)$$

The n th row of this matrix equation is

$$\alpha_n \mathbf{q}_{n-1}^T + \beta_n \mathbf{q}_n^T = \mathbf{q}_n^T \cdot \mathbf{A} \quad (11.3.13)$$

Since \mathbf{Q} is orthogonal,

$$\mathbf{q}_n^T \cdot \mathbf{q}_m = \delta_{nm} \quad (11.3.14)$$

Thus if we postmultiply equation (11.3.13) by \mathbf{q}_n , we find

$$\beta_n = \mathbf{q}_n^T \cdot \mathbf{A} \cdot \mathbf{q}_n \quad (11.3.15)$$

which is known since \mathbf{q}_n is known. Then equation (11.3.13) gives

$$\alpha_n \mathbf{q}_{n-1}^T = \mathbf{z}_{n-1}^T \quad (11.3.16)$$

where

$$\mathbf{z}_{n-1}^T \equiv \mathbf{q}_n^T \cdot \mathbf{A} - \beta_n \mathbf{q}_n^T \quad (11.3.17)$$

is known. Therefore

$$\alpha_n^2 = \mathbf{z}_{n-1}^T \mathbf{z}_{n-1}, \quad (11.3.18)$$

or

$$\alpha_n = |\mathbf{z}_{n-1}| \quad (11.3.19)$$

and

$$\mathbf{q}_{n-1}^T = \mathbf{z}_{n-1}^T / \alpha_n \quad (11.3.20)$$

(where α_n is nonzero by hypothesis). Similarly, one can show by induction that if we know $\mathbf{q}_n, \mathbf{q}_{n-1}, \dots, \mathbf{q}_{n-j}$ and the α 's, β 's, and γ 's up to level $n - j$, one can determine the quantities at level $n - (j + 1)$.

To apply the lemma in practice, suppose one can somehow find a tridiagonal matrix $\bar{\mathbf{A}}_{s+1}$ such that

$$\bar{\mathbf{A}}_{s+1} = \bar{\mathbf{Q}}_s^T \cdot \bar{\mathbf{A}}_s \cdot \bar{\mathbf{Q}}_s \quad (11.3.21)$$

where $\bar{\mathbf{Q}}_s^T$ is orthogonal and has the same last row as \mathbf{Q}_s^T in the original *QL* algorithm. Then $\bar{\mathbf{Q}}_s = \mathbf{Q}_s$ and $\bar{\mathbf{A}}_{s+1} = \mathbf{A}_{s+1}$.

Now, in the original algorithm, from equation (11.3.11) we see that the last row of \mathbf{Q}_s^T is the same as the last row of $\mathbf{P}_{n-1}^{(s)}$. But recall that $\mathbf{P}_{n-1}^{(s)}$ is a plane rotation designed to annihilate the $(n-1, n)$ element of $\mathbf{A}_s - k_s \mathbf{1}$. A simple calculation using the expression (11.1.1) shows that it has parameters

$$c = \frac{d_n - k_s}{\sqrt{e_n^2 + (d_n - k_s)^2}}, \quad s = \frac{-e_{n-1}}{\sqrt{e_n^2 + (d_n - k_s)^2}} \quad (11.3.22)$$

The matrix $\mathbf{P}_{n-1}^{(s)} \cdot \mathbf{A}_s \cdot \mathbf{P}_{n-1}^{(s)T}$ is tridiagonal with 2 extra elements:

$$\begin{bmatrix} \dots & & & \\ & \times & \times & \times \\ & \times & \times & \times & \mathbf{x} \\ & \times & \times & \times \\ & \mathbf{x} & \times & \times \end{bmatrix} \quad (11.3.23)$$

We must now reduce this to tridiagonal form with an orthogonal matrix whose last row is $[0, 0, \dots, 0, 1]$ so that the last row of $\bar{\mathbf{Q}}_s^T$ will stay equal to $\mathbf{P}_{n-1}^{(s)}$. This can be done by a sequence of Householder or Givens transformations. For the special form of the matrix (11.3.23), Givens is better. We rotate in the plane $(n-2, n-1)$ to annihilate the $(n-2, n)$ element. [By symmetry, the $(n, n-2)$ element will also be zeroed.] This leaves us with tridiagonal form except for extra elements $(n-3, n-1)$ and $(n-1, n-3)$. We annihilate these with a rotation in the $(n-3, n-2)$ plane, and so on. Thus a sequence of $n-2$ Givens rotations is required. The result is that

$$\mathbf{Q}_s^T = \bar{\mathbf{Q}}_s^T = \bar{\mathbf{P}}_1^{(s)} \cdot \bar{\mathbf{P}}_2^{(s)} \cdots \bar{\mathbf{P}}_{n-2}^{(s)} \cdot \mathbf{P}_{n-1}^{(s)} \quad (11.3.24)$$

where the $\bar{\mathbf{P}}$'s are the Givens rotations and \mathbf{P}_{n-1} is the same plane rotation as in the original algorithm. Then equation (11.3.21) gives the next iterate of \mathbf{A} . Note that the shift k_s enters implicitly through the parameters (11.3.22).

The following routine `tqli` (“Tridiagonal *QL* Implicit”), based algorithmically on the implementations in [2,3], works extremely well in practice. The number of iterations for the first few eigenvalues might be 4 or 5, say, but meanwhile the off-diagonal elements in the lower right-hand corner have been reduced too. The later eigenvalues are liberated with very little work. The average number of iterations per eigenvalue is typically $1.3 - 1.6$. The operation count per iteration is $O(n)$, with a fairly large effective coefficient, say, $\sim 20n$. The total operation count for the diagonalization is then $\sim 20n \times (1.3 - 1.6)n \sim 30n^2$. If the eigenvectors are required, the statements indicated by comments are included and there is an additional, much larger, workload of about $3n^3$ operations.

C

```
SUBROUTINE tqli(d,e,n,np,z)
INTEGER n,np
REAL d(np),e(np),z(np,np)
USES pythag
```

QL algorithm with implicit shifts, to determine the eigenvalues and eigenvectors of a real, symmetric, tridiagonal matrix, or of a real, symmetric matrix previously reduced by `tred2` §11.2. d is a vector of length np . On input, its first n elements are the diagonal elements of the tridiagonal matrix. On output, it returns the eigenvalues. The vector e inputs the sub-diagonal elements of the tridiagonal matrix, with $e(1)$ arbitrary. On output e is destroyed. When finding only the eigenvalues, several lines may be omitted, as noted in the comments. If the eigenvectors of a tridiagonal matrix are desired, the matrix z (n by n matrix stored in np by np array) is input as the identity matrix. If the eigenvectors of a matrix that has been reduced by `tred2` are required, then z is input as the matrix output by `tred2`. In either case, the k th column of z returns the normalized eigenvector corresponding to $d(k)$.

11.4 Hermitian Matrices

The complex analog of a real, symmetric matrix is a Hermitian matrix, satisfying equation (11.0.4). Jacobi transformations can be used to find eigenvalues and eigenvectors, as also can Householder reduction to tridiagonal form followed by QL iteration. Complex versions of the previous routines `jacobi`, `tred2`, and `tqli` are quite analogous to their real counterparts. For working routines, consult [1,2].

An alternative, using the routines in this book, is to convert the Hermitian problem to a real, symmetric one: If $\mathbf{C} = \mathbf{A} + i\mathbf{B}$ is a Hermitian matrix, then the $n \times n$ complex eigenvalue problem

$$(\mathbf{A} + i\mathbf{B}) \cdot (\mathbf{u} + i\mathbf{v}) = \lambda(\mathbf{u} + i\mathbf{v}) \quad (11.4.1)$$

is equivalent to the $2n \times 2n$ real problem

$$\begin{bmatrix} \mathbf{A} & -\mathbf{B} \\ \mathbf{B} & \mathbf{A} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} = \lambda \begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} \quad (11.4.2)$$

Note that the $2n \times 2n$ matrix in (11.4.2) is symmetric: $\mathbf{A}^T = \mathbf{A}$ and $\mathbf{B}^T = -\mathbf{B}$ if \mathbf{C} is Hermitian.

Corresponding to a given eigenvalue λ , the vector

$$\begin{bmatrix} -\mathbf{v} \\ \mathbf{u} \end{bmatrix} \quad (11.4.3)$$

is also an eigenvector, as you can verify by writing out the two matrix equations implied by (11.4.2). Thus if $\lambda_1, \lambda_2, \dots, \lambda_n$ are the eigenvalues of \mathbf{C} , then the $2n$ eigenvalues of the augmented problem (11.4.2) are $\lambda_1, \lambda_1, \lambda_2, \lambda_2, \dots, \lambda_n, \lambda_n$; each, in other words, is repeated twice. The eigenvectors are pairs of the form $\mathbf{u} + i\mathbf{v}$ and $i(\mathbf{u} + i\mathbf{v})$; that is, they are the same up to an inessential phase. Thus we solve the augmented problem (11.4.2), and choose one eigenvalue and eigenvector from each pair. These give the eigenvalues and eigenvectors of the original matrix \mathbf{C} .

Working with the augmented matrix requires a factor of 2 more storage than the original complex matrix. In principle, a complex algorithm is also a factor of 2 more efficient in computer time than is the solution of the augmented problem. In practice, most complex implementations do not achieve this factor unless they are written entirely in real arithmetic. (Good library routines always do this.)

11.4 Hermitian Matrices

The complex analog of a real, symmetric matrix is a Hermitian matrix, satisfying equation (11.0.4). Jacobi transformations can be used to find eigenvalues and eigenvectors, as also can Householder reduction to tridiagonal form followed by QL iteration. Complex versions of the previous routines `jacobi`, `tred2`, and `tqli` are quite analogous to their real counterparts. For working routines, consult [1,2].

An alternative, using the routines in this book, is to convert the Hermitian problem to a real, symmetric one: If $\mathbf{C} = \mathbf{A} + i\mathbf{B}$ is a Hermitian matrix, then the $n \times n$ complex eigenvalue problem

$$(\mathbf{A} + i\mathbf{B}) \cdot (\mathbf{u} + i\mathbf{v}) = \lambda(\mathbf{u} + i\mathbf{v}) \quad (11.4.1)$$

is equivalent to the $2n \times 2n$ real problem

$$\begin{bmatrix} \mathbf{A} & -\mathbf{B} \\ \mathbf{B} & \mathbf{A} \end{bmatrix} \cdot \begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} = \lambda \begin{bmatrix} \mathbf{u} \\ \mathbf{v} \end{bmatrix} \quad (11.4.2)$$

Note that the $2n \times 2n$ matrix in (11.4.2) is symmetric: $\mathbf{A}^T = \mathbf{A}$ and $\mathbf{B}^T = -\mathbf{B}$ if \mathbf{C} is Hermitian.

Corresponding to a given eigenvalue λ , the vector

$$\begin{bmatrix} -\mathbf{v} \\ \mathbf{u} \end{bmatrix} \quad (11.4.3)$$

is also an eigenvector, as you can verify by writing out the two matrix equations implied by (11.4.2). Thus if $\lambda_1, \lambda_2, \dots, \lambda_n$ are the eigenvalues of \mathbf{C} , then the $2n$ eigenvalues of the augmented problem (11.4.2) are $\lambda_1, \lambda_1, \lambda_2, \lambda_2, \dots, \lambda_n, \lambda_n$; each, in other words, is repeated twice. The eigenvectors are pairs of the form $\mathbf{u} + i\mathbf{v}$ and $i(\mathbf{u} + i\mathbf{v})$; that is, they are the same up to an inessential phase. Thus we solve the augmented problem (11.4.2), and choose one eigenvalue and eigenvector from each pair. These give the eigenvalues and eigenvectors of the original matrix \mathbf{C} .

Working with the augmented matrix requires a factor of 2 more storage than the original complex matrix. In principle, a complex algorithm is also a factor of 2 more efficient in computer time than is the solution of the augmented problem. In practice, most complex implementations do not achieve this factor unless they are written entirely in real arithmetic. (Good library routines always do this.)

11.5 Reduction of a General Matrix to Hessenberg Form

The algorithms for symmetric matrices, given in the preceding sections, are highly satisfactory in practice. By contrast, it is impossible to design equally satisfactory algorithms for the nonsymmetric case. There are two reasons for this. First, the eigenvalues of a nonsymmetric matrix can be very sensitive to small changes in the matrix elements. Second, the matrix itself can be defective, so that there is no complete set of eigenvectors. We emphasize that these difficulties are intrinsic properties of certain nonsymmetric matrices, and no numerical procedure can “cure” them. The best we can hope for are procedures that don’t exacerbate such problems.

The presence of rounding error can only make the situation worse. With finite-precision arithmetic, one cannot even design a foolproof algorithm to determine whether a given matrix is defective or not. Thus current algorithms generally *try* to find a *complete* set of eigenvectors, and rely on the user to inspect the results. If any eigenvectors are almost parallel, the matrix is probably defective.

Apart from referring you to the literature, and to the collected routines in [1,2], we are going to sidestep the problem of eigenvectors, giving algorithms for eigenvalues only. If you require just a few eigenvectors, you can read §11.7 and consider finding them by inverse iteration. We consider the problem of finding *all* eigenvectors of a nonsymmetric matrix as lying beyond the scope of this book.

Balancing

The sensitivity of eigenvalues to rounding errors during the execution of some algorithms can be reduced by the procedure of *balancing*. The errors in the eigensystem found by a numerical procedure are generally proportional to the Euclidean norm of the matrix, that is, to the square root of the sum of the squares of the elements. The idea of balancing is to use similarity transformations to make corresponding rows and columns of the matrix have comparable norms, thus reducing the overall norm of the matrix while leaving the eigenvalues unchanged. A symmetric matrix is already balanced.

Balancing is a procedure with of order N^2 operations. Thus, the time taken by the procedure `balanc`, given below, should never be more than a few percent of the total time required to find the eigenvalues. It is therefore recommended that you *always* balance nonsymmetric matrices. It never hurts, and it can substantially improve the accuracy of the eigenvalues computed for a badly balanced matrix.

The actual algorithm used is due to Osborne, as discussed in [1]. It consists of a sequence of similarity transformations by diagonal matrices **D**. To avoid introducing rounding errors during the balancing process, the elements of **D** are restricted to be exact powers of the radix base employed for floating-point arithmetic (i.e., 2 for most machines, but 16 for IBM mainframe architectures). The output is a matrix that is balanced in the norm given by summing the absolute magnitudes of the matrix elements. This is more efficient than using the Euclidean norm, and equally effective: A large reduction in one norm implies a large reduction in the other.

Note that if the off-diagonal elements of any row or column of a matrix are all zero, then the diagonal element is an eigenvalue. If the eigenvalue happens to

11.5 Reduction of a General Matrix to Hessenberg Form

The algorithms for symmetric matrices, given in the preceding sections, are highly satisfactory in practice. By contrast, it is impossible to design equally satisfactory algorithms for the nonsymmetric case. There are two reasons for this. If you require just a few eigenvectors, you can read §11.7 and consider finding them by inverse iteration. We consider the problem of finding *all* eigenvectors of a nonsymmetric matrix as lying beyond the scope of this book.

Balancing

The sensitivity of eigenvalues to rounding errors during the execution of some algorithms can be reduced by the procedure of *balancing*. The errors in the eigensystem found by a numerical procedure are generally proportional to the Euclidean norm of the matrix, that is, to the square root of the sum of the squares of the elements. The idea of balancing is to use similarity transformations to make corresponding rows and columns of the matrix have comparable norms, thus reducing the overall norm of the matrix while leaving the eigenvalues unchanged. A symmetric matrix is already balanced.

Balancing is a procedure with of order N^2 operations. Thus, the time taken by the procedure `balanc`, given below, should never be more than a few percent of the total time required to find the eigenvalues. It is therefore recommended that you *always* balance nonsymmetric matrices. It never hurts, and it can substantially improve the accuracy of the eigenvalues computed for a badly balanced matrix.

The actual algorithm used is due to Osborne, as discussed in [1]. It consists of a sequence of similarity transformations by diagonal matrices **D**. To avoid introducing rounding errors during the balancing process, the elements of **D** are restricted to be exact powers of the radix base employed for floating-point arithmetic (i.e., 2 for most machines, but 16 for IBM mainframe architectures). The output is a matrix that is balanced in the norm given by summing the absolute magnitudes of the matrix elements. This is more efficient than using the Euclidean norm, and equally effective: A large reduction in one norm implies a large reduction in the other.

Note that if the off-diagonal elements of any row or column of a matrix are all zero, then the diagonal element is an eigenvalue. If the eigenvalue happens to

be ill-conditioned (sensitive to small changes in the matrix elements), it will have relatively large errors when determined by the routine `hqr` (§11.6). Had we merely inspected the matrix beforehand, we could have determined the isolated eigenvalue exactly and then deleted the corresponding row and column from the matrix. You should consider whether such a pre-inspection might be useful in your application. (For symmetric matrices, the routines we gave will determine isolated eigenvalues accurately in all cases.)

The routine `balanc` does not keep track of the accumulated similarity transformation of the original matrix, since we will only be concerned with finding eigenvalues of nonsymmetric matrices, not eigenvectors. Consult [1-3] if you want to keep track of the transformation.

```

SUBROUTINE balanc(a,n,np)
INTEGER n,np
REAL a(np,np),RADIX,SQRDX
PARAMETER (RADIX=2.,SQRDX=RADIX**2)
      Given an n by n matrix a stored in an array of physical dimensions np by np, this routine
      replaces it by a balanced matrix with identical eigenvalues. A symmetric matrix is already
      balanced and is unaffected by this procedure. The parameter RADIX should be the machine's
      floating-point radix.

Reduction to Hessenberg Form

The strategy for finding the eigensystem of a general matrix parallels that of the symmetric case. First we reduce the matrix to a simpler form, and then we perform an iterative procedure on the simplified matrix. The simpler structure we use here is called *Hessenberg* form. An *upper Hessenberg* matrix has zeros everywhere below the diagonal except for the first subdiagonal row. For example, in the 6×6 case, the nonzero elements are:

$$\begin{bmatrix} \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times \\ & \times & \times & \times & \times & \times \\ & & \times & \times & \times & \times \\ & & & \times & \times & \times \end{bmatrix}$$

By now you should be able to tell at a glance that such a structure can be achieved by a sequence of Householder transformations, each one zeroing the required elements in a column of the matrix. Householder reduction to Hessenberg form is in fact an accepted technique. An alternative, however, is a procedure analogous to Gaussian elimination with pivoting. We will use this elimination procedure since it is about a factor of 2 more efficient than the Householder method, and also since we want to teach you the method. It is possible to construct matrices for which the Householder reduction, being orthogonal, is stable and elimination is not, but such matrices are extremely rare in practice.

Straight Gaussian elimination is not a similarity transformation of the matrix. Accordingly, the actual elimination procedure used is slightly different. Before the r th stage, the original matrix $\mathbf{A} \equiv \mathbf{A}_1$ has become \mathbf{A}_r , which is upper Hessenberg in its first $r - 1$ rows and columns. The r th stage then consists of the following sequence of operations:

- Find the element of maximum magnitude in the r th column below the diagonal. If it is zero, skip the next two “bullets” and the stage is done. Otherwise, suppose the maximum element was in row r' .
- Interchange rows r' and $r + 1$. This is the pivoting procedure. To make the permutation a similarity transformation, also interchange columns r' and $r + 1$.
- For $i = r + 2, r + 3, \dots, N$, compute the multiplier

$$n_{i,r+1} \equiv \frac{a_{ir}}{a_{r+1,r}}$$

Subtract $n_{i,r+1}$ times row $r + 1$ from row i . To make the elimination a similarity transformation, also *add* $n_{i,r+1}$ times column i to column $r + 1$. A total of $N - 2$ such stages are required.

When the magnitudes of the matrix elements vary over many orders, you should try to rearrange the matrix so that the largest elements are in the top left-hand corner. This reduces the roundoff error, since the reduction proceeds from left to right.

Since we are concerned only with eigenvalues, the routine `elmhes` does not keep track of the accumulated similarity transformation. The operation count is about $5N^3/6$ for large N .

```
SUBROUTINE elmhes(a,n,np)
INTEGER n,np
REAL a(np,np)
      Reduction to Hessenberg form by the elimination method. The real, nonsymmetric, n by n matrix a, stored in an array of physical dimensions np by np, is replaced by an upper Hessenberg matrix with identical eigenvalues. Recommended, but not required, is that this routine be preceded by balanc. On output, the Hessenberg matrix is in elements a(i,j) with  $i \leq j+1$ . Elements with  $i > j+1$  are to be thought of as zero, but are returned with random values.
INTEGER i,j,m
REAL x,y
do 17 m=2,n-1           m is called r + 1 in the text.
  x=0.
  i=m
  do 11 j=m,n             Find the pivot.
    if(abs(a(j,m-1)).gt.abs(x))then
      x=a(j,m-1)
      i=j
    endif
  enddo 11
  if(i.ne.m)then          Interchange rows and columns.
    do 12 j=m-1,n
      y=a(i,j)
      a(i,j)=a(m,j)
      a(m,j)=y
    enddo 12
    do 13 j=1,n
      y=a(j,i)
      a(j,i)=a(j,m)
      a(j,m)=y
    enddo 13
  endif
  if(x.ne.0.)then         Carry out the elimination.
    do 16 i=m+1,n
      y=a(i,m-1)
      if(y.ne.0.)then
        y=y/x
        a(i,m-1)=y
        do 14 j=m,n
          a(i,j)=a(i,j)-y*a(m,j)
        enddo 14
        do 15 j=1,n
          a(j,m)=a(j,m)+y*a(j,i)
        enddo 15
      endif
    enddo 16
  endif
enddo 17
return
END
```

11.6 The QR Algorithm for Real Hessenberg Matrices

Recall the following relations for the *QR* algorithm with shifts:

$$\mathbf{Q}_s \cdot (\mathbf{A}_s - k_s \mathbf{1}) = \mathbf{R}_s \quad (11.6.1)$$

where \mathbf{Q} is orthogonal and \mathbf{R} is upper triangular, and

$$\begin{aligned} \mathbf{A}_{s+1} &= \mathbf{R}_s \cdot \mathbf{Q}_s^T + k_s \mathbf{1} \\ &= \mathbf{Q}_s \cdot \mathbf{A}_s \cdot \mathbf{Q}_s^T \end{aligned} \quad (11.6.2)$$

The *QR* transformation preserves the upper Hessenberg form of the original matrix $\mathbf{A} \equiv \mathbf{A}_1$, and the workload on such a matrix is $O(n^2)$ per iteration as opposed to $O(n^3)$ on a general matrix. As $s \rightarrow \infty$, \mathbf{A}_s converges to a form where the eigenvalues are either isolated on the diagonal or are eigenvalues of a 2×2 submatrix on the diagonal.

As we pointed out in §11.3, shifting is essential for rapid convergence. A key difference here is that a nonsymmetric real matrix can have complex eigenvalues. This means that good choices for the shifts k_s may be complex, apparently necessitating complex arithmetic.

Complex arithmetic can be avoided, however, by a clever trick. The trick depends on a result analogous to the lemma we used for implicit shifts in §11.3. The lemma we need here states that if \mathbf{B} is a nonsingular matrix such that

$$\mathbf{B} \cdot \mathbf{Q} = \mathbf{Q} \cdot \mathbf{H} \quad (11.6.3)$$

where \mathbf{Q} is orthogonal and \mathbf{H} is upper Hessenberg, then \mathbf{Q} and \mathbf{H} are fully determined by the first column of \mathbf{Q} . (The determination is unique if \mathbf{H} has positive subdiagonal elements.) The lemma can be proved by induction analogously to the proof given for tridiagonal matrices in §11.3.

The lemma is used in practice by taking two steps of the *QR* algorithm, either with two real shifts k_s and k_{s+1} , or with complex conjugate values k_s and $k_{s+1} = k_s^*$. This gives a real matrix \mathbf{A}_{s+2} , where

$$\mathbf{A}_{s+2} = \mathbf{Q}_{s+1} \cdot \mathbf{Q}_s \cdot \mathbf{A}_s \cdot \mathbf{Q}_s^T \cdot \mathbf{Q}_{s+1}^T. \quad (11.6.4)$$

11.6 The QR Algorithm for Real Hessenberg Matrices

Recall the following relations for the *QR* algorithm with shifts:

$$\mathbf{Q}_s \cdot (\mathbf{A}_s - k_s \mathbf{1}) = \mathbf{R}_s \quad (11.6.1)$$

where \mathbf{Q} is orthogonal and \mathbf{R} is upper triangular, and

$$\begin{aligned} \mathbf{A}_{s+1} &= \mathbf{R}_s \cdot \mathbf{Q}_s^T + k_s \mathbf{1} \\ &= \mathbf{Q}_s \cdot \mathbf{A}_s \cdot \mathbf{Q}_s^T \end{aligned} \quad (11.6.2)$$

The *QR* transformation preserves the upper Hessenberg form of the original matrix $\mathbf{A} \equiv \mathbf{A}_1$, and the workload on such a matrix is $O(n^2)$ per iteration as opposed to $O(n^3)$ on a general matrix. As $s \rightarrow \infty$, \mathbf{A}_s converges to a form where the eigenvalues are either isolated on the diagonal or are eigenvalues of a 2×2 submatrix on the diagonal.

As we pointed out in §11.3, shifting is essential for rapid convergence. A key difference here is that a nonsymmetric real matrix can have complex eigenvalues. This means that good choices for the shifts k_s may be complex, apparently necessitating complex arithmetic.

Complex arithmetic can be avoided, however, by a clever trick. The trick depends on a result analogous to the lemma we used for implicit shifts in §11.3. The lemma we need here states that if \mathbf{B} is a nonsingular matrix such that

$$\mathbf{B} \cdot \mathbf{Q} = \mathbf{Q} \cdot \mathbf{H} \quad (11.6.3)$$

where \mathbf{Q} is orthogonal and \mathbf{H} is upper Hessenberg, then \mathbf{Q} and \mathbf{H} are fully determined by the first column of \mathbf{Q} . (The determination is unique if \mathbf{H} has positive subdiagonal elements.) The lemma can be proved by induction analogously to the proof given for tridiagonal matrices in §11.3.

The lemma is used in practice by taking two steps of the *QR* algorithm, either with two real shifts k_s and k_{s+1} , or with complex conjugate values k_s and $k_{s+1} = k_s^*$. This gives a real matrix \mathbf{A}_{s+2} , where

$$\mathbf{A}_{s+2} = \mathbf{Q}_{s+1} \cdot \mathbf{Q}_s \cdot \mathbf{A}_s \cdot \mathbf{Q}_s^T \cdot \mathbf{Q}_{s+1}^T. \quad (11.6.4)$$

The \mathbf{Q} 's are determined by

$$\mathbf{A}_s - k_s \mathbf{1} = \mathbf{Q}_s^T \cdot \mathbf{R}_s \quad (11.6.5)$$

$$\mathbf{A}_{s+1} = \mathbf{Q}_s \cdot \mathbf{A}_s \cdot \mathbf{Q}_s^T \quad (11.6.6)$$

$$\mathbf{A}_{s+1} - k_{s+1} \mathbf{1} = \mathbf{Q}_{s+1}^T \cdot \mathbf{R}_{s+1} \quad (11.6.7)$$

Using (11.6.6), equation (11.6.7) can be rewritten

$$\mathbf{A}_s - k_{s+1} \mathbf{1} = \mathbf{Q}_s^T \cdot \mathbf{Q}_{s+1}^T \cdot \mathbf{R}_{s+1} \cdot \mathbf{Q}_s \quad (11.6.8)$$

Hence, if we define

$$\mathbf{M} = (\mathbf{A}_s - k_{s+1} \mathbf{1}) \cdot (\mathbf{A}_s - k_s \mathbf{1}) \quad (11.6.9)$$

equations (11.6.5) and (11.6.8) give

$$\mathbf{R} = \mathbf{Q} \cdot \mathbf{M} \quad (11.6.10)$$

where

$$\mathbf{Q} = \mathbf{Q}_{s+1} \cdot \mathbf{Q}_s \quad (11.6.11)$$

$$\mathbf{R} = \mathbf{R}_{s+1} \cdot \mathbf{R}_s \quad (11.6.12)$$

Equation (11.6.4) can be rewritten

$$\mathbf{A}_s \cdot \mathbf{Q}^T = \mathbf{Q}^T \cdot \mathbf{A}_{s+2} \quad (11.6.13)$$

Thus suppose we can somehow find an upper Hessenberg matrix \mathbf{H} such that

$$\mathbf{A}_s \cdot \overline{\mathbf{Q}}^T = \overline{\mathbf{Q}}^T \cdot \mathbf{H} \quad (11.6.14)$$

where $\overline{\mathbf{Q}}$ is orthogonal. If $\overline{\mathbf{Q}}^T$ has the same first column as \mathbf{Q}^T (i.e., $\overline{\mathbf{Q}}$ has the same first row as \mathbf{Q}), then $\overline{\mathbf{Q}} = \mathbf{Q}$ and $\mathbf{A}_{s+2} = \mathbf{H}$.

The first row of \mathbf{Q} is found as follows. Equation (11.6.10) shows that \mathbf{Q} is the orthogonal matrix that triangularizes the real matrix \mathbf{M} . Any real matrix can be triangularized by premultiplying it by a sequence of Householder matrices \mathbf{P}_1 (acting on the first column), \mathbf{P}_2 (acting on the second column), \dots , \mathbf{P}_{n-1} . Thus $\mathbf{Q} = \mathbf{P}_{n-1} \cdots \mathbf{P}_2 \cdot \mathbf{P}_1$, and the first row of \mathbf{Q} is the first row of \mathbf{P}_1 since \mathbf{P}_i is an $(i-1) \times (i-1)$ identity matrix in the top left-hand corner. We now must find $\overline{\mathbf{Q}}$ satisfying (11.6.14) whose first row is that of \mathbf{P}_1 .

The Householder matrix \mathbf{P}_1 is determined by the first column of \mathbf{M} . Since \mathbf{A}_s is upper Hessenberg, equation (11.6.9) shows that the first column of \mathbf{M} has the form $[p_1, q_1, r_1, 0, \dots, 0]^T$, where

$$\begin{aligned} p_1 &= a_{11}^2 - a_{11}(k_s + k_{s+1}) + k_s k_{s+1} + a_{12} a_{21} \\ q_1 &= a_{21}(a_{11} + a_{22} - k_s - k_{s+1}) \\ r_1 &= a_{21} a_{32} \end{aligned} \quad (11.6.15)$$

Hence

$$\mathbf{P}_1 = \mathbf{I} - 2\mathbf{w}_1 \cdot \mathbf{w}_1^T \quad (11.6.16)$$

where \mathbf{w}_1 has only its first 3 elements nonzero (cf. equation 11.2.5). The matrix $\mathbf{P}_1 \cdot \mathbf{A}_s \cdot \mathbf{P}_1^T$ is therefore upper Hessenberg with 3 extra elements:

$$\mathbf{P}_1 \cdot \mathbf{A}_1 \cdot \mathbf{P}_1^T = \begin{bmatrix} \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times \\ \mathbf{x} & \times & \times & \times & \times & \times & \times \\ \mathbf{x} & \mathbf{x} & \times & \times & \times & \times & \times \\ & & & & \times & \times & \times \\ & & & & & \times & \times \\ & & & & & & \times \end{bmatrix} \quad (11.6.17)$$

This matrix can be restored to upper Hessenberg form without affecting the first row by a sequence of Householder similarity transformations. The first such Householder matrix, \mathbf{P}_2 , acts on elements 2, 3, and 4 in the first column, annihilating elements 3 and 4. This produces a matrix of the same form as (11.6.17), with the 3 extra elements appearing one column over:

$$\begin{bmatrix} \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times \\ \times & \times & \times & \times & \times & \times & \times \\ \mathbf{x} & \times & \times & \times & \times & \times & \times \\ \mathbf{x} & \mathbf{x} & \times & \times & \times & \times & \times \\ & & & & \times & \times & \times \\ & & & & & \times & \times \end{bmatrix} \quad (11.6.18)$$

Proceeding in this way up to \mathbf{P}_{n-1} , we see that at each stage the Householder matrix \mathbf{P}_r has a vector \mathbf{w}_r that is nonzero only in elements r , $r+1$, and $r+2$. These elements are determined by the elements r , $r+1$, and $r+2$ in the $(r-1)$ st column of the current matrix. Note that the preliminary matrix \mathbf{P}_1 has the same structure as $\mathbf{P}_2, \dots, \mathbf{P}_{n-1}$.

The result is that

$$\mathbf{P}_{n-1} \cdots \mathbf{P}_2 \cdot \mathbf{P}_1 \cdot \mathbf{A}_s \cdot \mathbf{P}_1^T \cdot \mathbf{P}_2^T \cdots \mathbf{P}_{n-1}^T = \mathbf{H} \quad (11.6.19)$$

where \mathbf{H} is upper Hessenberg. Thus

$$\overline{\mathbf{Q}} = \mathbf{Q} = \mathbf{P}_{n-1} \cdots \mathbf{P}_2 \cdot \mathbf{P}_1 \quad (11.6.20)$$

and

$$\mathbf{A}_{s+2} = \mathbf{H} \quad (11.6.21)$$

The shifts of origin at each stage are taken to be the eigenvalues of the 2×2 matrix in the bottom right-hand corner of the current \mathbf{A}_s . This gives

$$\begin{aligned} k_s + k_{s+2} &= a_{n-1,n-1} + a_{nn} \\ k_s k_{s+1} &= a_{n-1,n-1} a_{nn} - a_{n-1,n} a_{n,n-1} \end{aligned} \quad (11.6.22)$$

Substituting (11.6.22) in (11.6.15), we get

$$\begin{aligned} p_1 &= a_{21} \{[(a_{nn} - a_{11})(a_{n-1,n-1} - a_{11}) - a_{n-1,n}a_{n,n-1}]/a_{21} + a_{12}\} \\ q_1 &= a_{21}[a_{22} - a_{11} - (a_{nn} - a_{11}) - (a_{n-1,n-1} - a_{11})] \\ r_1 &= a_{21}a_{32} \end{aligned} \quad (11.6.23)$$

We have judiciously grouped terms to reduce possible roundoff when there are small off-diagonal elements. Since only the ratios of elements are relevant for a Householder transformation, we can omit the factor a_{21} from (11.6.23).

In summary, to carry out a double QR step we construct the Householder matrices \mathbf{P}_r , $r = 1, \dots, n-1$. For \mathbf{P}_1 we use p_1 , q_1 , and r_1 given by (11.6.23). For the remaining matrices, p_r , q_r , and r_r are determined by the $(r, r-1)$, $(r+1, r-1)$, and $(r+2, r-1)$ elements of the current matrix. The number of arithmetic operations can be reduced by writing the nonzero elements of the $2\mathbf{w} \cdot \mathbf{w}^T$ part of the Householder matrix in the form

$$2\mathbf{w} \cdot \mathbf{w}^T = \begin{bmatrix} (p \pm s)/(\pm s) \\ q/(\pm s) \\ r/(\pm s) \end{bmatrix} \cdot [1 \quad q/(p \pm s) \quad r/(p \pm s)] \quad (11.6.24)$$

where

$$s^2 = p^2 + q^2 + r^2 \quad (11.6.25)$$

(We have simply divided each element by a piece of the normalizing factor; cf. the equations in §11.2.)

If we proceed in this way, convergence is usually very fast. There are two possible ways of terminating the iteration for an eigenvalue. First, if $a_{n,n-1}$ becomes “negligible,” then a_{nn} is an eigenvalue. We can then delete the n th row and column of the matrix and look for the next eigenvalue. Alternatively, $a_{n-1,n-2}$ may become negligible. In this case the eigenvalues of the 2×2 matrix in the lower right-hand corner may be taken to be eigenvalues. We delete the n th and $(n-1)$ st rows and columns of the matrix and continue.

The test for convergence to an eigenvalue is combined with a test for negligible subdiagonal elements that allows splitting of the matrix into submatrices. We find the largest i such that $a_{i,i-1}$ is negligible. If $i = n$, we have found a single eigenvalue. If $i = n-1$, we have found two eigenvalues. Otherwise we continue the iteration on the submatrix in rows i to n (i being set to unity if there is no small subdiagonal element).

After determining i , the submatrix in rows i to n is examined to see if the *product* of any two consecutive subdiagonal elements is small enough that we can work with an even smaller submatrix, starting say in row m . We start with $m = n-2$ and decrement it down to $i+1$, computing p , q , and r according to equations (11.6.23) with 1 replaced by m and 2 by $m+1$. If these were indeed the elements of the special “first” Householder matrix in a double QR step, then applying the Householder matrix would lead to nonzero elements in positions $(m+1, m-1)$, $(m+2, m-1)$, and $(m+2, m)$. We require that the first two of these elements be

small compared with the local diagonal elements $a_{m-1,m-1}$, a_{mm} and $a_{m+1,m+1}$. A satisfactory approximate criterion is

$$|a_{m,m-1}|(|q| + |r|) \ll |p|(|a_{m+1,m+1}| + |a_{mm}| + |a_{m-1,m-1}|) \quad (11.6.26)$$

Very rarely, the procedure described so far will fail to converge. On such matrices, experience shows that if one double step is performed with any shifts that are of order the norm of the matrix, convergence is subsequently very rapid. Accordingly, if ten iterations occur without determining an eigenvalue, the usual shifts are replaced for the next iteration by shifts defined by

$$\begin{aligned} k_s + k_{s+1} &= 1.5 \times (|a_{n,n-1}| + |a_{n-1,n-2}|) \\ k_s k_{s+1} &= (|a_{n,n-1}| + |a_{n-1,n-2}|)^2 \end{aligned} \quad (11.6.27)$$

The factor 1.5 was arbitrarily chosen to lessen the likelihood of an “unfortunate” choice of shifts. This strategy is repeated after 20 unsuccessful iterations. After 30 unsuccessful iterations, the routine reports failure.

The operation count for the *QR* algorithm described here is $\sim 5k^2$ per iteration, where k is the current size of the matrix. The typical average number of iterations per eigenvalue is ~ 1.8 , so the total operation count for all the eigenvalues is $\sim 3n^3$. This estimate neglects any possible efficiency due to splitting or sparseness of the matrix.

The following routine `hqr` is based algorithmically on the above description, in turn following the implementations in [1,2].

```
SUBROUTINE hqr(a,n,np,wr,wi)
INTEGER n,np
REAL a(np,np),wi(np),wr(np)
Finds all eigenvalues of an n by n upper Hessenberg matrix a that is stored in an np by np
array. On input a can be exactly as output from elmhes §11.5; on output it is destroyed.
The real and imaginary parts of the eigenvalues are returned in wr and wi, respectively.
INTEGER i,its,j,k,l,m,nn
REAL anorm,p,q,r,s,t,u,v,w,x,y,z
anorm=0.
Compute matrix norm for possible use
in locating single small subdiagonal
element.
do 12 i=1,n
    do 11 j=max(i-1,1),n
        anorm=anorm+abs(a(i,j))
    enddo 11
enddo 12
nn=n
t=0.
Gets changed only by an exceptional shift.
Begin search for next eigenvalue.
1  if(nn.ge.1)then
    its=0
2  do 13 l=nn,2,-1
        s=abs(a(l-1,1-1))+abs(a(1,1))
        if(s.eq.0.)s=anorm
        if(abs(a(1,1-1))+s.eq.s)then
            abs(a(1,1-1)=0.
            goto 3
        endif
    enddo 13
    l=1
3  x=a(nn,nn)
    if(l.eq.nn)then
        wr(nn)=x+t
        wi(nn)=0.
        nn=nn-1
    One root found.
```

```

11.7 Improving Eigenvalues and/or Finding Eigenvectors by Inverse Iteration

The basic idea behind inverse iteration is quite simple. Let \mathbf{y} be the solution of the linear system

$$(\mathbf{A} - \tau \mathbf{1}) \cdot \mathbf{y} = \mathbf{b} \quad (11.7.1)$$

where \mathbf{b} is a random vector and τ is close to some eigenvalue λ of \mathbf{A} . Then the solution \mathbf{y} will be close to the eigenvector corresponding to λ . The procedure can be iterated: Replace \mathbf{b} by \mathbf{y} and solve for a new \mathbf{y} , which will be even closer to the true eigenvector.

We can see why this works by expanding both \mathbf{y} and \mathbf{b} as linear combinations of the eigenvectors \mathbf{x}_j of \mathbf{A} :

$$\mathbf{y} = \sum_j \alpha_j \mathbf{x}_j \quad \mathbf{b} = \sum_j \beta_j \mathbf{x}_j \quad (11.7.2)$$

Then (11.7.1) gives

$$\sum_j \alpha_j (\lambda_j - \tau) \mathbf{x}_j = \sum_j \beta_j \mathbf{x}_j \quad (11.7.3)$$

so that

$$\alpha_j = \frac{\beta_j}{\lambda_j - \tau} \quad (11.7.4)$$

and

$$\mathbf{y} = \sum_j \frac{\beta_j \mathbf{x}_j}{\lambda_j - \tau} \quad (11.7.5)$$

If τ is close to λ_n , say, then provided β_n is not accidentally too small, \mathbf{y} will be approximately \mathbf{x}_n , up to a normalization. Moreover, each iteration of this procedure gives another power of $\lambda_j - \tau$ in the denominator of (11.7.5). Thus the convergence is rapid for well-separated eigenvalues.

Suppose at the k th stage of iteration we are solving the equation

$$(\mathbf{A} - \tau_k \mathbf{1}) \cdot \mathbf{y} = \mathbf{b}_k \quad (11.7.6)$$

where \mathbf{b}_k and τ_k are our current guesses for some eigenvector and eigenvalue of interest (let's say, \mathbf{x}_n and λ_n). Normalize \mathbf{b}_k so that $\mathbf{b}_k \cdot \mathbf{b}_k = 1$. The exact eigenvector and eigenvalue satisfy

$$\mathbf{A} \cdot \mathbf{x}_n = \lambda_n \mathbf{x}_n \quad (11.7.7)$$

so

$$(\mathbf{A} - \tau_k \mathbf{1}) \cdot \mathbf{x}_n = (\lambda_n - \tau_k) \mathbf{x}_n \quad (11.7.8)$$

Since \mathbf{y} of (11.7.6) is an improved approximation to \mathbf{x}_n , we normalize it and set

$$\mathbf{b}_{k+1} = \frac{\mathbf{y}}{|\mathbf{y}|} \quad (11.7.9)$$

11.7 Improving Eigenvalues and/or Finding Eigenvectors by Inverse Iteration

The basic idea behind inverse iteration is quite simple. Let \mathbf{y} be the solution of the linear system

$$(\mathbf{A} - \tau \mathbf{1}) \cdot \mathbf{y} = \mathbf{b} \quad (11.7.1)$$

where \mathbf{b} is a random vector and τ is close to some eigenvalue λ of \mathbf{A} . Then the solution \mathbf{y} will be close to the eigenvector corresponding to λ . The procedure can be iterated: Replace \mathbf{b} by \mathbf{y} and solve for a new \mathbf{y} , which will be even closer to the true eigenvector.

We can see why this works by expanding both \mathbf{y} and \mathbf{b} as linear combinations of the eigenvectors \mathbf{x}_j of \mathbf{A} :

$$\mathbf{y} = \sum_j \alpha_j \mathbf{x}_j \quad \mathbf{b} = \sum_j \beta_j \mathbf{x}_j \quad (11.7.2)$$

Then (11.7.1) gives

$$\sum_j \alpha_j (\lambda_j - \tau) \mathbf{x}_j = \sum_j \beta_j \mathbf{x}_j \quad (11.7.3)$$

so that

$$\alpha_j = \frac{\beta_j}{\lambda_j - \tau} \quad (11.7.4)$$

and

$$\mathbf{y} = \sum_j \frac{\beta_j \mathbf{x}_j}{\lambda_j - \tau} \quad (11.7.5)$$

If τ is close to λ_n , say, then provided β_n is not accidentally too small, \mathbf{y} will be approximately \mathbf{x}_n , up to a normalization. Moreover, each iteration of this procedure gives another power of $\lambda_j - \tau$ in the denominator of (11.7.5). Thus the convergence is rapid for well-separated eigenvalues.

Suppose at the k th stage of iteration we are solving the equation

$$(\mathbf{A} - \tau_k \mathbf{1}) \cdot \mathbf{y} = \mathbf{b}_k \quad (11.7.6)$$

where \mathbf{b}_k and τ_k are our current guesses for some eigenvector and eigenvalue of interest (let's say, \mathbf{x}_n and λ_n). Normalize \mathbf{b}_k so that $\mathbf{b}_k \cdot \mathbf{b}_k = 1$. The exact eigenvector and eigenvalue satisfy

$$\mathbf{A} \cdot \mathbf{x}_n = \lambda_n \mathbf{x}_n \quad (11.7.7)$$

so

$$(\mathbf{A} - \tau_k \mathbf{1}) \cdot \mathbf{x}_n = (\lambda_n - \tau_k) \mathbf{x}_n \quad (11.7.8)$$

Since \mathbf{y} of (11.7.6) is an improved approximation to \mathbf{x}_n , we normalize it and set

$$\mathbf{b}_{k+1} = \frac{\mathbf{y}}{|\mathbf{y}|} \quad (11.7.9)$$

We get an improved estimate of the eigenvalue by substituting our improved guess \mathbf{y} for \mathbf{x}_n in (11.7.8). By (11.7.6), the left-hand side is \mathbf{b}_k , so calling λ_n our new value τ_{k+1} , we find

$$\tau_{k+1} = \tau_k + \frac{1}{\mathbf{b}_k \cdot \mathbf{y}} \quad (11.7.10)$$

While the above formulas look simple enough, in practice the implementation can be quite tricky. The first question to be resolved is *when* to use inverse iteration. Most of the computational load occurs in solving the linear system (11.7.6). Thus a possible strategy is first to reduce the matrix \mathbf{A} to a special form that allows easy solution of (11.7.6). Tridiagonal form for symmetric matrices or Hessenberg for nonsymmetric are the obvious choices. Then apply inverse iteration to generate all the eigenvectors. While this is an $O(N^3)$ method for symmetric matrices, it is many times less efficient than the *QL* method given earlier. In fact, even the best inverse iteration packages are less efficient than the *QL* method as soon as more than about 25 percent of the eigenvectors are required. Accordingly, inverse iteration is generally used when one already has good eigenvalues and wants only a few selected eigenvectors.

You can write a simple inverse iteration routine yourself using *LU* decomposition to solve (11.7.6). You can decide whether to use the general *LU* algorithm we gave in Chapter 2 or whether to take advantage of tridiagonal or Hessenberg form. Note that, since the linear system (11.7.6) is nearly singular, you must be careful to use a version of *LU* decomposition like that in §2.3 which replaces a zero pivot with a very small number.

We have chosen not to give a general inverse iteration routine in this book, because it is quite cumbersome to take account of all the cases that can arise. Routines are given, for example, in [1,2]. If you use these, or write your own routine, you may appreciate the following pointers.

One starts by supplying an initial value τ_0 for the eigenvalue λ_n of interest. Choose a random normalized vector \mathbf{b}_0 as the initial guess for the eigenvector \mathbf{x}_n , and solve (11.7.6). The new vector \mathbf{y} is bigger than \mathbf{b}_0 by a “growth factor” $|\mathbf{y}|$, which ideally should be large. Equivalently, the change in the eigenvalue, which by (11.7.10) is essentially $1/|\mathbf{y}|$, should be small. The following cases can arise:

- If the growth factor is too small initially, then we assume we have made a “bad” choice of random vector. This can happen not just because of a small β_n in (11.7.5), but also in the case of a defective matrix, when (11.7.5) does not even apply (see, e.g., [1] or [3] for details). We go back to the beginning and choose a new initial vector.
- The change $|\mathbf{b}_1 - \mathbf{b}_0|$ might be less than some tolerance ϵ . We can use this as a criterion for stopping, iterating until it is satisfied, with a maximum of 5 – 10 iterations, say.
- After a few iterations, if $|\mathbf{b}_{k+1} - \mathbf{b}_k|$ is not decreasing rapidly enough, we can try updating the eigenvalue according to (11.7.10). If $\tau_{k+1} = \tau_k$ to machine accuracy, we are not going to improve the eigenvector much more and can quit. Otherwise start another cycle of iterations with the new eigenvalue.

The reason we do not update the eigenvalue at every step is that when we solve the linear system (11.7.6) by *LU* decomposition, we can save the decomposition

if τ_k is fixed. We only need do the backsubstitution step each time we update \mathbf{b}_k . The number of iterations we decide to do with a fixed τ_k is a trade-off between the quadratic convergence but $O(N^3)$ workload for updating τ_k at each step and the linear convergence but $O(N^2)$ load for keeping τ_k fixed. If you have determined the eigenvalue by one of the routines given earlier in the chapter, it is probably correct to machine accuracy anyway, and you can omit updating it.

There are two different pathologies that can arise during inverse iteration. The first is multiple or closely spaced roots. This is more often a problem with symmetric matrices. Inverse iteration will find only one eigenvector for a given initial guess τ_0 . A good strategy is to perturb the last few significant digits in τ_0 and then repeat the iteration. Usually this provides an independent eigenvector. Special steps generally have to be taken to ensure orthogonality of the linearly independent eigenvectors, whereas the Jacobi and QL algorithms automatically yield orthogonal eigenvectors even in the case of multiple eigenvalues.

The second problem, peculiar to nonsymmetric matrices, is the defective case. Unless one makes a “good” initial guess, the growth factor is small. Moreover, iteration does not improve matters. In this case, the remedy is to choose random initial vectors, solve (11.7.6) once, and quit as soon as *any* vector gives an acceptably large growth factor. Typically only a few trials are necessary.

One further complication in the nonsymmetric case is that a real matrix can have complex-conjugate pairs of eigenvalues. You will then have to use complex arithmetic to solve (11.7.6) for the complex eigenvectors. For any moderate-sized (or larger) nonsymmetric matrix, our recommendation is to avoid inverse iteration in favor of a QR method that includes the eigenvector computation in complex arithmetic. You will find routines for this in [1,2] and other places.

Chapter 12. Fast Fourier Transform

12.0 Introduction

A very large class of important computational problems falls under the general rubric of “Fourier transform methods” or “spectral methods.” For some of these problems, the Fourier transform is simply an efficient computational tool for accomplishing certain common manipulations of data. In other cases, we have problems for which the Fourier transform (or the related “power spectrum”) is itself of intrinsic interest. These two kinds of problems share a common methodology.

Largely for historical reasons the literature on Fourier and spectral methods has been disjoint from the literature on “classical” numerical analysis. Nowadays there is no justification for such a split. Fourier methods are commonplace in research and we shall not treat them as specialized or arcane. At the same time, we realize that many computer users have had relatively less experience with this field than with, say, differential equations or numerical integration. Therefore our summary of analytical results will be more complete. Numerical algorithms, *per se*, begin in §12.2. Various applications of Fourier transform methods are discussed in Chapter 13.

A physical process can be described either in the *time domain*, by the values of some quantity h as a function of time t , e.g., $h(t)$, or else in the *frequency domain*, where the process is specified by giving its amplitude H (generally a complex number indicating phase also) as a function of frequency f , that is $H(f)$, with $-\infty < f < \infty$. For many purposes it is useful to think of $h(t)$ and $H(f)$ as being two different *representations* of the *same* function. One goes back and forth between these two representations by means of the *Fourier transform* equations,

$$\begin{aligned} H(f) &= \int_{-\infty}^{\infty} h(t)e^{2\pi ift}dt \\ h(t) &= \int_{-\infty}^{\infty} H(f)e^{-2\pi ift}df \end{aligned} \tag{12.0.1}$$

If t is measured in seconds, then f in equation (12.0.1) is in cycles per second, or Hertz (the unit of frequency). However, the equations work with other units too. If h is a function of position x (in meters), H will be a function of inverse wavelength (cycles per meter), and so on. If you are trained as a physicist or mathematician, you are probably more used to using *angular frequency* ω , which is given in radians per sec. The relation between ω and f , $H(\omega)$ and $H(f)$ is

$$\omega \equiv 2\pi f \quad H(\omega) \equiv [H(f)]_{f=\omega/2\pi} \tag{12.0.2}$$

and equation (12.0.1) looks like this

$$\begin{aligned} H(\omega) &= \int_{-\infty}^{\infty} h(t)e^{i\omega t} dt \\ h(t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} H(\omega)e^{-i\omega t} d\omega \end{aligned} \quad (12.0.3)$$

We were raised on the ω -convention, but we changed! There are fewer factors of 2π to remember if you use the f -convention, especially when we get to discretely sampled data in §12.1.

From equation (12.0.1) it is evident at once that Fourier transformation is a *linear* operation. The transform of the sum of two functions is equal to the sum of the transforms. The transform of a constant times a function is that same constant times the transform of the function.

In the time domain, function $h(t)$ may happen to have one or more special symmetries. It might be *purely real* or *purely imaginary* or it might be *even*, $h(t) = h(-t)$, or *odd*, $h(t) = -h(-t)$. In the frequency domain, these symmetries lead to relationships between $H(f)$ and $H(-f)$. The following table gives the correspondence between symmetries in the two domains:

If . . .	then . . .
$h(t)$ is real	$H(-f) = [H(f)]^*$
$h(t)$ is imaginary	$H(-f) = -[H(f)]^*$
$h(t)$ is even	$H(-f) = H(f)$ [i.e., $H(f)$ is even]
$h(t)$ is odd	$H(-f) = -H(f)$ [i.e., $H(f)$ is odd]
$h(t)$ is real and even	$H(f)$ is real and even
$h(t)$ is real and odd	$H(f)$ is imaginary and odd
$h(t)$ is imaginary and even	$H(f)$ is imaginary and even
$h(t)$ is imaginary and odd	$H(f)$ is real and odd

In subsequent sections we shall see how to use these symmetries to increase computational efficiency.

Here are some other elementary properties of the Fourier transform. (We'll use the “ \iff ” symbol to indicate transform pairs.) If

$$h(t) \iff H(f)$$

is such a pair, then other transform pairs are

$$h(at) \iff \frac{1}{|a|} H\left(\frac{f}{a}\right) \quad \text{“time scaling”} \quad (12.0.4)$$

$$\frac{1}{|b|} h\left(\frac{t}{b}\right) \iff H(bf) \quad \text{“frequency scaling”} \quad (12.0.5)$$

$$h(t - t_0) \iff H(f) e^{2\pi i f t_0} \quad \text{“time shifting”} \quad (12.0.6)$$

$$h(t) e^{-2\pi i f_0 t} \iff H(f - f_0) \quad \text{“frequency shifting”} \quad (12.0.7)$$

With two functions $h(t)$ and $g(t)$, and their corresponding Fourier transforms $H(f)$ and $G(f)$, we can form two combinations of special interest. The *convolution* of the two functions, denoted $g * h$, is defined by

$$g * h \equiv \int_{-\infty}^{\infty} g(\tau)h(t - \tau) d\tau \quad (12.0.8)$$

Note that $g * h$ is a function in the time domain and that $g * h = h * g$. It turns out that the function $g * h$ is one member of a simple transform pair

$$g * h \iff G(f)H(f) \quad \text{“Convolution Theorem”} \quad (12.0.9)$$

In other words, the Fourier transform of the convolution is just the product of the individual Fourier transforms.

The *correlation* of two functions, denoted $\text{Corr}(g, h)$, is defined by

$$\text{Corr}(g, h) \equiv \int_{-\infty}^{\infty} g(\tau + t)h(\tau) d\tau \quad (12.0.10)$$

The correlation is a function of t , which is called the *lag*. It therefore lies in the time domain, and it turns out to be one member of the transform pair:

$$\text{Corr}(g, h) \iff G(f)H^*(f) \quad \text{“Correlation Theorem”} \quad (12.0.11)$$

[More generally, the second member of the pair is $G(f)H(-f)$, but we are restricting ourselves to the usual case in which g and h are real functions, so we take the liberty of setting $H(-f) = H^*(f)$.] This result shows that multiplying the Fourier transform of one function by the complex conjugate of the Fourier transform of the other gives the Fourier transform of their correlation. The correlation of a function with itself is called its *autocorrelation*. In this case (12.0.11) becomes the transform pair

$$\text{Corr}(g, g) \iff |G(f)|^2 \quad \text{“Wiener-Khinchin Theorem”} \quad (12.0.12)$$

The *total power* in a signal is the same whether we compute it in the time domain or in the frequency domain. This result is known as *Parseval’s theorem*:

$$\text{Total Power} \equiv \int_{-\infty}^{\infty} |h(t)|^2 dt = \int_{-\infty}^{\infty} |H(f)|^2 df \quad (12.0.13)$$

Frequently one wants to know “how much power” is contained in the frequency interval between f and $f + df$. In such circumstances one does not usually distinguish between positive and negative f , but rather regards f as varying from 0 (“zero frequency” or D.C.) to $+\infty$. In such cases, one defines the *one-sided power spectral density (PSD)* of the function h as

$$P_h(f) \equiv |H(f)|^2 + |H(-f)|^2 \quad 0 \leq f < \infty \quad (12.0.14)$$

so that the total power is just the integral of $P_h(f)$ from $f = 0$ to $f = \infty$. When the function $h(t)$ is real, then the two terms in (12.0.14) are equal, so $P_h(f) = 2|H(f)|^2$.

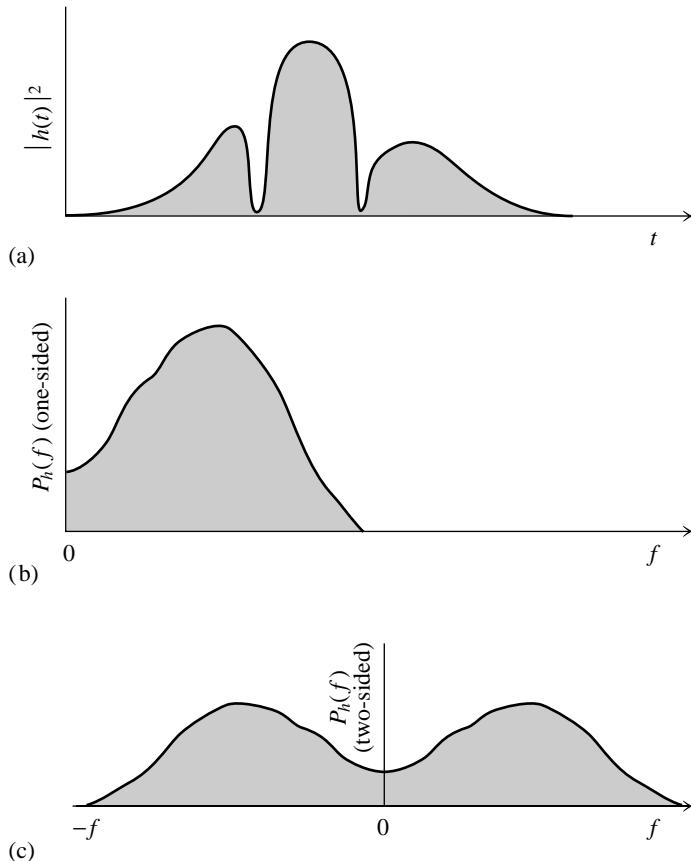

Figure 12.0.1. Normalizations of one- and two-sided power spectra. The area under the square of the function, (a), equals the area under its one-sided power spectrum at positive frequencies, (b), and also equals the area under its two-sided power spectrum at positive and negative frequencies, (c).

Be warned that one occasionally sees PSDs defined without this factor two. These, strictly speaking, are called *two-sided power spectral densities*, but some books are not careful about stating whether one- or two-sided is to be assumed. We will always use the one-sided density given by equation (12.0.14). Figure 12.0.1 contrasts the two conventions.

If the function $h(t)$ goes endlessly from $-\infty < t < \infty$, then its total power and power spectral density will, in general, be infinite. Of interest then is the (*one- or two-sided*) *power spectral density per unit time*. This is computed by taking a long, but finite, stretch of the function $h(t)$, computing its PSD [that is, the PSD of a function that equals $h(t)$ in the finite stretch but is zero everywhere else], and then dividing the resulting PSD by the length of the stretch used. Parseval's theorem in this case states that the integral of the one-sided PSD-per-unit-time over positive frequency is equal to the mean square amplitude of the signal $h(t)$.

You might well worry about how the PSD-per-unit-time, which is a function of frequency f , converges as one evaluates it using longer and longer stretches of data. This interesting question is the content of the subject of “power spectrum estimation,” and will be considered below in §13.4–§13.7. A crude answer for now is: The

PSD-per-unit-time converges to finite values at all frequencies *except* those where $h(t)$ has a discrete sine-wave (or cosine-wave) component of finite amplitude. At those frequencies, it becomes a delta-function, i.e., a sharp spike, whose width gets narrower and narrower, but whose area converges to be the mean square amplitude of the discrete sine or cosine component at that frequency.

We have by now stated all of the analytical formalism that we will need in this chapter with one exception: In computational work, especially with experimental data, we are almost never given a continuous function $h(t)$ to work with, but are given, rather, a list of measurements of $h(t_i)$ for a discrete set of t_i 's. The profound implications of this seemingly unimportant fact are the subject of the next section.

12.1 Fourier Transform of Discretely Sampled Data

In the most common situations, function $h(t)$ is sampled (i.e., its value is recorded) at evenly spaced intervals in time. Let Δ denote the time interval between consecutive samples, so that the sequence of sampled values is

$$h_n = h(n\Delta) \quad n = \dots, -3, -2, -1, 0, 1, 2, 3, \dots \quad (12.1.1)$$

The reciprocal of the time interval Δ is called the *sampling rate*; if Δ is measured in seconds, for example, then the sampling rate is the number of samples recorded per second.

Sampling Theorem and Aliasing

For any sampling interval Δ , there is also a special frequency f_c , called the *Nyquist critical frequency*, given by

$$f_c \equiv \frac{1}{2\Delta} \quad (12.1.2)$$

If a sine wave of the Nyquist critical frequency is sampled at its positive peak value, then the next sample will be at its negative trough value, the sample after that at the positive peak again, and so on. Expressed otherwise: *Critical sampling of a sine wave is two sample points per cycle*. One frequently chooses to measure time in units of the sampling interval Δ . In this case the Nyquist critical frequency is just the constant 1/2.

The Nyquist critical frequency is important for two related, but distinct, reasons. One is good news, and the other bad news. First the good news. It is the remarkable

12.1 Fourier Transform of Discretely Sampled Data

In the most common situations, function $h(t)$ is sampled (i.e., its value is recorded) at evenly spaced intervals in time. Let Δ denote the time interval between consecutive samples, so that the sequence of sampled values is

$$h_n = h(n\Delta) \quad n = \dots, -3, -2, -1, 0, 1, 2, 3, \dots \quad (12.1.1)$$

The reciprocal of the time interval Δ is called the *sampling rate*; if Δ is measured in seconds, for example, then the sampling rate is the number of samples recorded per second.

Sampling Theorem and Aliasing

For any sampling interval Δ , there is also a special frequency f_c , called the *Nyquist critical frequency*, given by

$$f_c \equiv \frac{1}{2\Delta} \quad (12.1.2)$$

If a sine wave of the Nyquist critical frequency is sampled at its positive peak value, then the next sample will be at its negative trough value, the sample after that at the positive peak again, and so on. Expressed otherwise: *Critical sampling of a sine wave is two sample points per cycle*. One frequently chooses to measure time in units of the sampling interval Δ . In this case the Nyquist critical frequency is just the constant $1/2$.

The Nyquist critical frequency is important for two related, but distinct, reasons. One is good news, and the other bad news. First the good news. It is the remarkable

fact known as the *sampling theorem*: If a continuous function $h(t)$, sampled at an interval Δ , happens to be *bandwidth limited* to frequencies smaller in magnitude than f_c , i.e., if $H(f) = 0$ for all $|f| \geq f_c$, then the function $h(t)$ is *completely determined* by its samples h_n . In fact, $h(t)$ is given explicitly by the formula

$$h(t) = \Delta \sum_{n=-\infty}^{+\infty} h_n \frac{\sin[2\pi f_c(t - n\Delta)]}{\pi(t - n\Delta)} \quad (12.1.3)$$

This is a remarkable theorem for many reasons, among them that it shows that the “information content” of a bandwidth limited function is, in some sense, infinitely smaller than that of a general continuous function. Fairly often, one is dealing with a signal that is known on physical grounds to be bandwidth limited (or at least approximately bandwidth limited). For example, the signal may have passed through an amplifier with a known, finite frequency response. In this case, the sampling theorem tells us that the entire information content of the signal can be recorded by sampling it at a rate Δ^{-1} equal to twice the maximum frequency passed by the amplifier (cf. 12.1.2).

Now the bad news. The bad news concerns the effect of sampling a continuous function that is *not* bandwidth limited to less than the Nyquist critical frequency. In that case, it turns out that all of the power spectral density that lies outside of the frequency range $-f_c < f < f_c$ is spuriously moved into that range. This phenomenon is called *aliasing*. Any frequency component outside of the frequency range $(-f_c, f_c)$ is *aliased* (falsely translated) into that range by the very act of discrete sampling. You can readily convince yourself that two waves $\exp(2\pi i f_1 t)$ and $\exp(2\pi i f_2 t)$ give the same samples at an interval Δ if and only if f_1 and f_2 differ by a multiple of $1/\Delta$, which is just the width in frequency of the range $(-f_c, f_c)$. There is little that you can do to remove aliased power once you have discretely sampled a signal. The way to overcome aliasing is to (i) know the natural bandwidth limit of the signal — or else enforce a known limit by analog filtering of the continuous signal, and then (ii) sample at a rate sufficiently rapid to give at least two points per cycle of the highest frequency present. Figure 12.1.1 illustrates these considerations.

To put the best face on this, we can take the alternative point of view: If a continuous function has been competently sampled, then, when we come to estimate its Fourier transform from the discrete samples, we can *assume* (or rather we *might as well assume*) that its Fourier transform is equal to zero outside of the frequency range in between $-f_c$ and f_c . Then we look to the Fourier transform to tell whether the continuous function *has* been competently sampled (aliasing effects minimized). We do this by looking to see whether the Fourier transform is already approaching zero as the frequency approaches f_c from below, or $-f_c$ from above. If, on the contrary, the transform is going towards some finite value, then chances are that components outside of the range have been folded back over onto the critical range.

Discrete Fourier Transform

We now estimate the Fourier transform of a function from a finite number of its sampled points. Suppose that we have N consecutive sampled values

$$h_k \equiv h(t_k), \quad t_k \equiv k\Delta, \quad k = 0, 1, 2, \dots, N - 1 \quad (12.1.4)$$

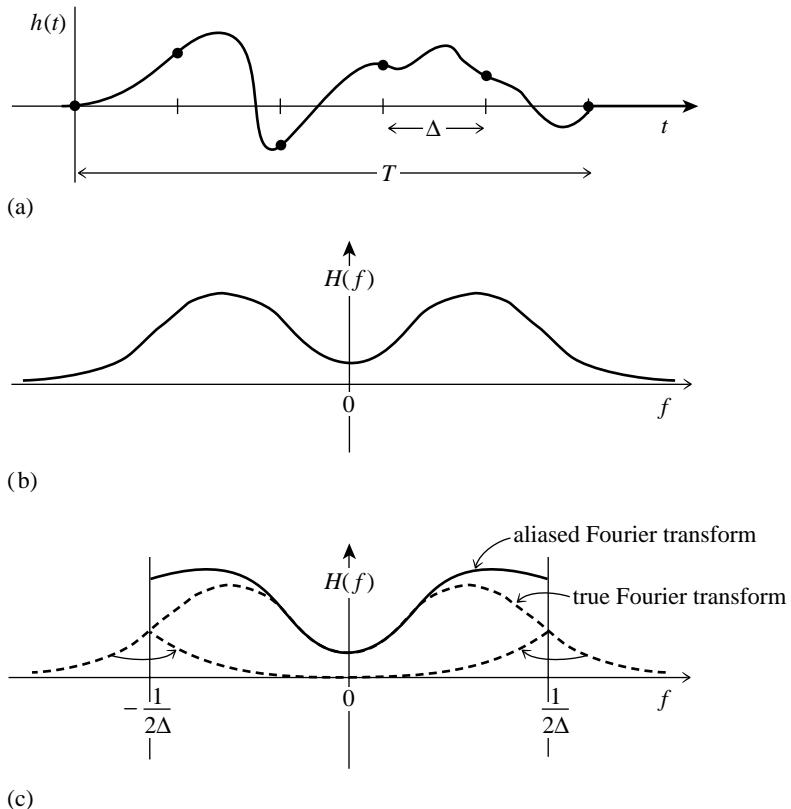

Figure 12.1.1. The continuous function shown in (a) is nonzero only for a finite interval of time T . It follows that its Fourier transform, whose modulus is shown schematically in (b), is not bandwidth limited but has finite amplitude for all frequencies. If the original function is sampled with a sampling interval Δ , as in (a), then the Fourier transform (c) is defined only between plus and minus the Nyquist critical frequency. Power outside that range is folded over or “aliased” into the range. The effect can be eliminated only by low-pass filtering the original function *before sampling*.

so that the sampling interval is Δ . To make things simpler, let us also suppose that N is even. If the function $h(t)$ is nonzero only in a finite interval of time, then that whole interval of time is supposed to be contained in the range of the N points given. Alternatively, if the function $h(t)$ goes on forever, then the sampled points are supposed to be at least “typical” of what $h(t)$ looks like at all other times.

With N numbers of input, we will evidently be able to produce no more than N independent numbers of output. So, instead of trying to estimate the Fourier transform $H(f)$ at all values of f in the range $-f_c$ to f_c , let us seek estimates only at the discrete values

$$f_n \equiv \frac{n}{N\Delta}, \quad n = -\frac{N}{2}, \dots, \frac{N}{2} \quad (12.1.5)$$

The extreme values of n in (12.1.5) correspond exactly to the lower and upper limits of the Nyquist critical frequency range. If you are really on the ball, you will have noticed that there are $N + 1$, not N , values of n in (12.1.5); it will turn out that the two extreme values of n are not independent (in fact they are equal), but all the others are. This reduces the count to N .

The remaining step is to approximate the integral in (12.0.1) by a discrete sum:

$$H(f_n) = \int_{-\infty}^{\infty} h(t)e^{2\pi i f_n t} dt \approx \sum_{k=0}^{N-1} h_k e^{2\pi i f_n t_k} \Delta = \Delta \sum_{k=0}^{N-1} h_k e^{2\pi i k n / N} \quad (12.1.6)$$

Here equations (12.1.4) and (12.1.5) have been used in the final equality. The final summation in equation (12.1.6) is called the *discrete Fourier transform* of the N points h_k . Let us denote it by H_n ,

$$H_n \equiv \sum_{k=0}^{N-1} h_k e^{2\pi i k n / N} \quad (12.1.7)$$

The discrete Fourier transform maps N complex numbers (the h_k 's) into N complex numbers (the H_n 's). It does not depend on any dimensional parameter, such as the time scale Δ . The relation (12.1.6) between the discrete Fourier transform of a set of numbers and their continuous Fourier transform when they are viewed as samples of a continuous function sampled at an interval Δ can be rewritten as

$$H(f_n) \approx \Delta H_n \quad (12.1.8)$$

where f_n is given by (12.1.5).

Up to now we have taken the view that the index n in (12.1.7) varies from $-N/2$ to $N/2$ (cf. 12.1.5). You can easily see, however, that (12.1.7) is periodic in n , with period N . Therefore, $H_{-n} = H_{N-n}$ $n = 1, 2, \dots$. With this conversion in mind, one generally lets the n in H_n vary from 0 to $N - 1$ (one complete period). Then n and k (in h_k) vary exactly over the same range, so the mapping of N numbers into N numbers is manifest. When this convention is followed, you must remember that zero frequency corresponds to $n = 0$, positive frequencies $0 < f < f_c$ correspond to values $1 \leq n \leq N/2 - 1$, while negative frequencies $-f_c < f < 0$ correspond to $N/2 + 1 \leq n \leq N - 1$. The value $n = N/2$ corresponds to both $f = f_c$ and $f = -f_c$.

The discrete Fourier transform has symmetry properties almost exactly the same as the continuous Fourier transform. For example, all the symmetries in the table following equation (12.0.3) hold if we read h_k for $h(t)$, H_n for $H(f)$, and H_{N-n} for $H(-f)$. (Likewise, “even” and “odd” in time refer to whether the values h_k at k and $N - k$ are identical or the negative of each other.)

The formula for the discrete *inverse* Fourier transform, which recovers the set of h_k 's exactly from the H_n 's is:

$$h_k = \frac{1}{N} \sum_{n=0}^{N-1} H_n e^{-2\pi i k n / N} \quad (12.1.9)$$

Notice that the only differences between (12.1.9) and (12.1.7) are (i) changing the sign in the exponential, and (ii) dividing the answer by N . This means that a routine for calculating discrete Fourier transforms can also, with slight modification, calculate the inverse transforms.

The discrete form of Parseval's theorem is

$$\sum_{k=0}^{N-1} |h_k|^2 = \frac{1}{N} \sum_{n=0}^{N-1} |H_n|^2 \quad (12.1.10)$$

There are also discrete analogs to the convolution and correlation theorems (equations 12.0.9 and 12.0.11), but we shall defer them to §13.1 and §13.2, respectively.

12.2 Fast Fourier Transform (FFT)

How much computation is involved in computing the discrete Fourier transform (12.1.7) of N points? For many years, until the mid-1960s, the standard answer was this: Define W as the complex number

$$W \equiv e^{2\pi i/N} \quad (12.2.1)$$

Then (12.1.7) can be written as

$$H_n = \sum_{k=0}^{N-1} W^{nk} h_k \quad (12.2.2)$$

In other words, the vector of h_k 's is multiplied by a matrix whose (n, k) th element is the constant W to the power $n \times k$. The matrix multiplication produces a vector result whose components are the H_n 's. This matrix multiplication evidently requires N^2 complex multiplications, plus a smaller number of operations to generate the required powers of W . So, the discrete Fourier transform appears to be an $O(N^2)$ process. These appearances are deceiving! The discrete Fourier transform can, in fact, be computed in $O(N \log_2 N)$ operations with an algorithm called the *fast Fourier transform*, or *FFT*. The difference between $N \log_2 N$ and N^2 is immense. With $N = 10^6$, for example, it is the difference between, roughly, 30 seconds of CPU time and 2 weeks of CPU time on a microsecond cycle time computer. The existence of an FFT algorithm became generally known only in the mid-1960s, from the work of J.W. Cooley and J.W. Tukey. Retrospectively, we now know (see [1]) that efficient methods for computing the DFT had been independently discovered, and in some cases implemented, by as many as a dozen individuals, starting with Gauss in 1805!

One "rediscovery" of the FFT, that of Danielson and Lanczos in 1942, provides one of the clearest derivations of the algorithm. Danielson and Lanczos showed that a discrete Fourier transform of length N can be rewritten as the sum of two discrete Fourier transforms, each of length $N/2$. One of the two is formed from the

The discrete form of Parseval's theorem is

$$\sum_{k=0}^{N-1} |h_k|^2 = \frac{1}{N} \sum_{n=0}^{N-1} |H_n|^2 \quad (12.1.10)$$

There are also discrete analogs to the convolution and correlation theorems (equations 12.0.9 and 12.0.11), but we shall defer them to §13.1 and §13.2, respectively.

12.2 Fast Fourier Transform (FFT)

How much computation is involved in computing the discrete Fourier transform (12.1.7) of N points? For many years, until the mid-1960s, the standard answer was this: Define W as the complex number

$$W \equiv e^{2\pi i/N} \quad (12.2.1)$$

Then (12.1.7) can be written as

$$H_n = \sum_{k=0}^{N-1} W^{nk} h_k \quad (12.2.2)$$

In other words, the vector of h_k 's is multiplied by a matrix whose (n, k) th element is the constant W to the power $n \times k$. The matrix multiplication produces a vector result whose components are the H_n 's. This matrix multiplication evidently requires N^2 complex multiplications, plus a smaller number of operations to generate the required powers of W . So, the discrete Fourier transform appears to be an $O(N^2)$ process. These appearances are deceiving! The discrete Fourier transform can, in fact, be computed in $O(N \log_2 N)$ operations with an algorithm called the *fast Fourier transform*, or *FFT*. The difference between $N \log_2 N$ and N^2 is immense. With $N = 10^6$, for example, it is the difference between, roughly, 30 seconds of CPU time and 2 weeks of CPU time on a microsecond cycle time computer. The existence of an FFT algorithm became generally known only in the mid-1960s, from the work of J.W. Cooley and J.W. Tukey. Retrospectively, we now know (see [1]) that efficient methods for computing the DFT had been independently discovered, and in some cases implemented, by as many as a dozen individuals, starting with Gauss in 1805!

One "rediscovery" of the FFT, that of Danielson and Lanczos in 1942, provides one of the clearest derivations of the algorithm. Danielson and Lanczos showed that a discrete Fourier transform of length N can be rewritten as the sum of two discrete Fourier transforms, each of length $N/2$. One of the two is formed from the

even-numbered points of the original N , the other from the odd-numbered points. The proof is simply this:

$$\begin{aligned}
 F_k &= \sum_{j=0}^{N-1} e^{2\pi i j k / N} f_j \\
 &= \sum_{j=0}^{N/2-1} e^{2\pi i k(2j)/N} f_{2j} + \sum_{j=0}^{N/2-1} e^{2\pi i k(2j+1)/N} f_{2j+1} \\
 &= \sum_{j=0}^{N/2-1} e^{2\pi i k j / (N/2)} f_{2j} + W^k \sum_{j=0}^{N/2-1} e^{2\pi i k j / (N/2)} f_{2j+1} \\
 &= F_k^e + W^k F_k^o
 \end{aligned} \tag{12.2.3}$$

In the last line, W is the same complex constant as in (12.2.1), F_k^e denotes the k th component of the Fourier transform of length $N/2$ formed from the even components of the original f_j 's, while F_k^o is the corresponding transform of length $N/2$ formed from the odd components. Notice also that k in the last line of (12.2.3) varies from 0 to N , not just to $N/2$. Nevertheless, the transforms F_k^e and F_k^o are periodic in k with length $N/2$. So each is repeated through two cycles to obtain F_k .

The wonderful thing about the *Danielson-Lanczos Lemma* is that it can be used recursively. Having reduced the problem of computing F_k to that of computing F_k^e and F_k^o , we can do the same reduction of F_k^e to the problem of computing the transform of its $N/4$ even-numbered input data and $N/4$ odd-numbered data. In other words, we can define F_k^{ee} and F_k^{eo} to be the discrete Fourier transforms of the points which are respectively even-even and even-odd on the successive subdivisions of the data.

Although there are ways of treating other cases, by far the easiest case is the one in which the original N is an integer power of 2. In fact, we categorically recommend that you *only* use FFTs with N a power of two. If the length of your data set is not a power of two, pad it with zeros up to the next power of two. (We will give more sophisticated suggestions in subsequent sections below.) With this restriction on N , it is evident that we can continue applying the Danielson-Lanczos Lemma until we have subdivided the data all the way down to transforms of length 1. What is the Fourier transform of length one? It is just the identity operation that copies its one input number into its one output slot! In other words, for every pattern of $\log_2 N$ e's and o's, there is a one-point transform that is just one of the input numbers f_n

$$F_k^{eeeee...oe} = f_n \quad \text{for some } n \tag{12.2.4}$$

(Of course this one-point transform actually does not depend on k , since it is periodic in k with period 1.)

The next trick is to figure out which value of n corresponds to which pattern of e's and o's in equation (12.2.4). The answer is: Reverse the pattern of e's and o's, then let $e = 0$ and $o = 1$, and you will have, *in binary* the value of n . Do you see why it works? It is because the successive subdivisions of the data into even and odd are tests of successive low-order (least significant) bits of n . This idea of *bit reversal* can be exploited in a very clever way which, along with the Danielson-Lanczos

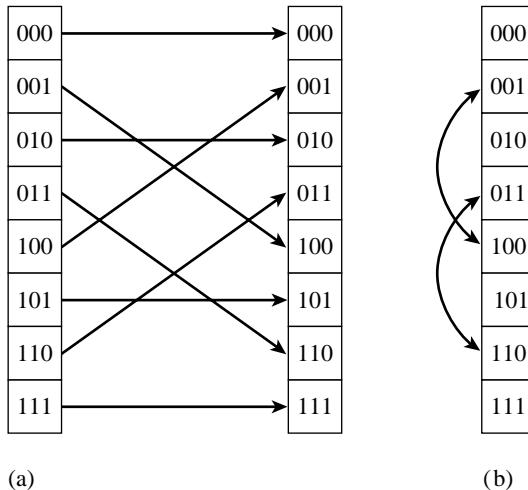

Figure 12.2.1. Reordering an array (here of length 8) by bit reversal, (a) between two arrays, versus (b) in place. Bit reversal reordering is a necessary part of the fast Fourier transform (FFT) algorithm.

Lemma, makes FFTs practical: Suppose we take the original vector of data f_j and rearrange it into bit-reversed order (see Figure 12.2.1), so that the individual numbers are in the order not of j , but of the number obtained by bit-reversing j . Then the bookkeeping on the recursive application of the Danielson-Lanczos Lemma becomes extraordinarily simple. The points as given are the one-point transforms. We combine adjacent pairs to get two-point transforms, then combine adjacent pairs of pairs to get 4-point transforms, and so on, until the first and second halves of the whole data set are combined into the final transform. Each combination takes of order N operations, and there are evidently $\log_2 N$ combinations, so the whole algorithm is of order $N \log_2 N$ (assuming, as is the case, that the process of sorting into bit-reversed order is no greater in order than $N \log_2 N$).

This, then, is the structure of an FFT algorithm: It has two sections. The first section sorts the data into bit-reversed order. Luckily this takes no additional storage, since it involves only swapping pairs of elements. (If k_1 is the bit reverse of k_2 , then k_2 is the bit reverse of k_1 .) The second section has an outer loop that is executed $\log_2 N$ times and calculates, in turn, transforms of length 2, 4, 8, ..., N . For each stage of this process, two nested inner loops range over the subtransforms already computed and the elements of each transform, implementing the Danielson-Lanczos Lemma. The operation is made more efficient by restricting external calls for trigonometric sines and cosines to the outer loop, where they are made only $\log_2 N$ times. Computation of the sines and cosines of multiple angles is through simple recurrence relations in the inner loops (cf. 5.5.6).

The FFT routine given below is based on one originally written by N. M. Brenner. The input quantities are the number of complex data points (`nn`), the data array (`data`), and `isign`, which should be set to either ± 1 and is the sign of i in the exponential of equation (12.1.7). When `isign` is set to -1 , the routine thus calculates the inverse transform (12.1.9) — except that it does not multiply by the normalizing factor $1/N$ that appears in that equation. You can do that yourself.

Notice that the argument `nn` is the number of *complex* data points, although

we avoid the use of complex arithmetic because of the inefficient implementations found on many computers. The actual length of the real array (`data`) is 2 times `nn`, with each complex value occupying two consecutive locations. In other words, `data(1)` is the real part of f_0 , `data(2)` is the imaginary part of f_0 , and so on up to `data(2*nn-1)`, which is the real part of f_{N-1} , and `data(2*nn)`, which is the imaginary part of f_{N-1} . The FFT routine returns the F_n 's packed in exactly the same fashion, as `nn` complex numbers.

The real and imaginary parts of the zero frequency component F_0 are in `data(1)` and `data(2)`; the smallest nonzero positive frequency has real and imaginary parts in `data(3)` and `data(4)`; the smallest (in magnitude) nonzero negative frequency has real and imaginary parts in `data(2*nn-1)` and `data(2*nn)`. Positive frequencies increasing in magnitude are stored in the real-imaginary pairs `data(5)`, `data(6)` up to `data(nn-1)`, `data(nn)`. Negative frequencies of increasing magnitude are stored in `data(2*nn-3)`, `data(2*nn-2)` down to `data(nn+3)`, `data(nn+4)`. Finally, the pair `data(nn+1)`, `data(nn+2)` contain the real and imaginary parts of the one aliased point that contains the most positive and the most negative frequency. You should try to develop a familiarity with this storage arrangement of complex spectra, also shown in Figure 12.2.2, since it is the practical standard.

```
SUBROUTINE four1(data,nn,isign)
INTEGER isign,nn
REAL data(2*nn)
    Replaces data(1:2*nn) by its discrete Fourier transform, if isign is input as 1; or replaces
    data(1:2*nn) by nn times its inverse discrete Fourier transform, if isign is input as -1.
    data is a complex array of length nn or, equivalently, a real array of length 2*nn. nn

(A double precision version of `four1`, named `dfour1`, is used by the routine `mpmul` in §20.6. You can easily make the conversion, or else get the converted routine from the *Numerical Recipes* diskette.)

Other FFT Algorithms

We should mention that there are a number of variants on the basic FFT algorithm given above. As we have seen, that algorithm first rearranges the input elements into bit-reverse order, then builds up the output transform in $\log_2 N$ iterations. In the literature, this sequence is called a *decimation-in-time* or *Cooley-Tukey* FFT algorithm. It is also possible to derive FFT algorithms that first go through a set of $\log_2 N$ iterations on the input data, and rearrange the *output* values into bit-reverse order. These are called *decimation-in-frequency* or *Sande-Tukey* FFT algorithms. For some applications, such as convolution (§13.1), one takes a data set into the Fourier domain and then, after some manipulation, back out again. In these cases it is possible to avoid all bit reversing. You use a decimation-in-frequency algorithm (without its bit reversing) to get into the “scrambled” Fourier domain, do your operations there, and then use an inverse algorithm (without *its* bit reversing) to get back to the time domain. While elegant in principle, this procedure does not in practice save much computation time, since the bit reversals represent only a small fraction of an FFT’s operations count, and since most useful operations in the frequency domain require a knowledge of which points correspond to which frequencies.

Another class of FFTs subdivides the initial data set of length N not all the way down to the trivial transform of length 1, but rather only down to some other small power of 2, for example $N = 4$, *base-4 FFTs*, or $N = 8$, *base-8 FFTs*. These small transforms are then done by small sections of highly optimized coding which take advantage of special symmetries of that particular small N . For example, for $N = 4$, the trigonometric sines and cosines that enter are all ± 1 or 0, so many multiplications are eliminated, leaving largely additions and subtractions. These can be faster than simpler FFTs by some significant, but not overwhelming, factor, e.g., 20 or 30 percent.

There are also FFT algorithms for data sets of length N not a power of two. They work by using relations analogous to the Danielson-Lanczos Lemma to subdivide the initial problem into successively smaller problems, not by factors of 2, but by whatever small prime factors happen to divide N . The larger that the largest prime factor of N is, the worse this method works. If N is prime, then no subdivision is possible, and the user (whether he knows it or not) is taking a *slow* Fourier transform, of order N^2 instead of order $N \log_2 N$. Our advice is to stay clear of such FFT implementations, with perhaps one class of exceptions, the *Winograd Fourier transform algorithms*. Winograd algorithms are in some ways analogous to the base-4 and base-8 FFTs. Winograd has derived highly optimized codings for taking small- N discrete Fourier transforms, e.g., for $N = 2, 3, 4, 5, 7, 8, 11, 13, 16$. The algorithms also use a new and clever way of combining the subfactors. The method involves a reordering of the data both before the hierarchical processing and after it, but it allows a significant reduction in the number of multiplications in the algorithm. For some especially favorable values of N , the Winograd algorithms can be significantly (e.g., up to a factor of 2) faster than the simpler FFT algorithms of the nearest integer power of 2. This advantage in speed, however, must be weighed against the considerably more complicated data indexing involved in these transforms, and the fact that the Winograd transform cannot be done “in place.”

Finally, an interesting class of transforms for doing convolutions quickly are number theoretic transforms. These schemes replace floating-point arithmetic with

integer arithmetic modulo some large prime $N+1$, and the N th root of 1 by the modulo arithmetic equivalent. Strictly speaking, these are not *Fourier* transforms at all, but the properties are quite similar and computational speed can be far superior. On the other hand, their use is somewhat restricted to quantities like correlations and convolutions since the transform itself is not easily interpretable as a “frequency” spectrum.

12.3 FFT of Real Functions, Sine and Cosine Transforms

It happens frequently that the data whose FFT is desired consist of real-valued samples f_j , $j = 0 \dots N - 1$. To use `four1`, we put these into a complex array with all imaginary parts set to zero. The resulting transform F_n , $n = 0 \dots N - 1$ satisfies $F_{N-n}^* = F_n$. Since this complex-valued array has real values for F_0 and $F_{N/2}$, and $(N/2) - 1$ other independent values $F_1 \dots F_{N/2-1}$, it has the same $2(N/2 - 1) + 2 = N$ “degrees of freedom” as the original, real data set. However, the use of the full complex FFT algorithm for real data is inefficient, both in execution time and in storage required. You would think that there is a better way.

There are *two* better ways. The first is “mass production”: Pack two separate real functions into the input array in such a way that their individual transforms can be separated from the result. This is implemented in the program `twofft` below. This may remind you of a one-cent sale, at which you are coerced to purchase two of an item when you only need one. However, remember that for correlations and convolutions the Fourier transforms of two functions are involved, and this is a handy way to do them both at once. The second method is to pack the real input array cleverly, without extra zeros, into a complex array of half its length. One then performs a complex FFT on this shorter length; the trick is then to get the required answer out of the result. This is done in the program `realfft` below.

integer arithmetic modulo some large prime $N+1$, and the N th root of 1 by the modulo arithmetic equivalent. Strictly speaking, these are not *Fourier* transforms at all, but the properties are quite similar and computational speed can be far superior. On the other hand, their use is somewhat restricted to quantities like correlations and convolutions since the transform itself is not easily interpretable as a “frequency” spectrum.

12.3 FFT of Real Functions, Sine and Cosine Transforms

It happens frequently that the data whose FFT is desired consist of real-valued samples f_j , $j = 0 \dots N - 1$. To use `four1`, we put these into a complex array with all imaginary parts set to zero. The resulting transform F_n , $n = 0 \dots N - 1$ satisfies $F_{N-n}^* = F_n$. Since this complex-valued array has real values for F_0 and $F_{N/2}$, and $(N/2) - 1$ other independent values $F_1 \dots F_{N/2-1}$, it has the same $2(N/2 - 1) + 2 = N$ “degrees of freedom” as the original, real data set. However, the use of the full complex FFT algorithm for real data is inefficient, both in execution time and in storage required. You would think that there is a better way.

There are *two* better ways. The first is “mass production”: Pack two separate real functions into the input array in such a way that their individual transforms can be separated from the result. This is implemented in the program `twofft` below. This may remind you of a one-cent sale, at which you are coerced to purchase two of an item when you only need one. However, remember that for correlations and convolutions the Fourier transforms of two functions are involved, and this is a handy way to do them both at once. The second method is to pack the real input array cleverly, without extra zeros, into a complex array of half its length. One then performs a complex FFT on this shorter length; the trick is then to get the required answer out of the result. This is done in the program `realfft` below.

Transform of Two Real Functions Simultaneously

First we show how to exploit the symmetry of the transform F_n to handle two real functions at once: Since the input data f_j are real, the components of the discrete Fourier transform satisfy

$$F_{N-n} = (F_n)^* \quad (12.3.1)$$

where the asterisk denotes complex conjugation. By the same token, the discrete Fourier transform of a purely imaginary set of g_j 's has the opposite symmetry.

$$G_{N-n} = -(G_n)^* \quad (12.3.2)$$

Therefore we can take the discrete Fourier transform of two real functions each of length N simultaneously by packing the two data arrays as the real and imaginary parts, respectively, of the complex input array of `four1`. Then the resulting transform array can be unpacked into two complex arrays with the aid of the two symmetries. Routine `twofft` works out these ideas.

```
SUBROUTINE twofft(data1,data2,fft1,fft2,n)
INTEGER n
REAL data1(n),data2(n)
COMPLEX fft1(n),fft2(n)
C USES four1
      Given two real input arrays data1(1:n) and data2(1:n), this routine calls four1 and
      returns two complex output arrays, fft1(1:n) and fft2(1:n), each of complex length n
      (i.e., real length 2*n), which contain the discrete Fourier transforms of the respective data
      arrays. n MUST be an integer power of 2.
      INTEGER j,n2
      COMPLEX h1,h2,c1,c2
      c1=cmplx(0.5,0.0)
      c2=cmplx(0.0,-0.5)
      do 11 j=1,n
         fft1(j)=cmplx(data1(j),data2(j))      Pack the two real arrays into one complex
      enddo 11
      call four1(fft1,n,1)                      array.
      fft2(1)=cmplx(aimag(fft1(1)),0.0)          Transform the complex array.
      fft1(1)=cmplx(real(fft1(1)),0.0)
      n2=n+2
      do 12 j=2,n/2+1
         h1=c1*(fft1(j)+conjg(fft1(n2-j)))
         h2=c2*(fft1(j)-conjg(fft1(n2-j)))
         fft1(j)=h1                                Use symmetries to separate the two trans-
         fft1(n2-j)=conjg(h1)                      forms.
         fft2(j)=h2                                Ship them out in two complex arrays.
         fft2(n2-j)=conjg(h2)
      enddo 12
      return
END
```

What about the reverse process? Suppose you have two complex transform arrays, each of which has the symmetry (12.3.1), so that you know that the inverses of both transforms are real functions. Can you invert both in a single FFT? This is even easier than the other direction. Use the fact that the FFT is linear and form the sum of the first transform plus i times the second. Invert using `four1` with

`isign` = -1. The real and imaginary parts of the resulting complex array are the two desired real functions.

FFT of Single Real Function

To implement the second method, which allows us to perform the FFT of a *single* real function without redundancy, we split the data set in half, thereby forming two real arrays of half the size. We can apply the program above to these two, but of course the result will not be the transform of the original data. It will be a schizophrenic combination of two transforms, each of which has half of the information we need. Fortunately, this schizophrenia is treatable. It works like this:

The right way to split the original data is to take the even-numbered f_j as one data set, and the odd-numbered f_j as the other. The beauty of this is that we can take the original real array and treat it as a complex array h_j of half the length. The first data set is the real part of this array, and the second is the imaginary part, as prescribed for `twofft`. No repacking is required. In other words $h_j = f_{2j} + if_{2j+1}$, $j = 0, \dots, N/2 - 1$. We submit this to `four1`, and it will return a complex array $H_n = F_n^e + iF_n^o$, $n = 0, \dots, N/2 - 1$ with

$$\begin{aligned} F_n^e &= \sum_{k=0}^{N/2-1} f_{2k} e^{2\pi i kn/(N/2)} \\ F_n^o &= \sum_{k=0}^{N/2-1} f_{2k+1} e^{2\pi i kn/(N/2)} \end{aligned} \quad (12.3.3)$$

The discussion of program `twofft` tells you how to separate the two transforms F_n^e and F_n^o out of H_n . How do you work them into the transform F_n of the original data set f_j ? Simply glance back at equation (12.2.3):

$$F_n = F_n^e + e^{2\pi in/N} F_n^o \quad n = 0, \dots, N - 1 \quad (12.3.4)$$

Expressed directly in terms of the transform H_n of our real (masquerading as complex) data set, the result is

$$F_n = \frac{1}{2}(H_n + H_{N/2-n}^*) - \frac{i}{2}(H_n - H_{N/2-n}^*)e^{2\pi in/N} \quad n = 0, \dots, N - 1 \quad (12.3.5)$$

A few remarks:

- Since $F_{N-n}^* = F_n$ there is no point in saving the entire spectrum. The positive frequency half is sufficient and can be stored in the same array as the original data. The operation can, in fact, be done in place.
- Even so, we need values H_n , $n = 0, \dots, N/2$ whereas `four1` returns only the values $n = 0, \dots, N/2 - 1$. Symmetry to the rescue, $H_{N/2} = H_0$.
- The values F_0 and $F_{N/2}$ are real and independent. In order to actually get the entire F_n in the original array space, it is convenient to return $F_{N/2}$ as the imaginary part of F_0 .

- Despite its complicated form, the process above is invertible. First peel $F_{N/2}$ out of F_0 . Then construct

$$\begin{aligned} F_n^e &= \frac{1}{2}(F_n + F_{N/2-n}^*) & n = 0, \dots, N/2 - 1 \\ F_n^o &= \frac{1}{2}e^{-2\pi in/N}(F_n - F_{N/2-n}^*) \end{aligned} \quad (12.3.6)$$

and use `four1` to find the inverse transform of $H_n = F_n^{(1)} + iF_n^{(2)}$. Surprisingly, the actual algebraic steps are virtually identical to those of the forward transform.

Here is a representation of what we have said:

```
SUBROUTINE realft(data,n,isign)
INTEGER isign,n
REAL data(n)
C USES four1
      Calculates the Fourier transform of a set of n real-valued data points. Replaces this data
      (which is stored in array data(1:n)) by the positive frequency half of its complex Fourier
      transform. The real-valued first and last components of the complex transform are returned
      as elements data(1) and data(2), respectively. n must be a power of 2. This routine
      also calculates the inverse transform of a complex data array if it is the transform of real
      data. (Result in this case must be multiplied by 2/n.)
      INTEGER i,i1,i2,i3,i4,n2p3
      REAL c1,c2,h1i,h1r,h2i,h2r,wis,wrs
      DOUBLE PRECISION theta,wi,wpi,wpr,
      *          wr,wtemp
      theta=3.141592653589793d0/dble(n/2)      Double precision for the trigonometric recurrences.
      c1=0.5                                     Initialize the recurrence.
      if (isign.eq.1) then
          c2=-0.5
          call four1(data,n/2,+1)                  The forward transform is here.
      else
          c2=0.5
          theta=-theta
      endif
      wpr=-2.0d0*sin(0.5d0*theta)**2
      wpi=sin(theta)
      wr=1.0d0+wpr
      wi=wpi
      n2p3=n+3
      do 11 i=2,n/4
          i1=2*i-1
          i2=i1+1
          i3=n2p3-i2
          i4=i3+1
          wrs=sngl(wr)
          wis=sngl(wi)
          hir=c1*(data(i1)+data(i3))
          h1i=c1*(data(i2)-data(i4))
          h2r=-c2*(data(i2)+data(i4))
          h2i=c2*(data(i1)-data(i3))
          data(i1)=hir+wrs*h2r-wis*h2i
          data(i2)=h1i+wrs*h2i+wis*h2r
          data(i3)=hir-wrs*h2r+wis*h2i
          data(i4)=-h1i+wrs*h2i+wis*h2r
          wtemp=wr
          wr=wr*wpr-wi*wpi+wr
          wi=wi*wpr+wtemp*wpi+wi
11    enddo 11
      Case i=1 done separately below.
      The two separate transforms are separated out of
      data.
      Here they are recombined to form the true trans-
      form of the original real data.
      The recurrence.
```

```

if (isign.eq.1) then
    h1r=data(1)
    data(1)=h1r+data(2)
    data(2)=h1r-data(2)
else
    h1r=data(1)
    data(1)=c1*(h1r+data(2))
    data(2)=c1*(h1r-data(2))
    call four1(data,n/2,-1)
endif
return
END

```

Squeeze the first and last data together to get them all within the original array.

This is the inverse transform for the case isign=-1.

Fast Sine and Cosine Transforms

Among their other uses, the Fourier transforms of functions can be used to solve differential equations (see §19.4). The most common boundary conditions for the solutions are 1) they have the value zero at the boundaries, or 2) their derivatives are zero at the boundaries. In the first instance, the natural transform to use is the *sine* transform, given by

$$F_k = \sum_{j=1}^{N-1} f_j \sin(\pi j k / N) \quad \text{sine transform} \quad (12.3.7)$$

where f_j , $j = 0, \dots, N - 1$ is the data array, and $f_0 \equiv 0$.

At first blush this appears to be simply the imaginary part of the discrete Fourier transform. However, the argument of the sine differs by a factor of two from the value that would make this so. The sine transform uses *sines only* as a complete set of functions in the interval from 0 to 2π , and, as we shall see, the cosine transform uses *cosines only*. By contrast, the normal FFT uses both sines and cosines, but only half as many of each. (See Figure 12.3.1.)

The expression (12.3.7) can be “force-fit” into a form that allows its calculation via the FFT. The idea is to extend the given function rightward past its last tabulated value. We extend the data to twice their length in such a way as to make them an *odd* function about $j = N$, with $f_N = 0$,

$$f_{2N-j} \equiv -f_j \quad j = 0, \dots, N - 1 \quad (12.3.8)$$

Consider the FFT of this extended function:

$$F_k = \sum_{j=0}^{2N-1} f_j e^{2\pi i j k / (2N)} \quad (12.3.9)$$

The half of this sum from $j = N$ to $j = 2N - 1$ can be rewritten with the substitution $j' = 2N - j$

$$\begin{aligned} \sum_{j=N}^{2N-1} f_j e^{2\pi i j k / (2N)} &= \sum_{j'=1}^N f_{2N-j'} e^{2\pi i (2N-j') k / (2N)} \\ &= - \sum_{j'=0}^{N-1} f_{j'} e^{-2\pi i j' k / (2N)} \end{aligned} \quad (12.3.10)$$

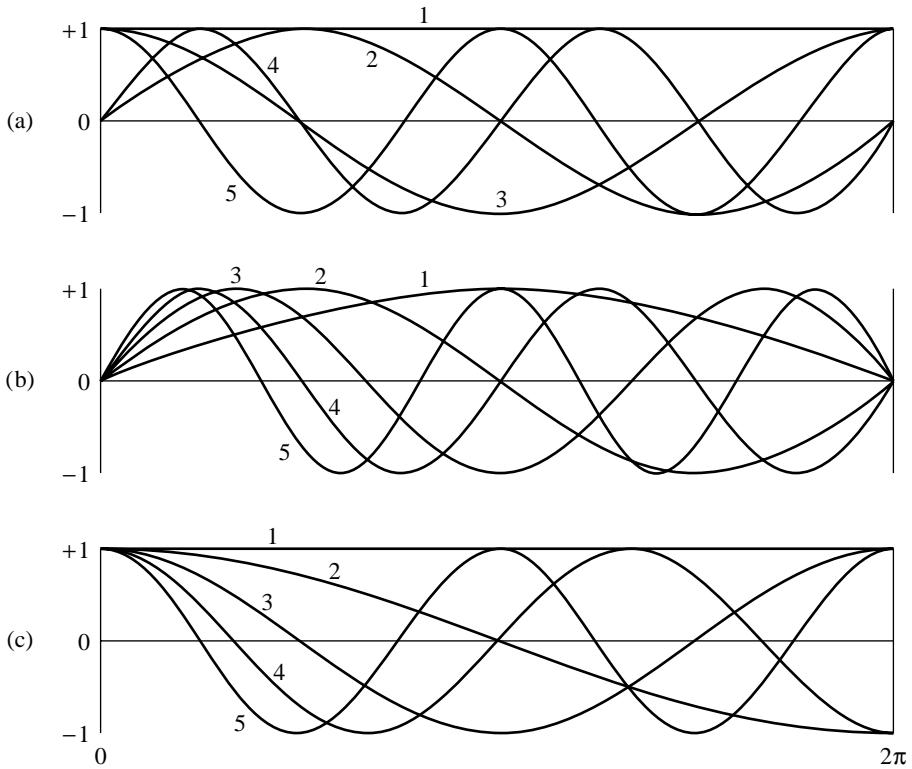

Figure 12.3.1. Basis functions used by the Fourier transform (a), sine transform (b), and cosine transform (c), are plotted. The first five basis functions are shown in each case. (For the Fourier transform, the real and imaginary parts of the basis functions are both shown.) While some basis functions occur in more than one transform, the basis sets are distinct. For example, the sine transform functions labeled (1), (3), (5) are not present in the Fourier basis. Any of the three sets can expand any function in the interval shown; however, the sine or cosine transform best expands functions matching the boundary conditions of the respective basis functions, namely zero function values for sine, zero derivatives for cosine.

so that

$$\begin{aligned} F_k &= \sum_{j=0}^{N-1} f_j \left[e^{2\pi i j k / (2N)} - e^{-2\pi i j k / (2N)} \right] \\ &= 2i \sum_{j=0}^{N-1} f_j \sin(\pi j k / N) \end{aligned} \tag{12.3.11}$$

Thus, up to a factor $2i$ we get the sine transform from the FFT of the extended function.

This method introduces a factor of two inefficiency into the computation by extending the data. This inefficiency shows up in the FFT output, which has zeros for the real part of every element of the transform. For a one-dimensional problem, the factor of two may be bearable, especially in view of the simplicity of the method. When we work with partial differential equations in two or three dimensions, though, the factor becomes four or eight, so efforts to eliminate the inefficiency are well rewarded.

From the original real data array f_j we will construct an auxiliary array y_j and apply to it the routine `realft`. The output will then be used to construct the desired transform. For the sine transform of data f_j , $j = 1, \dots, N - 1$, the auxiliary array is

$$\begin{aligned} y_0 &= 0 \\ y_j &= \sin(j\pi/N)(f_j + f_{N-j}) + \frac{1}{2}(f_j - f_{N-j}) \quad j = 1, \dots, N - 1 \end{aligned} \quad (12.3.12)$$

This array is of the same dimension as the original. Notice that the first term is symmetric about $j = N/2$ and the second is antisymmetric. Consequently, when `realft` is applied to y_j , the result has real parts R_k and imaginary parts I_k given by

$$\begin{aligned} R_k &= \sum_{j=0}^{N-1} y_j \cos(2\pi jk/N) \\ &= \sum_{j=1}^{N-1} (f_j + f_{N-j}) \sin(j\pi/N) \cos(2\pi jk/N) \\ &= \sum_{j=0}^{N-1} 2f_j \sin(j\pi/N) \cos(2\pi jk/N) \\ &= \sum_{j=0}^{N-1} f_j \left[\sin \frac{(2k+1)j\pi}{N} - \sin \frac{(2k-1)j\pi}{N} \right] \\ &= F_{2k+1} - F_{2k-1} \end{aligned} \quad (12.3.13)$$

$$\begin{aligned} I_k &= \sum_{j=0}^{N-1} y_j \sin(2\pi jk/N) \\ &= \sum_{j=1}^{N-1} (f_j - f_{N-j}) \frac{1}{2} \sin(2\pi jk/N) \\ &= \sum_{j=0}^{N-1} f_j \sin(2\pi jk/N) \\ &= F_{2k} \end{aligned} \quad (12.3.14)$$

Therefore F_k can be determined as follows:

$$F_{2k} = I_k \quad F_{2k+1} = F_{2k-1} + R_k \quad k = 0, \dots, (N/2 - 1) \quad (12.3.15)$$

The even terms of F_k are thus determined very directly. The odd terms require a recursion, the starting point of which follows from setting $k = 0$ in equation (12.3.15) and using $F_1 = -F_{-1}$:

$$F_1 = \frac{1}{2}R_0 \quad (12.3.16)$$

The implementing program is

```

SUBROUTINE sinft(y,n)
INTEGER n
REAL y(n)
C USES realft
      Calculates the sine transform of a set of n real-valued data points stored in array y(1:n).
      The number n must be a power of 2. On exit y is replaced by its transform. This program,
      without changes, also calculates the inverse sine transform, but in this case the output array
      should be multiplied by 2/n.
      INTEGER j
      REAL sum,y1,y2
      DOUBLE PRECISION theta,wi,wpi,wpr,
*           wr,wtemp               Double precision in the trigonometric recurrences.
theta=3.141592653589793d0/dble(n)   Initialize the recurrence.
wr=1.0d0
wi=0.0d0
wpr=-2.0d0*sin(0.5d0*theta)**2
wpi=sin(theta)
y(1)=0.0
do 11 j=1,n/2
    wtemp=wr
    wr=wr*wpr-wi*wpi+wr
    wi=wi*wpr+wtemp*wpi+wi
    y1=wi*(y(j+1)+y(n-j+1))
    y2=0.5*(y(j+1)-y(n-j+1))
    y(j+1)=y1+y2
    y(n-j+1)=y1-y2
 11 enddo 11
call realft(y,n,+1)
sum=0.0
y(1)=0.5*y(1)
y(2)=0.0
do 12 j=1,n-1,2
    sum=sum+y(j)
    y(j)=y(j+1)
    y(j+1)=sum
 12 enddo 12
return
END

```

Calculate the sine for the auxiliary array.
The cosine is needed to continue the recurrence.
Construct the auxiliary array.

Terms j and $N - j$ are related.

Transform the auxiliary array.

Initialize the sum used for odd terms below.

Even terms in the transform are determined directly.
Odd terms are determined by this running sum.

The sine transform, curiously, is its own inverse. If you apply it twice, you get the original data, but multiplied by a factor of $N/2$.

The other common boundary condition for differential equations is that the derivative of the function is zero at the boundary. In this case the natural transform is the *cosine* transform. There are several possible ways of defining the transform. Each can be thought of as resulting from a different way of extending a given array to create an even array of double the length, and/or from whether the extended array contains $2N - 1$, $2N$, or some other number of points. In practice, only two of the numerous possibilities are useful so we will restrict ourselves to just these two.

The first form of the cosine transform uses $N + 1$ data points:

$$F_k = \frac{1}{2}[f_0 + (-1)^k f_N] + \sum_{j=1}^{N-1} f_j \cos(\pi j k / N) \quad (12.3.17)$$

It results from extending the given array to an even array about $j = N$, with

$$f_{2N-j} = f_j, \quad j = 0, \dots, N-1 \quad (12.3.18)$$

If you substitute this extended array into equation (12.3.9), and follow steps analogous to those leading up to equation (12.3.11), you will find that the Fourier transform is just twice the cosine transform (12.3.17). Another way of thinking about the formula (12.3.17) is to notice that it is the Chebyshev Gauss-Lobatto quadrature formula (see §4.5), often used in Clenshaw-Curtis adaptive quadrature (see §5.9, equation 5.9.4).

Once again the transform can be computed without the factor of two inefficiency. In this case the auxiliary function is

$$y_j = \frac{1}{2}(f_j + f_{N-j}) - \sin(j\pi/N)(f_j - f_{N-j}) \quad j = 0, \dots, N-1 \quad (12.3.19)$$

Instead of equation (12.3.15), `realft` now gives

$$F_{2k} = R_k \quad F_{2k+1} = F_{2k-1} + I_k \quad k = 0, \dots, (N/2-1) \quad (12.3.20)$$

The starting value for the recursion for odd k in this case is

$$F_1 = \frac{1}{2}(f_0 - f_N) + \sum_{j=1}^{N-1} f_j \cos(j\pi/N) \quad (12.3.21)$$

This sum does not appear naturally among the R_k and I_k , and so we accumulate it during the generation of the array y_j .

Once again this transform is its own inverse, and so the following routine works for both directions of the transformation. Note that although this form of the cosine transform has $N + 1$ input and output values, it passes an array only of length N to `realft`.

```
SUBROUTINE cosft1(y,n)
INTEGER n
REAL y(n+1)
C USES realft
    Calculates the cosine transform of a set y(1:n+1) of real-valued data points. The trans-
    formed data replace the original data in array y. n must be a power of 2. This program,
    without changes, also calculates the inverse cosine transform, but in this case the output
    array should be multiplied by 2/n.
INTEGER j
REAL sum,y1,y2
DOUBLE PRECISION theta,wi,wpi,wpr,wr,wtemp      For trig. recurrences.
theta=3.141592653589793d0/n      Initialize the recurrence.
wr=1.0d0
wi=0.0d0
wpr=-2.0d0*sin(0.5d0*theta)**2
wpi=sin(theta)
sum=0.5*(y(1)-y(n+1))
y(1)=0.5*(y(1)+y(n+1))
do 11 j=1,n/2-1
    wtemp=wr
    wr=wr*wpr-wi*wpi+wr
    wi=wi*wpr+wtemp*wpi+wi
    y1=0.5*(y(j+1)+y(n-j+1))
    y2=(y(j+1)-y(n-j+1))
    y(j+1)=y1-wi*y2
    y(n-j+1)=y1+wi*y2
    sum=sum+wr*y2
11   enddo
```

j=n/2 unnecessary since y(n/2+1) unchanged.

Carry out the recurrence.

Calculate the auxiliary function.

The values for j and $N - j$ are related.

Carry along this sum for later use in unfolding the transform.

```

call realft(y,n,+1)          Calculate the transform of the auxiliary function.
y(n+1)=y(2)
y(2)=sum
do 12 j=4,n,2
    sum=sum+y(j)
    y(j)=sum
  enddo 12
return
END

```

The second important form of the cosine transform is defined by

$$F_k = \sum_{j=0}^{N-1} f_j \cos \frac{\pi k(j + \frac{1}{2})}{N} \quad (12.3.22)$$

with inverse

$$f_j = \frac{2}{N} \sum_{k=0}^{N-1}' F_k \cos \frac{\pi k(j + \frac{1}{2})}{N} \quad (12.3.23)$$

Here the prime on the summation symbol means that the term for $k = 0$ has a coefficient of $\frac{1}{2}$ in front. This form arises by extending the given data, defined for $j = 0, \dots, N - 1$, to $j = N, \dots, 2N - 1$ in such a way that it is even about the point $N - \frac{1}{2}$ and periodic. (It is therefore also even about $j = -\frac{1}{2}$.) The form (12.3.23) is related to Gauss-Chebyshev quadrature (see equation 4.5.19), to Chebyshev approximation (§5.8, equation 5.8.7), and Clenshaw-Curtis quadrature (§5.9).

This form of the cosine transform is useful when solving differential equations on “staggered” grids, where the variables are centered midway between mesh points. It is also the standard form in the field of data compression and image processing.

The auxiliary function used in this case is similar to equation (12.3.19):

$$y_j = \frac{1}{2}(f_j + f_{N-j-1}) + \sin \frac{\pi(j + \frac{1}{2})}{N}(f_j - f_{N-j-1}) \quad j = 0, \dots, N - 1 \quad (12.3.24)$$

Carrying out the steps similar to those used to get from (12.3.12) to (12.3.15), we find

$$F_{2k} = \cos \frac{\pi k}{N} R_k - \sin \frac{\pi k}{N} I_k \quad (12.3.25)$$

$$F_{2k-1} = \sin \frac{\pi k}{N} R_k + \cos \frac{\pi k}{N} I_k + F_{2k+1} \quad (12.3.26)$$

Note that equation (12.3.26) gives

$$F_{N-1} = \frac{1}{2} R_{N/2} \quad (12.3.27)$$

Thus the even components are found directly from (12.3.25), while the odd components are found by recursing (12.3.26) down from $k = N/2 - 1$, using (12.3.27) to start.

Since the transform is not self-inverting, we have to reverse the above steps to find the inverse. Here is the routine:

```

SUBROUTINE cosft2(y,n,isign)
INTEGER isign,n
REAL y(n)
C USES realft
   Calculates the "staggered" cosine transform of a set y(1:n) of real-valued data points.
   The transformed data replace the original data in array y. n must be a power of 2. Set
   isign to +1 for a transform, and to -1 for an inverse transform. For an inverse transform,
   the output array should be multiplied by 2/n.
INTEGER i
REAL sum,sum1,y1,y2,ytemp
DOUBLE PRECISION theta,wi,wi1,wpi,wpr,wr,wr1,wtemp,PI
   Double precision for the trigonometric recurrences.
PARAMETER (PI=3.141592653589793d0)
theta=0.5d0*PI/n                           Initialize the recurrences.
wr=1.0d0
wi=0.0d0
wr1=cos(theta)
wi1=sin(theta)
wpr=-2.0d0*wi1**2
wpi=sin(2.d0*theta)
if(isign.eq.1)then                         Forward transform.
   do 11 i=1,n/2
      y1=0.5*(y(i)+y(n-i+1))           Calculate the auxiliary function.
      y2=wi1*(y(i)-y(n-i+1))
      y(i)=y1+y2
      y(n-i+1)=y1-y2
      wtemp=wr1
      wr1=wr1*wpr-wi1*wpi+wr1
      wi1=wi1*wpr+wtemp*wpi+wi1
   enddo 11
   call realft(y,n,1)
   do 12 i=3,n,2
      wtemp=wr
      wr=wr*wpr-wi*wpi+wr
      wi=wi*wpr+wtemp*wpi+wi
      y1=y(i)*wr-y(i+1)*wi
      y2=y(i+1)*wr+y(i)*wi
      y(i)=y1
      y(i+1)=y2
   enddo 12
   sum=0.5*y(2)
   do 13 i=n,2,-2
      sum1=sum
      sum=sum+y(i)
      y(i)=sum1
   enddo 13
else if(isign.eq.-1)then                   Inverse transform.
   ytemp=y(n)
   do 14 i=n,4,-2
      y(i)=y(i-2)-y(i)
   enddo 14
   y(2)=2.0*ytemp
   do 15 i=3,n,2
      wtemp=wr
      wr=wr*wpr-wi*wpi+wr
      wi=wi*wpr+wtemp*wpi+wi
      y1=y(i)*wr+y(i+1)*wi
      y2=y(i+1)*wr-y(i)*wi
      y(i)=y1
      y(i+1)=y2
   enddo 15
   call realft(y,n,-1)
   do 16 i=1,n/2
      y1=y(i)+y(n-i+1)

```

```

y2=(0.5/wi1)*(y(i)-y(n-i+1))
y(i)=0.5*(y1+y2)
y(n-i+1)=0.5*(y1-y2)
wtemp=wr1
wr1=wr1*wpr-wi1*wpi+wr1
wi1=wi1*wpr+wtemp*wpi+wi1
enddo 16
endif
return
END

```

An alternative way of implementing this algorithm is to form an auxiliary function by copying the even elements of f_j into the first $N/2$ locations, and the odd elements into the next $N/2$ elements in reverse order. However, it is not easy to implement the alternative algorithm without a temporary storage array and we prefer the above in-place algorithm.

Finally, we mention that there exist fast cosine transforms for small N that do not rely on an auxiliary function or use an FFT routine. Instead, they carry out the transform directly, often coded in hardware for fixed N of small dimension [1].

12.4 FFT in Two or More Dimensions

Given a complex function $h(k_1, k_2)$ defined over the two-dimensional grid $0 \leq k_1 \leq N_1 - 1$, $0 \leq k_2 \leq N_2 - 1$, we can define its two-dimensional discrete Fourier transform as a complex function $H(n_1, n_2)$, defined over the same grid,

$$H(n_1, n_2) \equiv \sum_{k_2=0}^{N_2-1} \sum_{k_1=0}^{N_1-1} \exp(2\pi i k_2 n_2 / N_2) \exp(2\pi i k_1 n_1 / N_1) h(k_1, k_2) \quad (12.4.1)$$

By pulling the “subscripts 2” exponential outside of the sum over k_1 , or by reversing the order of summation and pulling the “subscripts 1” outside of the sum over k_2 ,

```

y2=(0.5/wi1)*(y(i)-y(n-i+1))
y(i)=0.5*(y1+y2)
y(n-i+1)=0.5*(y1-y2)
wtemp=wr1
wr1=wr1*wpr-wi1*wpi+wr1
wi1=wi1*wpr+wtemp*wpi+wi1
enddo 16
endif
return
END

```

An alternative way of implementing this algorithm is to form an auxiliary function by copying the even elements of f_j into the first $N/2$ locations, and the odd elements into the next $N/2$ elements in reverse order. However, it is not easy to implement the alternative algorithm without a temporary storage array and we prefer the above in-place algorithm.

Finally, we mention that there exist fast cosine transforms for small N that do not rely on an auxiliary function or use an FFT routine. Instead, they carry out the transform directly, often coded in hardware for fixed N of small dimension [1].

12.4 FFT in Two or More Dimensions

Given a complex function $h(k_1, k_2)$ defined over the two-dimensional grid $0 \leq k_1 \leq N_1 - 1$, $0 \leq k_2 \leq N_2 - 1$, we can define its two-dimensional discrete Fourier transform as a complex function $H(n_1, n_2)$, defined over the same grid,

$$H(n_1, n_2) \equiv \sum_{k_2=0}^{N_2-1} \sum_{k_1=0}^{N_1-1} \exp(2\pi i k_2 n_2 / N_2) \exp(2\pi i k_1 n_1 / N_1) h(k_1, k_2) \quad (12.4.1)$$

By pulling the “subscripts 2” exponential outside of the sum over k_1 , or by reversing the order of summation and pulling the “subscripts 1” outside of the sum over k_2 ,

we can see instantly that the two-dimensional FFT can be computed by taking one-dimensional FFTs sequentially on each index of the original function. Symbolically,

$$\begin{aligned} H(n_1, n_2) &= \text{FFT-on-index-1}(\text{FFT-on-index-2}[h(k_1, k_2)]) \\ &= \text{FFT-on-index-2}(\text{FFT-on-index-1}[h(k_1, k_2)]) \end{aligned} \quad (12.4.2)$$

For this to be practical, of course, both N_1 and N_2 should be some efficient length for an FFT, usually a power of 2. Programming a two-dimensional FFT, using (12.4.2) with a one-dimensional FFT routine, is a bit clumsier than it seems at first. Because the one-dimensional routine requires that its input be in consecutive order as a one-dimensional complex array, you find that you are endlessly copying things out of the multidimensional input array and then copying things back into it. This is not recommended technique. Rather, you should use a multidimensional FFT routine, such as the one we give below.

The generalization of (12.4.1) to more than two dimensions, say to L -dimensions, is evidently

$$\begin{aligned} H(n_1, \dots, n_L) &\equiv \sum_{k_L=0}^{N_L-1} \cdots \sum_{k_1=0}^{N_1-1} \exp(2\pi i k_L n_L / N_L) \times \cdots \\ &\quad \times \exp(2\pi i k_1 n_1 / N_1) h(k_1, \dots, k_L) \end{aligned} \quad (12.4.3)$$

where n_1 and k_1 range from 0 to $N_1 - 1, \dots, n_L$ and k_L range from 0 to $N_L - 1$. How many calls to a one-dimensional FFT are in (12.4.3)? Quite a few! For each value of k_1, k_2, \dots, k_{L-1} you FFT to transform the L index. Then for each value of k_1, k_2, \dots, k_{L-2} and n_L you FFT to transform the $L - 1$ index. And so on. It is best to rely on someone else having done the bookkeeping for once and for all.

The inverse transforms of (12.4.1) or (12.4.3) are just what you would expect them to be: Change the i 's in the exponentials to $-i$'s, and put an overall factor of $1/(N_1 \times \cdots \times N_L)$ in front of the whole thing. Most other features of multidimensional FFTs are also analogous to features already discussed in the one-dimensional case:

- Frequencies are arranged in wrap-around order in the transform, but now for each separate dimension.
- The input data are also treated as if they were wrapped around. If they are discontinuous across this periodic identification (in any dimension) then the spectrum will have some excess power at high frequencies because of the discontinuity. The fix, if you care, is to remove multidimensional linear trends.
- If you are doing spatial filtering and are worried about wrap-around effects, then you need to zero-pad all around the border of the multidimensional array. However, be sure to notice how costly zero-padding is in multidimensional transforms. If you use too thick a zero-pad, you are going to waste a *lot* of storage, especially in 3 or more dimensions!
- Aliasing occurs as always if sufficient bandwidth limiting does not exist along one or more of the dimensions of the transform.

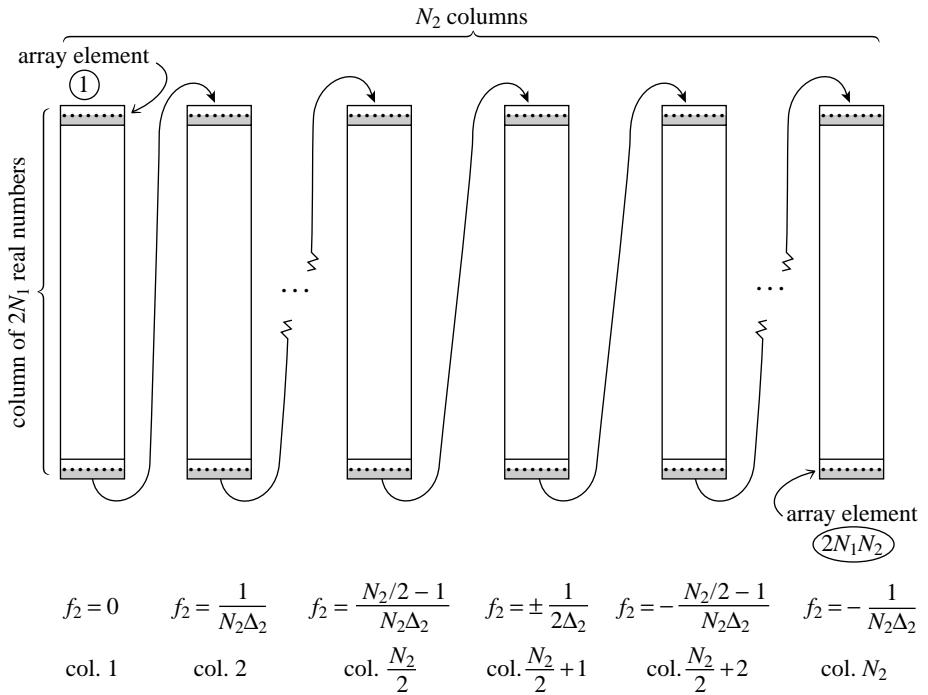

Figure 12.4.1. Storage arrangement of frequencies in the output $H(f_1, f_2)$ of a two-dimensional FFT. The input data is a two-dimensional $N_1 \times N_2$ array $h(t_1, t_2)$ (stored by columns of complex numbers). The output is also stored by complex columns. Each column corresponds to a particular value of f_2 , as shown in the figure. Within each column, the arrangement of frequencies f_1 is exactly as shown in Figure 12.2.2. Δ_1 and Δ_2 are the sampling intervals in the 1 and 2 directions, respectively. The total number of (real) array elements is $2N_1 N_2$. The program `fourn` can also do more than two dimensions, and the storage arrangement generalizes in the obvious way.

The routine `fourn` that we furnish herewith is a descendant of one written by N. M. Brenner. It requires as input (i) a scalar, telling the number of dimensions, e.g., 2; (ii) a vector, telling the length of the array in each dimension, e.g., (32,64). Note that these lengths *must all* be powers of 2, and are the numbers of *complex* values in each direction; (iii) the usual scalar equal to ± 1 indicating whether you want the transform or its inverse; and, finally (iv) the array of data.

A few words about the data array: `fourn` accesses it as a one-dimensional array of real numbers, of length equal to twice the product of the lengths of the L dimensions. It assumes that the array represents an L -dimensional complex array, in normal FORTRAN order. Normal FORTRAN order means: (i) each complex value occupies two sequential locations, real part followed by imaginary; (ii) the first subscript changes most rapidly as one goes through the array; the last subscript changes least rapidly; (iii) subscripts range from 1 to their maximum values (N_1, N_2, \dots, N_L , respectively), rather than from 0 to $N_1 - 1, N_2 - 1, \dots, N_L - 1$. Almost all failures to get `fourn` to work result from improper understanding of the above ordering of the data array. (Figure 12.4.1 illustrates the format of the output array.)

```

SUBROUTINE fourn(data,nn,ndim,isign)
INTEGER isign,ndim,nn(ndim)
REAL data(*)
    Replaces data by its ndim-dimensional discrete Fourier transform, if isign is input as
    1. nn(1:ndim) is an integer array containing the lengths of each dimension (number of
       complex values), which MUST all be powers of 2. data is a real array of length twice the
       product of these lengths, in which the data are stored as in a multidimensional complex
       FORTRAN array. If isign is input as -1, data is replaced by its inverse transform times
       the product of the lengths of all dimensions.

12.5 Fourier Transforms of Real Data in Two and Three Dimensions

Two-dimensional FFTs are particularly important in the field of image processing. An image is usually represented as a two-dimensional array of pixel intensities, real (and usually positive) numbers. One commonly desires to filter high, or low, frequency spatial components from an image; or to convolve or deconvolve the image with some instrumental point spread function. Use of the FFT is by far the most efficient technique.

In three dimensions, a common use of the FFT is to solve Poisson's equation for a potential (e.g., electromagnetic or gravitational) on a three-dimensional lattice that represents the discretization of three-dimensional space. Here the source terms (mass or charge distribution) and the desired potentials are also real. In two and three dimensions, with large arrays, memory is often at a premium. It is therefore important to perform the FFTs, insofar as possible, on the data "in place." We want a routine with functionality similar to the multidimensional FFT routine `fourn` (§12.4), but which operates on real, not complex, input data. We give such a routine in this section. The development is analogous to that of §12.3 leading to the one-dimensional routine `realft`. (You might wish to review that material at this point, particularly equation 12.3.5.)

It is convenient to think of the independent variables n_1, \dots, n_L in equation (12.4.3) as representing an L -dimensional vector \vec{n} in wave-number space, with values on the lattice of integers. The transform $H(n_1, \dots, n_L)$ is then denoted $H(\vec{n})$.

It is easy to see that the transform $H(\vec{n})$ is periodic in each of its L dimensions. Specifically, if $\vec{P}_1, \vec{P}_2, \vec{P}_3, \dots$ denote the vectors $(N_1, 0, 0, \dots)$, $(0, N_2, 0, \dots)$, $(0, 0, N_3, \dots)$, and so forth, then

$$H(\vec{n} \pm \vec{P}_j) = H(\vec{n}) \quad j = 1, \dots, L \quad (12.5.1)$$

```

12.5 Fourier Transforms of Real Data in Two and Three Dimensions

Two-dimensional FFTs are particularly important in the field of image processing. An image is usually represented as a two-dimensional array of pixel intensities, real (and usually positive) numbers. One commonly desires to filter high, or low, frequency spatial components from an image; or to convolve or deconvolve the image with some instrumental point spread function. Use of the FFT is by far the most efficient technique.

In three dimensions, a common use of the FFT is to solve Poisson's equation for a potential (e.g., electromagnetic or gravitational) on a three-dimensional lattice that represents the discretization of three-dimensional space. Here the source terms (mass or charge distribution) and the desired potentials are also real. In two and three dimensions, with large arrays, memory is often at a premium. It is therefore important to perform the FFTs, insofar as possible, on the data "in place." We want a routine with functionality similar to the multidimensional FFT routine `fourn` (§12.4), but which operates on real, not complex, input data. We give such a routine in this section. The development is analogous to that of §12.3 leading to the one-dimensional routine `realft`. (You might wish to review that material at this point, particularly equation 12.3.5.)

It is convenient to think of the independent variables n_1, \dots, n_L in equation (12.4.3) as representing an L -dimensional vector \vec{n} in wave-number space, with values on the lattice of integers. The transform $H(n_1, \dots, n_L)$ is then denoted $H(\vec{n})$.

It is easy to see that the transform $H(\vec{n})$ is periodic in each of its L dimensions. Specifically, if $\vec{P}_1, \vec{P}_2, \vec{P}_3, \dots$ denote the vectors $(N_1, 0, 0, \dots)$, $(0, N_2, 0, \dots)$, $(0, 0, N_3, \dots)$, and so forth, then

$$H(\vec{n} \pm \vec{P}_j) = H(\vec{n}) \quad j = 1, \dots, L \quad (12.5.1)$$

Equation (12.5.1) holds for any input data, real or complex. When the data is real, we have the additional symmetry

$$H(-\vec{n}) = H(\vec{n})^* \quad (12.5.2)$$

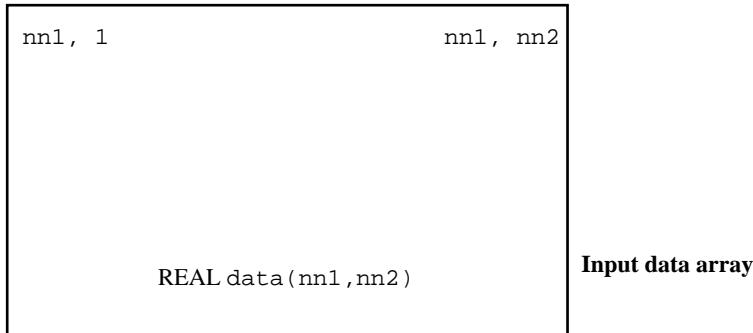

Equations (12.5.1) and (12.5.2) imply that the full transform can be trivially obtained from the subset of lattice values \vec{n} that have

$$\begin{aligned} 0 \leq n_1 &\leq \frac{N_1}{2} \\ 0 \leq n_2 &\leq N_2 - 1 \\ &\dots \\ 0 \leq n_L &\leq N_L - 1 \end{aligned} \quad (12.5.3)$$

In fact, this set of values is overcomplete, because there are additional symmetry relations among the transform values that have $n_1 = 0$ and $n_1 = N_1/2$. However these symmetries are complicated and their use becomes extremely confusing. Therefore, we will compute our FFT on the lattice subset of equation (12.5.3), even though this requires a small amount of extra storage for the answer, i.e., the transform is not *quite* “in place.” (Although an in-place transform is in fact possible, we have found it virtually impossible to explain to any user how to unscramble its output, i.e., where to find the real and imaginary components of the transform at some particular frequency!)

Figure 12.5.1 shows the storage scheme that we will use for the input data and the output transform. The figure is specialized to the case of two dimensions, $L = 2$, but the generalization to higher dimensions is obvious. The input data is a two-dimensional real array of dimensions N_1 (called `nn1`) by N_2 (called `nn2`). Notice that the FORTRAN subscripts number from 1 to `nn1`, and not from 0 to $N_1 - 1$. The output spectrum is in two complex arrays, one two-dimensional and the other one-dimensional. The two-dimensional one, `spec`, has dimensions $nn1/2$ by `nn2`. This is exactly half the size of the input data array; but since it is complex, it is the same amount of storage. In fact, `spec` will share storage with (and overwrite) the input data array. As the figure shows, `spec` contains those spectral components whose first component of frequency, f_1 , ranges from zero to just short of the Nyquist frequency f_c . The full range of positive and negative second-component of frequencies, f_2 , is stored, in wrap-around order (see §12.2), with negative frequencies shifted by exactly one period to put them “above” the positive frequencies, as the figure indicates. The figure also indicates how the additional $L - 1$ (here, one-) dimensional array `speq` stores only that single value of n_1 that corresponds to the Nyquist frequency, but all values of n_2 , etc.

With this much introduction, the implementing procedure, called `r1fft3`, is something of an anticlimax. The routine is written for the case of $L = 3$ dimensions, but (we will explain below) it can be used without modification for $L = 2$ also; and it is quite trivial to generalize it to larger L . Look at the innermost (“do 13”) loop in the procedure, and you will see equation (12.3.5) implemented on the *first* transform index. The case of `i1=1` is coded separately, to account for the fact that `speq` is to be filled instead of `spec` (which is here called `data` since it shares storage with

$f_2 = -f_c$		1	COMPLEX <code>spec(nn2)</code>	$f_1 = f_c$	nn2
		$f_2 = 0$	$nn1/2, 1$		$nn1/2, nn2$
				$f_2 = f_c$	
			COMPLEX <code>spec(nn1/2,nn2)</code>		
		1, 1		$f_1 = 0$	1, nn2
				$f_1 = -f_c$	

Output spectrum arrays

Figure 12.5.1. Input and output data arrangement for `r1ft3` in the case of two-dimensional data. The input data array is a real, two-dimensional array. The output data array `spec` is a complex, two-dimensional array whose (1, 1) element contains the $f_1 = f_2 = 0$ spectral component; a complete set of f_2 values are stored in wrap-around order, while only positive f_1 values are stored (others being obtainable by symmetry). The output array `spec` contains components with f_1 equal to the Nyquist frequency.

the input array). The three enclosing do loops (indices i_2 , i_1 , and i_3 , from inside to outside) could in fact be done in any order — their actions all commute. We chose the order shown because of the following considerations: (i) i_1 should not be the inner loop, because if it is, then the recurrence relations on w_r and w_i become burdensome. (ii) On virtual-memory machines, i_3 should be the outer loop, because (with FORTRAN order of array storage) this results in the array data, which might be very large, being accessed in block sequential order.

Note that the work done in `r1ft3` is quite (logarithmically) small, compared to the associated complex FFT, `fourn`. For this reason, we allow ourselves the clarity of using FORTRAN complex arithmetic even when (as in the multiplications by c_1 and c_2) there are a few unnecessary operations. The routine `r1ft3` is based on an earlier routine by G.B. Rybicki.

```
SUBROUTINE r1ft3(data,speq,nn1,nn2,nn3,isign)
INTEGER isign,nn1,nn2,nn3
COMPLEX data(nn1/2,nn2,nn3),speq(nn2,nn3)
C USES fourn
Given a two- or three-dimensional real array data whose dimensions are nn1, nn2, nn3
(where nn3 is 1 for the case of a two-dimensional array), this routine returns (for isign=1)
the complex fast Fourier transform as two complex arrays: On output, data contains the
zero and positive frequency values of the first frequency component, while speq contains
the Nyquist critical frequency values of the first frequency component. Second (and third)
frequency components are stored for zero, positive, and negative frequencies, in standard
wrap-around order. For isign=-1, the inverse transform (times nn1*nn2*nn3/2 as a
constant multiplicative factor) is performed, with output data (viewed as a real array)
deriving from input data (viewed as complex) and speq. For inverse transforms on data
not generated first by a forward transform, make sure the complex input data array satisfies
property (12.5.2). The dimensions nn1, nn2, nn3 must always be integer powers of 2.
INTEGER i1,i2,i3,j1,j2,j3,nn(3)

```

We now give some fragments from notional calling programs, to clarify the use of `rlft3` for two- and three-dimensional data. Note that the routine does not actually distinguish between two and three dimensions; two is treated like three, but with the third dimension having length 1. Since the third dimension is the outer loop, almost no inefficiency is introduced.

The first program fragment FFTs a two-dimensional data array, allows for some processing on it, e.g., filtering, and then takes the inverse transform. Figure 12.5.2 shows an example of the use of this kind of code: A sharp image becomes blurry when its high-frequency spatial components are suppressed by the factor (here) $\max(1 - 6f^2/f_c^2, 0)$. The second program example illustrates a three-dimensional transform, where the three dimensions have different lengths. The third program example is an example of convolution, as it might occur in a program to compute the potential generated by a three-dimensional distribution of sources.

```

PROGRAM exmpl1
  This fragment shows how one might filter a 256 by 256 digital image.
  INTEGER N1,N2,N3
  PARAMETER (N1=256,N2=256,N3=1) Note that the third component must be set to 1.
C  USES rlft3
  REAL data(N1,N2)
  COMPLEX spec(N1/2,N2),speq(N2)
  EQUIVALENCE (data,spec)
C  ... Here the image would be loaded into data.
  call rlft3(data,speq,N1,N2,N3,1)
C  ... Here the arrays spec and speq would be multiplied by a suit-
  call rlft3(data,speq,N1,N2,N3,-1) able filter function (of frequency).
C  ... Here the filtered image would be unloaded from data.
END

PROGRAM exmpl2
  This fragment shows how one might FFT a real three-dimensional array of size 32 by 64
  by 16.
  INTEGER N1,N2,N3
  PARAMETER (N1=32,N2=64,N3=16)
C  USES rlft3
  REAL data(N1,N2,N3)
  COMPLEX spec(N1/2,N2,N3),speq(N2,N3)
  EQUIVALENCE (data,spec)
C  ... Here load data.
  call rlft3(data,speq,N1,N2,N3,1)
C  ... Here unload spec and speq.
END

PROGRAM exmpl3
  This fragment shows how one might convolve two real, three-dimensional arrays of size 32
  by 32 by 32, replacing the first array by the result.
  INTEGER N
  PARAMETER (N=32)
C  USES rlft3
  INTEGER j
  REAL fac,data1(N,N,N),data2(N,N,N)
  COMPLEX spec1(N/2,N,N),speq1(N,N),spec2(N/2,N,N),speq2(N,N),
*      zpec1(N*N*N/2),zpeq1(N*N),zpec2(N*N*N/2),zpeq2(N*N)
  EQUIVALENCE (data1,spec1,zpec1), (data2,spec2,zpec2),
*      (speq1,zpeq1), (speq2,zpeq2)
C  ...
  call rlft3(data1,speq1,N,N,N,1)      FFT both input arrays.
  call rlft3(data2,speq2,N,N,N,1)
  fac=2./(N*N*N)
  do 11 j=1,N*N*N/2                  Factor needed to get normalized inverse.
  zpec1(j)=fac*zpec1(j)*zpec2(j)      The sole purpose of the zpecs and zpeqs is to make
  enddo 11                            this a single do-loop instead of three-nested ones.
  do 12 j=1,N*N
    zpeq1(j)=fac*zpeq1(j)*zpeq2(j)
  enddo 12
  call rlft3(data1,speq1,N,N,N,-1)    Inverse FFT the product of the two FFTs.
C  ...
END

```

To extend `rlft3` to four dimensions, you simply add an additional (outer) nested do loop in `i4`, analogous to the present `i3`. (Modifying the routine to do an *arbitrary* number of dimensions, as in `fourn`, is a good programming exercise for the reader.)

12.6 External Storage or Memory-Local FFTs

Sometime in your life, you might have to compute the Fourier transform of a *really large* data set, larger than the size of your computer's physical memory. In such a case, the data will be stored on some external medium, such as magnetic or optical tape or disk. Needed is an algorithm that makes some manageable number of sequential passes through the external data, processing it on the fly and outputting intermediate results to other external media, which can be read on subsequent passes.

In fact, an algorithm of just this description was developed by Singleton [1] very soon after the discovery of the FFT. The algorithm requires four sequential storage devices, each capable of holding half of the input data. The first half of the input data is initially on one device, the second half on another.

Singleton's algorithm is based on the observation that it is possible to bit-reverse 2^M values by the following sequence of operations: On the first pass, values are read alternately from the two input devices, and written to a single output device (until it holds half the data), and then to the other output device. On the second pass, the output devices become input devices, and vice versa. Now, we copy *two* values from the first device, then *two* values from the second, writing them (as before) first to fill one output device, then to fill a second. Subsequent passes read 4, 8, etc., input values at a time. After completion of pass $M - 1$, the data are in bit-reverse order.

Singleton's next observation is that it is possible to alternate the passes of essentially this bit-reversal technique with passes that implement one stage of the Danielson-Lanczos combination formula (12.2.3). The scheme, roughly, is this: One starts as before with half the input data on one device, half on another. In the first pass, one complex value is read from each input device. Two combinations are formed, and one is written to each of two output devices. After this "computing" pass, the devices are rewound, and a "permutation" pass is performed, where groups of values are read from the first input device and alternately written to the first and second output devices; when the first input device is exhausted, the second is similarly processed. This sequence of computing and permutation passes is repeated $M - K - 1$ times, where 2^K is the size of internal buffer available to the program. The second phase of the computation consists of a final K computation passes. What distinguishes the second phase from the first is that, now, the permutations are local enough to do in place during the computation. There are thus no separate permutation passes in the second phase. In all, there are $2M - K - 2$ passes through the data.

Here is an implementation of Singleton's algorithm, based on [1]:

```

SUBROUTINE fourfs(iunit,nn,ndim,isign)
INTEGER ndim,nn(ndim),isign,iunit(4),KBF
PARAMETER (KBF=128)
C USES fourew
      One- or multi-dimensional Fourier transform of a large data set stored on external media.
      On input, ndim is the number of dimensions, and nn(1:ndim) contains the lengths of
      each dimension (number of complex values), which must be powers of two. iunit(1:4)
      contains the unit numbers of 4 sequential files, each large enough to hold half of the data.
      The four units must be opened for FORTRAN unformatted access. The input data must be
      in FORTRAN normal order, with its first half stored on unit iunit(1), its second half on
      iunit(2), in unformatted form, with KBF real numbers per record. isign should be set
      to 1 for the Fourier transform, to -1 for its inverse. On output, values in the array iunit
      may have been permuted; the first half of the result is stored on iunit(3), the second
      half on iunit(4). N.B.: For ndim > 1, the output is stored by rows, i.e., not in FORTRAN
      normal order; in other words, the output is the transpose of that which would have been
      produced by routine fourn.

For one-dimensional data, Singleton's algorithm produces output in exactly the same order as a standard FFT (e.g., `four1`). For multidimensional data, the output is the *transpose* of the conventional arrangement (e.g., the output of `fourn`). This peculiarity, which is intrinsic to the method, is generally only a minor inconvenience. For convolutions, one simply computes the component-by-component product of two transforms in their nonstandard arrangement, and then does an inverse transform on the result. Note that, if the lengths of the different dimensions are not all the same, then you must reverse the order of the values in `nn(1:ndim)` (thus giving the transpose dimensions) before performing the inverse transform. Note also that, just like `fourn`, performing a transform and then an inverse results in multiplying the original data by the product of the lengths of all dimensions.

We leave it as an exercise for the reader to figure out how to reorder `fourfs`'s output into normal order, taking additional passes through the externally stored data. We doubt that such reordering is ever really needed.

You will likely want to modify `fourfs` to fit your particular application. For example, as written, $KBF \equiv 2^K$ plays the dual role of being the size of the internal buffers, and the record size of the unformatted reads and writes. The latter role limits its size to that allowed by your machine's I/O facility. It is a simple matter to perform multiple reads for a much larger KBF , thus reducing the number of passes by a few.

Another modification of `fourfs` would be for the case where your virtual memory machine has sufficient address space, but not sufficient physical memory, to do an efficient FFT by the conventional algorithm (whose memory references are extremely nonlocal). In that case, you will need to replace the reads, writes, and rewinds by mappings of the arrays `afa`, `afb`, and `afc` into your address space. In other words, these arrays are replaced by references to a single data array, with offsets that get modified wherever `fourfs` performs an I/O operation. The resulting algorithm will have its memory references local within blocks of size KBF . Execution speed is thereby sometimes increased enormously, albeit at the cost of requiring twice as much virtual memory as an in-place FFT.

Chapter 13. Fourier and Spectral Applications

13.0 *Introduction*

Fourier methods have revolutionized fields of science and engineering, from radio astronomy to medical imaging, from seismology to spectroscopy. In this chapter, we present some of the basic applications of Fourier and spectral methods that have made these revolutions possible.

Say the word “Fourier” to a numericist, and the response, as if by Pavlovian conditioning, will likely be “FFT.” Indeed, the wide application of Fourier methods must be credited principally to the existence of the fast Fourier transform. Better mousetraps stand aside: If you speed up *any* nontrivial algorithm by a factor of a million or so, the world will beat a path towards finding useful applications for it. The most direct applications of the FFT are to the convolution or deconvolution of data (§13.1), correlation and autocorrelation (§13.2), optimal filtering (§13.3), power spectrum estimation (§13.4), and the computation of Fourier integrals (§13.9).

As important as they are, however, FFT methods are not the be-all and end-all of spectral analysis. Section 13.5 is a brief introduction to the field of time-domain digital filters. In the spectral domain, one limitation of the FFT is that it always represents a function’s Fourier transform as a polynomial in $z = \exp(2\pi i f \Delta)$ (cf. equation 12.1.7). Sometimes, processes have spectra whose shapes are not well represented by this form. An alternative form, which allows the spectrum to have poles in z , is used in the techniques of linear prediction (§13.6) and maximum entropy spectral estimation (§13.7).

Another significant limitation of all FFT methods is that they require the input data to be sampled at evenly spaced intervals. For irregularly or incompletely sampled data, other (albeit slower) methods are available, as discussed in §13.8.

So-called wavelet methods inhabit a representation of function space that is neither in the temporal, nor in the spectral, domain, but rather something in-between. Section 13.10 is an introduction to this subject. Finally §13.11 is an excursion into numerical use of the Fourier sampling theorem.

13.1 Convolution and Deconvolution Using the FFT

We have defined the *convolution* of two functions for the continuous case in equation (12.0.8), and have given the *convolution theorem* as equation (12.0.9). The theorem says that the Fourier transform of the convolution of two functions is equal to the product of their individual Fourier transforms. Now, we want to deal with the discrete case. We will mention first the context in which convolution is a useful procedure, and then discuss how to compute it efficiently using the FFT.

The convolution of two functions $r(t)$ and $s(t)$, denoted $r * s$, is mathematically equal to their convolution in the opposite order, $s * r$. Nevertheless, in most applications the two functions have quite different meanings and characters. One of the functions, say s , is typically a signal or data stream, which goes on indefinitely in time (or in whatever the appropriate independent variable may be). The other function r is a “response function,” typically a peaked function that falls to zero in both directions from its maximum. The effect of convolution is to smear the signal $s(t)$ in time according to the recipe provided by the response function $r(t)$, as shown in Figure 13.1.1. In particular, a spike or delta-function of unit area in s which occurs at some time t_0 is supposed to be smeared into the shape of the response function itself, but translated from time 0 to time t_0 as $r(t - t_0)$.

In the discrete case, the signal $s(t)$ is represented by its sampled values at equal time intervals s_j . The response function is also a discrete set of numbers r_k , with the following interpretation: r_0 tells what multiple of the input signal in one channel (one particular value of j) is copied into the identical output channel (same value of j); r_1 tells what multiple of input signal in channel j is additionally copied into output channel $j + 1$; r_{-1} tells the multiple that is copied into channel $j - 1$; and so on for both positive and negative values of k in r_k . Figure 13.1.2 illustrates the situation.

Example: a response function with $r_0 = 1$ and all other r_k 's equal to zero is just the identity filter: convolution of a signal with this response function gives identically the signal. Another example is the response function with $r_{14} = 1.5$ and all other r_k 's equal to zero. This produces convolved output that is the input signal multiplied by 1.5 and delayed by 14 sample intervals.

Evidently, we have just described in words the following definition of discrete convolution with a response function of finite duration M :

$$(r * s)_j \equiv \sum_{k=-M/2+1}^{M/2} s_{j-k} r_k \quad (13.1.1)$$

If a discrete response function is nonzero only in some range $-M/2 < k \leq M/2$, where M is a sufficiently large even integer, then the response function is called a *finite impulse response (FIR)*, and its *duration* is M . (Notice that we are defining M as the number of nonzero values of r_k ; these values span a time interval of $M - 1$ sampling times.) In most practical circumstances the case of finite M is the case of interest, either because the response really has a finite duration, or because we choose to truncate it at some point and approximate it by a finite-duration response function.

The *discrete convolution theorem* is this: If a signal s_j is *periodic* with period N , so that it is completely determined by the N values s_0, \dots, s_{N-1} , then its

13.1 Convolution and Deconvolution Using the FFT

We have defined the *convolution* of two functions for the continuous case in equation (12.0.8), and have given the *convolution theorem* as equation (12.0.9). The theorem says that the Fourier transform of the convolution of two functions is equal to the product of their individual Fourier transforms. Now, we want to deal with the discrete case. We will mention first the context in which convolution is a useful procedure, and then discuss how to compute it efficiently using the FFT.

The convolution of two functions $r(t)$ and $s(t)$, denoted $r * s$, is mathematically equal to their convolution in the opposite order, $s * r$. Nevertheless, in most applications the two functions have quite different meanings and characters. One of the functions, say s , is typically a signal or data stream, which goes on indefinitely in time (or in whatever the appropriate independent variable may be). The other function r is a “response function,” typically a peaked function that falls to zero in both directions from its maximum. The effect of convolution is to smear the signal $s(t)$ in time according to the recipe provided by the response function $r(t)$, as shown in Figure 13.1.1. In particular, a spike or delta-function of unit area in s which occurs at some time t_0 is supposed to be smeared into the shape of the response function itself, but translated from time 0 to time t_0 as $r(t - t_0)$.

In the discrete case, the signal $s(t)$ is represented by its sampled values at equal time intervals s_j . The response function is also a discrete set of numbers r_k , with the following interpretation: r_0 tells what multiple of the input signal in one channel (one particular value of j) is copied into the identical output channel (same value of j); r_1 tells what multiple of input signal in channel j is additionally copied into output channel $j + 1$; r_{-1} tells the multiple that is copied into channel $j - 1$; and so on for both positive and negative values of k in r_k . Figure 13.1.2 illustrates the situation.

Example: a response function with $r_0 = 1$ and all other r_k 's equal to zero is just the identity filter: convolution of a signal with this response function gives identically the signal. Another example is the response function with $r_{14} = 1.5$ and all other r_k 's equal to zero. This produces convolved output that is the input signal multiplied by 1.5 and delayed by 14 sample intervals.

Evidently, we have just described in words the following definition of discrete convolution with a response function of finite duration M :

$$(r * s)_j \equiv \sum_{k=-M/2+1}^{M/2} s_{j-k} r_k \quad (13.1.1)$$

If a discrete response function is nonzero only in some range $-M/2 < k \leq M/2$, where M is a sufficiently large even integer, then the response function is called a *finite impulse response (FIR)*, and its *duration* is M . (Notice that we are defining M as the number of nonzero values of r_k ; these values span a time interval of $M - 1$ sampling times.) In most practical circumstances the case of finite M is the case of interest, either because the response really has a finite duration, or because we choose to truncate it at some point and approximate it by a finite-duration response function.

The *discrete convolution theorem* is this: If a signal s_j is *periodic* with period N , so that it is completely determined by the N values s_0, \dots, s_{N-1} , then its

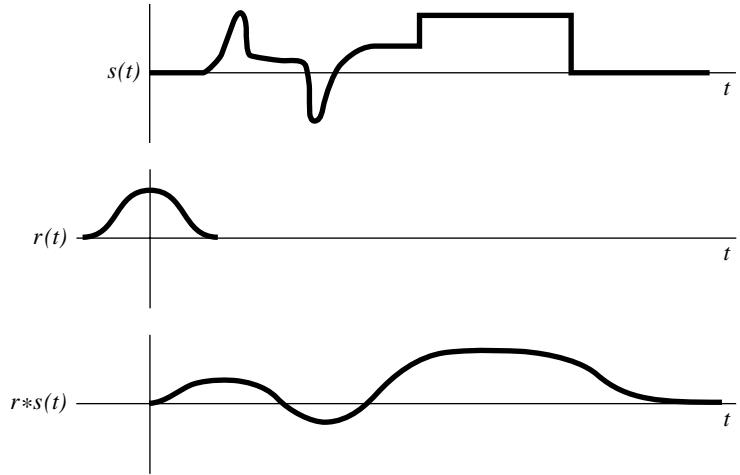

Figure 13.1.1. Example of the convolution of two functions. A signal $s(t)$ is convolved with a response function $r(t)$. Since the response function is broader than some features in the original signal, these are “washed out” in the convolution. In the absence of any additional noise, the process can be reversed by deconvolution.

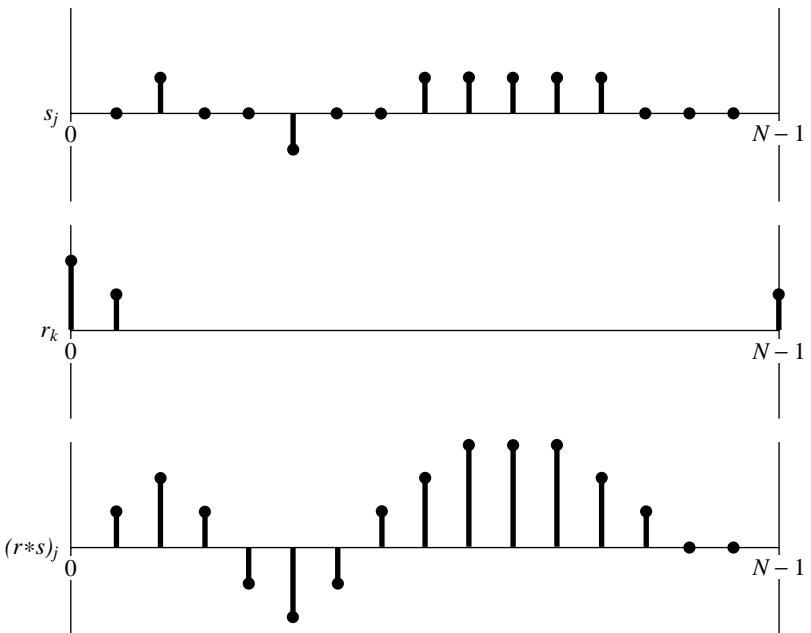

Figure 13.1.2. Convolution of discretely sampled functions. Note how the response function for negative times is wrapped around and stored at the extreme right end of the array η_k .

discrete convolution with a response function of *finite duration* N is a member of the discrete Fourier transform pair,

$$\sum_{k=-N/2+1}^{N/2} s_{j-k} r_k \iff S_n R_n \quad (13.1.2)$$

Here S_n , ($n = 0, \dots, N - 1$) is the discrete Fourier transform of the values s_j , ($j = 0, \dots, N - 1$), while R_n , ($n = 0, \dots, N - 1$) is the discrete Fourier transform of the values r_k , ($k = 0, \dots, N - 1$). These values of r_k are the same ones as for the range $k = -N/2 + 1, \dots, N/2$, but in wrap-around order, exactly as was described at the end of §12.2.

Treatment of End Effects by Zero Padding

The discrete convolution theorem presumes a set of two circumstances that are not universal. First, it assumes that the input signal is periodic, whereas real data often either go forever without repetition or else consist of one nonperiodic stretch of finite length. Second, the convolution theorem takes the duration of the response to be the same as the period of the data; they are both N . We need to work around these two constraints.

The second is very straightforward. Almost always, one is interested in a response function whose duration M is much shorter than the length of the data set N . In this case, you simply extend the response function to length N by padding it with zeros, i.e., define $r_k = 0$ for $M/2 \leq k \leq N/2$ and also for $-N/2 + 1 \leq k \leq -M/2 + 1$. Dealing with the first constraint is more challenging. Since the convolution theorem rashly assumes that the data are periodic, it will falsely “pollute” the first output channel $(r * s)_0$ with some wrapped-around data from the far end of the data stream s_{N-1}, s_{N-2} , etc. (See Figure 13.1.3.) So, we need to set up a buffer zone of zero-padded values at the end of the s_j vector, in order to make this pollution zero. How many zero values do we need in this buffer? Exactly as many as the most negative index for which the response function is nonzero. For example, if r_{-3} is nonzero, while r_{-4}, r_{-5}, \dots are all zero, then we need three zero pads at the end of the data: $s_{N-3} = s_{N-2} = s_{N-1} = 0$. These zeros will protect the first output channel $(r * s)_0$ from wrap-around pollution. It should be obvious that the second output channel $(r * s)_1$ and subsequent ones will also be protected by these same zeros. Let K denote the number of padding zeros, so that the last actual input data point is s_{N-K-1} .

What now about pollution of the very *last* output channel? Since the data now end with s_{N-K-1} , the last output channel of interest is $(r * s)_{N-K-1}$. This channel can be polluted by wrap-around from input channel s_0 unless the number K is also large enough to take care of the most positive index k for which the response function r_k is nonzero. For example, if r_0 through r_6 are nonzero, while r_7, r_8, \dots are all zero, then we need at least $K = 6$ padding zeros at the end of the data: $s_{N-6} = \dots = s_{N-1} = 0$.

To summarize — we need to pad the data with a number of zeros *on one end* equal to the maximum positive duration *or* maximum negative duration of the response function, *whichever is larger*. (For a symmetric response function of duration M , you will need only $M/2$ zero pads.) Combining this operation with the

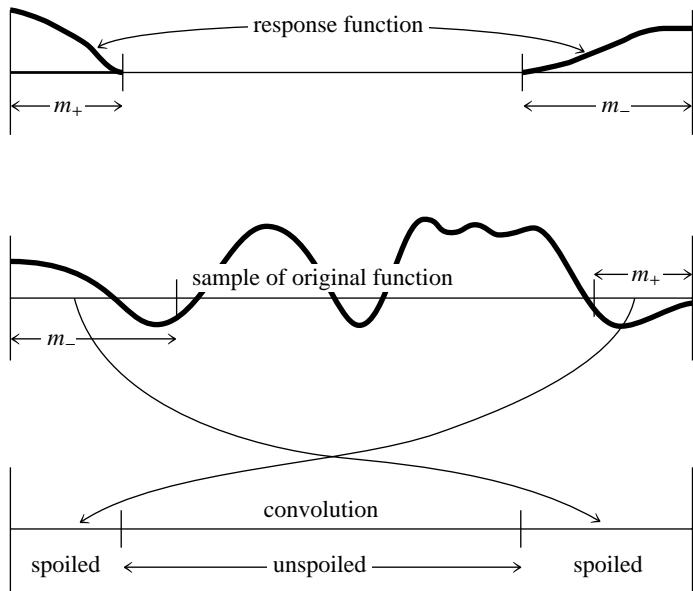

Figure 13.1.3. The wrap-around problem in convolving finite segments of a function. Not only must the response function wrap be viewed as cyclic, but so must the sampled original function. Therefore a portion at each end of the original function is erroneously wrapped around by convolution with the response function.

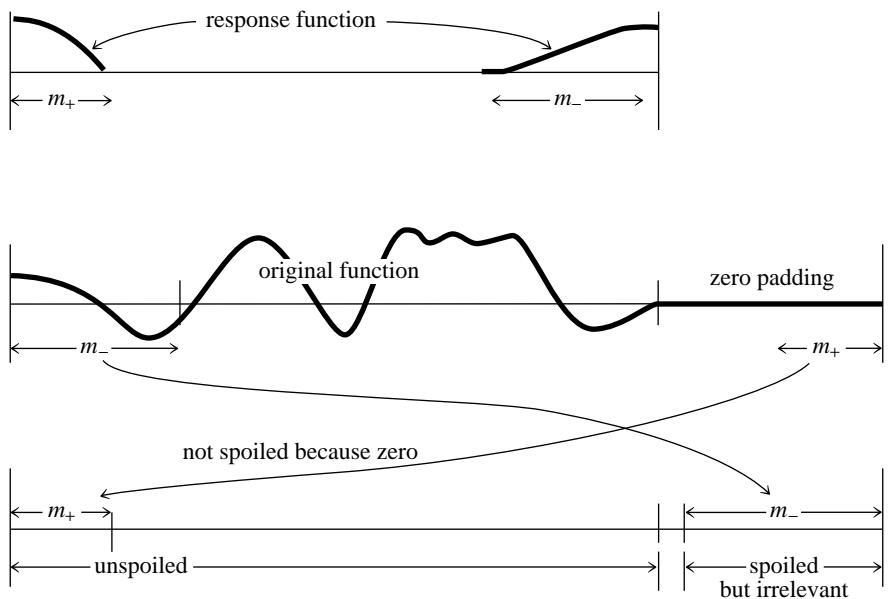

Figure 13.1.4. Zero padding as solution to the wrap-around problem. The original function is extended by zeros, serving a dual purpose: When the zeros wrap around, they do not disturb the true convolution; and while the original function wraps around onto the zero region, that region can be discarded.

padding of the response r_k described above, we effectively insulate the data from artifacts of undesired periodicity. Figure 13.1.4 illustrates matters.

Use of FFT for Convolution

The data, complete with zero padding, are now a set of real numbers s_j , $j = 0, \dots, N - 1$, and the response function is zero padded out to duration N and arranged in wrap-around order. (Generally this means that a large contiguous section of the r_k 's, in the middle of that array, is zero, with nonzero values clustered at the two extreme ends of the array.) You now compute the discrete convolution as follows: Use the FFT algorithm to compute the discrete Fourier transform of s and of r . Multiply the two transforms together component by component, remembering that the transforms consist of complex numbers. Then use the FFT algorithm to take the inverse discrete Fourier transform of the products. The answer is the convolution $r * s$.

What about *deconvolution*? Deconvolution is the process of *undoing* the smearing in a data set that has occurred under the influence of a known response function, for example, because of the known effect of a less-than-perfect measuring apparatus. The defining equation of deconvolution is the same as that for convolution, namely (13.1.1), except now the left-hand side is taken to be known, and (13.1.1) is to be considered as a set of N linear equations for the unknown quantities s_j . Solving these simultaneous linear equations in the time domain of (13.1.1) is unrealistic in most cases, but the FFT renders the problem almost trivial. Instead of multiplying the transform of the signal and response to get the transform of the convolution, we just divide the transform of the (known) convolution by the transform of the response to get the transform of the deconvolved signal.

This procedure can go wrong *mathematically* if the transform of the response function is exactly zero for some value R_n , so that we can't divide by it. This indicates that the original convolution has truly lost all information at that one frequency, so that a reconstruction of that frequency component is not possible. You should be aware, however, that apart from mathematical problems, the process of deconvolution has other practical shortcomings. The process is generally quite sensitive to noise in the input data, and to the accuracy to which the response function r_k is known. Perfectly reasonable attempts at deconvolution can sometimes produce nonsense for these reasons. In such cases you may want to make use of the additional process of *optimal filtering*, which is discussed in §13.3.

Here is our routine for convolution and deconvolution, using the FFT as implemented in `four1` of §12.2. Since the data and response functions are real, not complex, both of their transforms can be taken simultaneously using `twofft`. Note, however, that two calls to `realft` should be substituted if `data` and `respns` have very different magnitudes, to minimize roundoff. The data are assumed to be stored in a real array `data` of length `n`, which must be an integer power of two. The response function is assumed to be stored in wrap-around order in a real array `respns` of length `m`. The value of `m` can be any *odd* integer less than or equal to `n`, since the first thing the program does is to recopy the response function into the appropriate wrap-around order in an array of length `n`. The answer is returned in `ans`, which is also used as working space.

```

SUBROUTINE convlv(data,n,respns,m,isign,ans)
INTEGER isign,m,n,NMAX
REAL data(n),respns(n)
COMPLEX ans(n)
PARAMETER (NMAX=4096)                                Maximum anticipated size of FFT.
C USES realft,twofft
      Convolves or deconvolves a real data set data(1:n) (including any user-supplied zero
padding) with a response function respns, stored in wrap-around order in a real array of
length  $m \leq n$ . ( $m$  should be an odd integer.) Wrap-around order means that the first half
of the array respns contains the impulse response function at positive times, while the
second half of the array contains the impulse response function at negative times, counting
down from the highest element respns( $m$ ). On input isign is +1 for convolution, -1
for deconvolution. The answer is returned in the first  $n$  components of ans. However, ans
must be supplied in the calling program with length at least  $2*n$ , for consistency with
twofft.  $n$  MUST be an integer power of two.
INTEGER i,no2
COMPLEX fft(NMAX)
do 11 i=1,(m-1)/2                                  Put respns in array of length n.
      respns(n+1-i)=respns(m+1-i)
enddo 11
do 12 i=(m+3)/2,n-(m-1)/2                         Pad with zeros.
      respns(i)=0.0
enddo 12
call twofft(data,respns,fft,ans,n)                  FFT both at once.
no2=n/2
do 13 i=1,no2+1
      if (isign.eq.1) then                          Multiply FFTs to convolve.
          ans(i)=fft(i)*ans(i)/no2
      else if (isign.eq.-1) then
          if (abs(ans(i)).eq.0.0) pause 'deconvolving at response zero in convlv'
          ans(i)=fft(i)/ans(i)/no2                   Divide FFTs to deconvolve.
      else
          pause 'no meaning for isign in convlv'
      endif
enddo 13
ans(1)=cmplx(real(ans(1)),real(ans(no2+1)))    Pack last element with first for realft.
call realft(ans,n,-1)                            Inverse transform back to time domain.
return
END

```

Convolving or Deconvolving Very Large Data Sets

If your data set is so long that you do not want to fit it into memory all at once, then you must break it up into sections and convolve each section separately. Now, however, the treatment of end effects is a bit different. You have to worry not only about spurious wrap-around effects, but also about the fact that the ends of each section of data *should* have been influenced by data at the nearby ends of the immediately preceding and following sections of data, but were not so influenced since only one section of data is in the machine at a time.

There are two, related, standard solutions to this problem. Both are fairly obvious, so with a few words of description here, you ought to be able to implement them for yourself. The first solution is called the *overlap-save method*. In this technique you pad only the very beginning of the data with enough zeros to avoid wrap-around pollution. After this initial padding, you forget about zero padding altogether. Bring in a section of data and convolve or deconvolve it. Then throw out the points at each end that are polluted by wrap-around end effects. Output only the remaining good points in the middle. Now bring in the next section of data, but not all new data. The first points in each new section overlap the last points from the

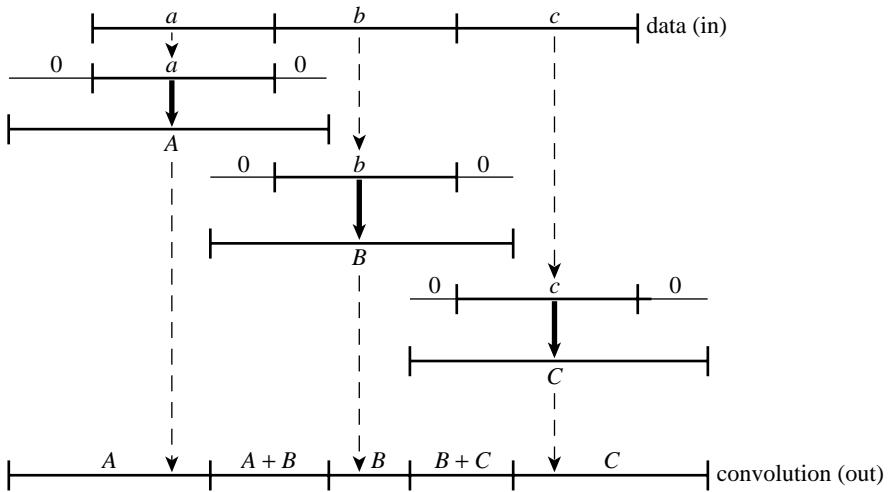

Figure 13.1.5. The overlap-add method for convolving a response with a very long signal. The signal data is broken up into smaller pieces. Each is zero padded at both ends and convolved (denoted by bold arrows in the figure). Finally the pieces are added back together, including the overlapping regions formed by the zero pads.

preceding section of data. The sections must be overlapped sufficiently so that the polluted output points at the end of one section are recomputed as the first of the unpolluted output points from the subsequent section. With a bit of thought you can easily determine how many points to overlap and save.

The second solution, called the *overlap-add method*, is illustrated in Figure 13.1.5. Here you *don't* overlap the input data. Each section of data is disjoint from the others and is used exactly once. However, you carefully zero-pad it at both ends so that there is no wrap-around ambiguity in the output convolution or deconvolution. Now you overlap *and add* these sections of output. Thus, an output point near the end of one section will have the response due to the input points at the beginning of the next section of data properly added in to it, and likewise for an output point near the beginning of a section, *mutatis mutandis*.

Even when computer memory is available, there is some slight gain in computing speed in segmenting a long data set, since the FFTs' $N \log_2 N$ is slightly slower than linear in N . However, the log term is so slowly varying that you will often be much happier to avoid the bookkeeping complexities of the overlap-add or overlap-save methods: If it is practical to do so, just cram the whole data set into memory and FFT away. Then you will have more time for the finer things in life, some of which are described in succeeding sections of this chapter.

13.2 Correlation and Autocorrelation Using the FFT

Correlation is the close mathematical cousin of convolution. It is in some ways simpler, however, because the two functions that go into a correlation are not as conceptually distinct as were the data and response functions that entered into convolution. Rather, in correlation, the functions are represented by different, but generally similar, data sets. We investigate their “correlation,” by comparing them both directly superposed, and with one of them shifted left or right.

We have already defined in equation (12.0.10) the correlation between two continuous functions $g(t)$ and $h(t)$, which is denoted $\text{Corr}(g, h)$, and is a function of *lag t*. We will occasionally show this time dependence explicitly, with the rather awkward notation $\text{Corr}(g, h)(t)$. The correlation will be large at some value of t if the first function (g) is a close copy of the second (h) but lags it in time by t , i.e., if the first function is shifted to the right of the second. Likewise, the correlation will be large for some negative value of t if the first function *leads* the second, i.e., is shifted to the left of the second. The relation that holds when the two functions are interchanged is

$$\text{Corr}(g, h)(t) = \text{Corr}(h, g)(-t) \quad (13.2.1)$$

The discrete correlation of two sampled functions g_k and h_k , each periodic with period N , is defined by

$$\text{Corr}(g, h)_j \equiv \sum_{k=0}^{N-1} g_{j+k} h_k \quad (13.2.2)$$

The *discrete correlation theorem* says that this discrete correlation of two real functions g and h is one member of the discrete Fourier transform pair

$$\text{Corr}(g, h)_j \iff G_k H_k^* \quad (13.2.3)$$

where G_k and H_k are the discrete Fourier transforms of g_j and h_j , and the asterisk denotes complex conjugation. This theorem makes the same presumptions about the functions as those encountered for the discrete convolution theorem.

We can compute correlations using the FFT as follows: FFT the two data sets, multiply one resulting transform by the complex conjugate of the other, and inverse transform the product. The result (call it r_k) will formally be a complex vector of length N . However, it will turn out to have all its imaginary parts zero since the original data sets were both real. The components of r_k are the values of the correlation at different lags, with positive and negative lags stored in the by now familiar wrap-around order: The correlation at zero lag is in r_0 , the first component; the correlation at lag 1 is in r_1 , the second component; the correlation at lag -1 is in r_{N-1} , the last component; etc.

Just as in the case of convolution we have to consider end effects, since our data will not, in general, be periodic as intended by the correlation theorem. Here again, we can use zero padding. If you are interested in the correlation for lags as large as $\pm K$, then you must append a buffer zone of K zeros at the end of both

13.2 Correlation and Autocorrelation Using the FFT

Correlation is the close mathematical cousin of convolution. It is in some ways simpler, however, because the two functions that go into a correlation are not as conceptually distinct as were the data and response functions that entered into convolution. Rather, in correlation, the functions are represented by different, but generally similar, data sets. We investigate their “correlation,” by comparing them both directly superposed, and with one of them shifted left or right.

We have already defined in equation (12.0.10) the correlation between two continuous functions $g(t)$ and $h(t)$, which is denoted $\text{Corr}(g, h)$, and is a function of *lag t*. We will occasionally show this time dependence explicitly, with the rather awkward notation $\text{Corr}(g, h)(t)$. The correlation will be large at some value of t if the first function (g) is a close copy of the second (h) but lags it in time by t , i.e., if the first function is shifted to the right of the second. Likewise, the correlation will be large for some negative value of t if the first function *leads* the second, i.e., is shifted to the left of the second. The relation that holds when the two functions are interchanged is

$$\text{Corr}(g, h)(t) = \text{Corr}(h, g)(-t) \quad (13.2.1)$$

The discrete correlation of two sampled functions g_k and h_k , each periodic with period N , is defined by

$$\text{Corr}(g, h)_j \equiv \sum_{k=0}^{N-1} g_{j+k} h_k \quad (13.2.2)$$

The *discrete correlation theorem* says that this discrete correlation of two real functions g and h is one member of the discrete Fourier transform pair

$$\text{Corr}(g, h)_j \iff G_k H_k^* \quad (13.2.3)$$

where G_k and H_k are the discrete Fourier transforms of g_j and h_j , and the asterisk denotes complex conjugation. This theorem makes the same presumptions about the functions as those encountered for the discrete convolution theorem.

We can compute correlations using the FFT as follows: FFT the two data sets, multiply one resulting transform by the complex conjugate of the other, and inverse transform the product. The result (call it r_k) will formally be a complex vector of length N . However, it will turn out to have all its imaginary parts zero since the original data sets were both real. The components of r_k are the values of the correlation at different lags, with positive and negative lags stored in the by now familiar wrap-around order: The correlation at zero lag is in r_0 , the first component; the correlation at lag 1 is in r_1 , the second component; the correlation at lag -1 is in r_{N-1} , the last component; etc.

Just as in the case of convolution we have to consider end effects, since our data will not, in general, be periodic as intended by the correlation theorem. Here again, we can use zero padding. If you are interested in the correlation for lags as large as $\pm K$, then you must append a buffer zone of K zeros at the end of both

input data sets. If you want all possible lags from N data points (not a usual thing), then you will need to pad the data with an equal number of zeros; this is the extreme case. So here is the program:

```
SUBROUTINE correl(data1,data2,n,ans)
INTEGER n,NMAX
REAL data1(n),data2(n)
COMPLEX ans(n)
PARAMETER (NMAX=4096)                                Maximum anticipated FFT size.
C USES realft,twofft
Computes the correlation of two real data sets data1(1:n) and data2(1:n) (including any user-supplied zero padding). n MUST be an integer power of two. The answer is returned as the first n points in ans stored in wrap-around order, i.e., correlations at increasingly negative lags are in ans(n) on down to ans(n/2+1), while correlations at increasingly positive lags are in ans(1) (zero lag) on up to ans(n/2). Note that ans must be supplied in the calling program with length at least 2*n, since it is also used as working space. Sign convention of this routine: if data1 lags data2, i.e., is shifted to the right of it, then ans will show a peak at positive lags.
INTEGER i,no2
COMPLEX fft(NMAX)
call twofft(data1,data2,fft,ans,n)                  Transform both data vectors at once.
no2=n/2                                              Normalization for inverse FFT.
do ii i=1,no2+1
    ans(i)=fft(i)*conjg(ans(i))/float(no2)          Multiply to find FFT of their corre-
enddo ii                                              lation.
ans(1)=cmplx(real(ans(1)),real(ans(no2+1)))        Pack first and last into one element.
call realft(ans,n,-1)                               Inverse transform gives correlation.
return
END
```

As in convlv, it would be better to substitute two calls to `realft` for the one call to `twofft`, if `data1` and `data2` have very different magnitudes, to minimize roundoff error.

The *discrete autocorrelation* of a sampled function g_j is just the discrete correlation of the function with itself. Obviously this is always symmetric with respect to positive and negative lags. Feel free to use the above routine `correl` to obtain autocorrelations, simply calling it with the same data vector in both arguments. If the inefficiency bothers you, routine `realft` can, of course, be used to transform the data vector instead.

13.3 Optimal (Wiener) Filtering with the FFT

There are a number of other tasks in numerical processing that are routinely handled with Fourier techniques. One of these is filtering for the removal of noise from a “corrupted” signal. The particular situation we consider is this: There is some underlying, uncorrupted signal $u(t)$ that we want to measure. The measurement process is imperfect, however, and what comes out of our measurement device is a corrupted signal $c(t)$. The signal $c(t)$ may be less than perfect in either or both of two respects. First, the apparatus may not have a perfect “delta-function” response,

input data sets. If you want all possible lags from N data points (not a usual thing), then you will need to pad the data with an equal number of zeros; this is the extreme case. So here is the program:

```
SUBROUTINE correl(data1,data2,n,ans)
INTEGER n,NMAX
REAL data1(n),data2(n)
COMPLEX ans(n)
PARAMETER (NMAX=4096)                                Maximum anticipated FFT size.
C USES realft,twofft
Computes the correlation of two real data sets data1(1:n) and data2(1:n) (including any user-supplied zero padding). n MUST be an integer power of two. The answer is returned as the first n points in ans stored in wrap-around order, i.e., correlations at increasingly negative lags are in ans(n) on down to ans(n/2+1), while correlations at increasingly positive lags are in ans(1) (zero lag) on up to ans(n/2). Note that ans must be supplied in the calling program with length at least 2*n, since it is also used as working space. Sign convention of this routine: if data1 lags data2, i.e., is shifted to the right of it, then ans will show a peak at positive lags.
INTEGER i,no2
COMPLEX fft(NMAX)

As in convlv, it would be better to substitute two calls to `realft` for the one call to `twofft`, if `data1` and `data2` have very different magnitudes, to minimize roundoff error.

The *discrete autocorrelation* of a sampled function g_j is just the discrete correlation of the function with itself. Obviously this is always symmetric with respect to positive and negative lags. Feel free to use the above routine `correl` to obtain autocorrelations, simply calling it with the same data vector in both arguments. If the inefficiency bothers you, routine `realft` can, of course, be used to transform the data vector instead.

13.3 Optimal (Wiener) Filtering with the FFT

There are a number of other tasks in numerical processing that are routinely handled with Fourier techniques. One of these is filtering for the removal of noise from a “corrupted” signal. The particular situation we consider is this: There is some underlying, uncorrupted signal $u(t)$ that we want to measure. The measurement process is imperfect, however, and what comes out of our measurement device is a corrupted signal $c(t)$. The signal $c(t)$ may be less than perfect in either or both of two respects. First, the apparatus may not have a perfect “delta-function” response,

so that the true signal $u(t)$ is convolved with (smeared out by) some known response function $r(t)$ to give a smeared signal $s(t)$,

$$s(t) = \int_{-\infty}^{\infty} r(t - \tau) u(\tau) d\tau \quad \text{or} \quad S(f) = R(f)U(f) \quad (13.3.1)$$

where S, R, U are the Fourier transforms of s, r, u , respectively. Second, the measured signal $c(t)$ may contain an additional component of noise $n(t)$,

$$c(t) = s(t) + n(t) \quad (13.3.2)$$

We already know how to deconvolve the effects of the response function r in the absence of any noise (§13.1); we just divide $C(f)$ by $R(f)$ to get a deconvolved signal. We now want to treat the analogous problem when noise is present. Our task is to find the *optimal filter*, $\phi(t)$ or $\Phi(f)$, which, when applied to the measured signal $c(t)$ or $C(f)$, and then deconvolved by $r(t)$ or $R(f)$, produces a signal $\tilde{u}(t)$ or $\tilde{U}(f)$ that is as close as possible to the uncorrected signal $u(t)$ or $U(f)$. In other words we will estimate the true signal U by

$$\tilde{U}(f) = \frac{C(f)\Phi(f)}{R(f)} \quad (13.3.3)$$

In what sense is \tilde{U} to be close to U ? We ask that they be *close in the least-square sense*

$$\int_{-\infty}^{\infty} |\tilde{u}(t) - u(t)|^2 dt = \int_{-\infty}^{\infty} |\tilde{U}(f) - U(f)|^2 df \quad \text{is minimized.} \quad (13.3.4)$$

Substituting equations (13.3.3) and (13.3.2), the right-hand side of (13.3.4) becomes

$$\begin{aligned} & \int_{-\infty}^{\infty} \left| \frac{[S(f) + N(f)]\Phi(f)}{R(f)} - \frac{S(f)}{R(f)} \right|^2 df \\ &= \int_{-\infty}^{\infty} |R(f)|^{-2} \left\{ |S(f)|^2 |1 - \Phi(f)|^2 + |N(f)|^2 |\Phi(f)|^2 \right\} df \end{aligned} \quad (13.3.5)$$

The signal S and the noise N are *uncorrelated*, so their cross product, when integrated over frequency f , gave zero. (This is practically the *definition* of what we mean by noise!) Obviously (13.3.5) will be a minimum if and only if the integrand is minimized with respect to $\Phi(f)$ at every value of f . Let us search for such a solution where $\Phi(f)$ is a real function. Differentiating with respect to Φ , and setting the result equal to zero gives

$$\Phi(f) = \frac{|S(f)|^2}{|S(f)|^2 + |N(f)|^2} \quad (13.3.6)$$

This is the formula for the optimal filter $\Phi(f)$.

Notice that equation (13.3.6) involves S , the smeared signal, and N , the noise. The two of these add up to be C , the measured signal. Equation (13.3.6) does not

contain U , the “true” signal. This makes for an important simplification: The optimal filter can be determined independently of the determination of the deconvolution function that relates S and U .

To determine the optimal filter from equation (13.3.6) we need some way of separately estimating $|S|^2$ and $|N|^2$. There is no way to do this from the measured signal C alone without some other information, or some assumption or guess. Luckily, the extra information is often easy to obtain. For example, we can sample a long stretch of data $c(t)$ and plot its power spectral density using equations (12.0.14), (12.1.8), and (12.1.5). This quantity is proportional to the sum $|S|^2 + |N|^2$, so we have

$$|S(f)|^2 + |N(f)|^2 \approx P_c(f) = |C(f)|^2 \quad 0 \leq f < f_c \quad (13.3.7)$$

(More sophisticated methods of estimating the power spectral density will be discussed in §13.4 and §13.7, but the estimation above is almost always good enough for the optimal filter problem.) The resulting plot (see Figure 13.3.1) will often immediately show the spectral signature of a signal sticking up above a continuous noise spectrum. The noise spectrum may be flat, or tilted, or smoothly varying; it doesn’t matter, as long as we can guess a reasonable hypothesis as to what it is. Draw a smooth curve through the noise spectrum, extrapolating it into the region dominated by the signal as well. Now draw a smooth curve through the signal plus noise power. The difference between these two curves is your smooth “model” of the signal power. The quotient of your model of signal power to your model of signal plus noise power is the optimal filter $\Phi(f)$. [Extend it to negative values of f by the formula $\Phi(-f) = \Phi(f)$.] Notice that $\Phi(f)$ will be close to unity where the noise is negligible, and close to zero where the noise is dominant. That is how it does its job! The intermediate dependence given by equation (13.3.6) just turns out to be the optimal way of going in between these two extremes.

Because the optimal filter results from a minimization problem, the quality of the results obtained by optimal filtering differs from the true optimum by an amount that is *second order* in the precision to which the optimal filter is determined. In other words, even a fairly crudely determined optimal filter (sloppy, say, at the 10 percent level) can give excellent results when it is applied to data. That is why the separation of the measured signal C into signal and noise components S and N can usefully be done “by eye” from a crude plot of power spectral density. All of this may give you thoughts about iterating the procedure we have just described. For example, after designing a filter with response $\Phi(f)$ and using it to make a respectable guess at the signal $\tilde{U}(f) = \Phi(f)C(f)/R(f)$, you might turn about and regard $\tilde{U}(f)$ as a fresh new signal which you could improve even further with the same filtering technique. Don’t waste your time on this line of thought. The scheme converges to a signal of $S(f) = 0$. Converging iterative methods do exist; this just isn’t one of them.

You can use the routine `four1` (§12.2) or `realft` (§12.3) to FFT your data when you are constructing an optimal filter. To apply the filter to your data, you can use the methods described in §13.1. The specific routine `conv1v` is not needed for optimal filtering, since your filter is constructed in the frequency domain to begin with. If you are also deconvolving your data with a known response function, however, you can modify `conv1v` to multiply by your optimal filter just before it takes the inverse Fourier transform.

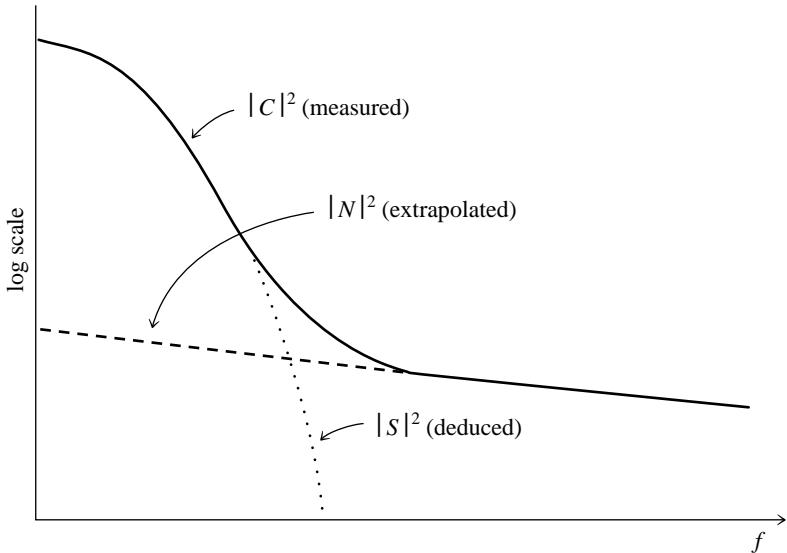

Figure 13.3.1. Optimal (Wiener) filtering. The power spectrum of signal plus noise shows a signal peak added to a noise tail. The tail is extrapolated back into the signal region as a “noise model.” Subtracting gives the “signal model.” The models need not be accurate for the method to be useful. A simple algebraic combination of the models gives the optimal filter (see text).

13.4 Power Spectrum Estimation Using the FFT

In the previous section we “informally” estimated the power spectral density of a function $c(t)$ by taking the modulus-squared of the discrete Fourier transform of some finite, sampled stretch of it. In this section we’ll do roughly the same thing, but with considerably greater attention to details. Our attention will uncover some surprises.

The first detail is power spectrum (also called a power spectral density or PSD) normalization. In general there is *some* relation of proportionality between a measure of the squared amplitude of the function and a measure of the amplitude of the PSD. Unfortunately there are several different conventions for describing the normalization in each domain, and many opportunities for getting wrong the relationship between the two domains. Suppose that our function $c(t)$ is sampled at N points to produce values $c_0 \dots c_{N-1}$, and that these points span a range of time T , that is $T = (N - 1)\Delta$, where Δ is the sampling interval. Then here are several

13.4 Power Spectrum Estimation Using the FFT

In the previous section we “informally” estimated the power spectral density of a function $c(t)$ by taking the modulus-squared of the discrete Fourier transform of some finite, sampled stretch of it. In this section we’ll do roughly the same thing, but with considerably greater attention to details. Our attention will uncover some surprises.

The first detail is power spectrum (also called a power spectral density or PSD) normalization. In general there is *some* relation of proportionality between a measure of the squared amplitude of the function and a measure of the amplitude of the PSD. Unfortunately there are several different conventions for describing the normalization in each domain, and many opportunities for getting wrong the relationship between the two domains. Suppose that our function $c(t)$ is sampled at N points to produce values $c_0 \dots c_{N-1}$, and that these points span a range of time T , that is $T = (N - 1)\Delta$, where Δ is the sampling interval. Then here are several

different descriptions of the total power:

$$\sum_{j=0}^{N-1} |c_j|^2 \equiv \text{"sum squared amplitude"} \quad (13.4.1)$$

$$\frac{1}{T} \int_0^T |c(t)|^2 dt \approx \frac{1}{N} \sum_{j=0}^{N-1} |c_j|^2 \equiv \text{"mean squared amplitude"} \quad (13.4.2)$$

$$\int_0^T |c(t)|^2 dt \approx \Delta \sum_{j=0}^{N-1} |c_j|^2 \equiv \text{"time-integral squared amplitude"} \quad (13.4.3)$$

PSD estimators, as we shall see, have an even greater variety. In this section, we consider a class of them that give estimates at discrete values of frequency f_i , where i will range over integer values. In the next section, we will learn about a different class of estimators that produce estimates that are continuous functions of frequency f . Even if it is agreed always to relate the PSD normalization to a particular description of the function normalization (e.g., 13.4.2), there are at least the following possibilities: The PSD is

- defined for discrete positive, zero, and negative frequencies, and its sum over these is the function mean squared amplitude
- defined for zero and discrete positive frequencies only, and its sum over these is the function mean squared amplitude
- defined in the Nyquist interval from $-f_c$ to f_c , and its integral over this range is the function mean squared amplitude
- defined from 0 to f_c , and its integral over this range is the function mean squared amplitude

It *never* makes sense to integrate the PSD of a sampled function outside of the Nyquist interval $-f_c$ and f_c since, according to the sampling theorem, power there will have been aliased into the Nyquist interval.

It is hopeless to define enough notation to distinguish all possible combinations of normalizations. In what follows, we use the notation $P(f)$ to mean *any* of the above PSDs, stating in each instance how the particular $P(f)$ is normalized. Beware the inconsistent notation in the literature.

The method of power spectrum estimation used in the previous section is a simple version of an estimator called, historically, the *periodogram*. If we take an N -point sample of the function $c(t)$ at equal intervals and use the FFT to compute its discrete Fourier transform

$$C_k = \sum_{j=0}^{N-1} c_j e^{2\pi i j k / N} \quad k = 0, \dots, N-1 \quad (13.4.4)$$

then the periodogram estimate of the power spectrum is defined at $N/2 + 1$

frequencies as

$$\begin{aligned} P(0) &= P(f_0) = \frac{1}{N^2} |C_0|^2 \\ P(f_k) &= \frac{1}{N^2} \left[|C_k|^2 + |C_{N-k}|^2 \right] \quad k = 1, 2, \dots, \left(\frac{N}{2} - 1 \right) \\ P(f_c) &= P(f_{N/2}) = \frac{1}{N^2} |C_{N/2}|^2 \end{aligned} \quad (13.4.5)$$

where f_k is defined only for the zero and positive frequencies

$$f_k \equiv \frac{k}{N\Delta} = 2f_c \frac{k}{N} \quad k = 0, 1, \dots, \frac{N}{2} \quad (13.4.6)$$

By Parseval's theorem, equation (12.1.10), we see immediately that equation (13.4.5) is normalized so that the sum of the $N/2 + 1$ values of P is equal to the mean squared amplitude of the function c_j .

We must now ask this question. In what sense is the periodogram estimate (13.4.5) a "true" estimator of the power spectrum of the underlying function $c(t)$? You can find the answer treated in considerable detail in the literature cited (see, e.g., [1] for an introduction). Here is a summary.

First, is the *expectation value* of the periodogram estimate equal to the power spectrum, i.e., is the estimator correct on average? Well, yes and no. We wouldn't really expect one of the $P(f_k)$'s to equal the continuous $P(f)$ at *exactly* f_k , since f_k is supposed to be representative of a whole frequency "bin" extending from halfway from the preceding discrete frequency to halfway to the next one. We *should* be expecting the $P(f_k)$ to be some kind of average of $P(f)$ over a narrow window function centered on its f_k . For the periodogram estimate (13.4.6) that window function, as a function of s the frequency offset *in bins*, is

$$W(s) = \frac{1}{N^2} \left[\frac{\sin(\pi s)}{\sin(\pi s/N)} \right]^2 \quad (13.4.7)$$

Notice that $W(s)$ has oscillatory lobes but, apart from these, falls off only about as $W(s) \approx (\pi s)^{-2}$. This is not a very rapid fall-off, and it results in significant *leakage* (that is the technical term) from one frequency to another in the periodogram estimate. Notice also that $W(s)$ happens to be zero for s equal to a nonzero integer. This means that if the function $c(t)$ is a pure sine wave of frequency exactly equal to one of the f_k 's, then there will be *no* leakage to adjacent f_k 's. But this is not the characteristic case! If the frequency is, say, one-third of the way between two adjacent f_k 's, then the leakage will extend *well* beyond those two adjacent bins. The solution to the problem of leakage is called *data windowing*, and we will discuss it below.

Turn now to another question about the periodogram estimate. What is the variance of that estimate as N goes to infinity? In other words, as we take more sampled points from the original function (either sampling a longer stretch of data at the same sampling rate, or else by resampling the same stretch of data with a faster sampling rate), then how much more accurate do the estimates P_k become? The unpleasant answer is that the periodogram estimates *do not become more accurate at all!* In fact, the variance of the periodogram estimate at a frequency f_k is always

equal to the square of its expectation value at that frequency. In other words, the standard deviation is always 100 percent of the value, independent of N ! How can this be? Where did all the information go as we added points? It all went into producing estimates at a greater number of discrete frequencies f_k . If we sample a longer run of data using the same sampling rate, then the Nyquist critical frequency f_c is unchanged, but we now have finer frequency resolution (more f_k 's) within the Nyquist frequency interval; alternatively, if we sample the same length of data with a finer sampling interval, then our frequency resolution is unchanged, but the Nyquist range now extends up to a higher frequency. In neither case do the additional samples reduce the variance of any one particular frequency's estimated PSD.

You don't have to live with PSD estimates with 100 percent standard deviations, however. You simply have to know some techniques for reducing the variance of the estimates. Here are two techniques that are very nearly identical mathematically, though different in implementation. The first is to compute a periodogram estimate with finer discrete frequency spacing than you really need, and then to sum the periodogram estimates at K consecutive discrete frequencies to get one "smoother" estimate at the mid frequency of those K . The variance of that summed estimate will be smaller than the estimate itself by a factor of exactly $1/K$, i.e., the standard deviation will be smaller than 100 percent by a factor $1/\sqrt{K}$. Thus, to estimate the power spectrum at $M + 1$ discrete frequencies between 0 and f_c inclusive, you begin by taking the FFT of $2MK$ points (which number had better be an integer power of two!). You then take the modulus square of the resulting coefficients, add positive and negative frequency pairs, and divide by $(2MK)^2$, all according to equation (13.4.5) with $N = 2MK$. Finally, you "bin" the results into summed (not averaged) groups of K . This procedure is very easy to program, so we will not bother to give a routine for it. The reason that you sum, rather than average, K consecutive points is so that your final PSD estimate will preserve the normalization property that the sum of its $M + 1$ values equals the mean square value of the function.

A second technique for estimating the PSD at $M + 1$ discrete frequencies in the range 0 to f_c is to partition the original sampled data into K segments each of $2M$ consecutive sampled points. Each segment is separately FFT'd to produce a periodogram estimate (equation 13.4.5 with $N \equiv 2M$). Finally, the K periodogram estimates are averaged at each frequency. It is this final averaging that reduces the variance of the estimate by a factor K (standard deviation by \sqrt{K}). This second technique is computationally more efficient than the first technique above by a modest factor, since it is logarithmically more efficient to take many shorter FFTs than one longer one. The principal advantage of the second technique, however, is that only $2M$ data points are manipulated at a single time, not $2KM$ as in the first technique. This means that the second technique is the natural choice for processing long runs of data, as from a magnetic tape or other data record. We will give a routine later for implementing this second technique, but we need first to return to the matters of leakage and data windowing which were brought up after equation (13.4.7) above.

Data Windowing

The purpose of data windowing is to modify equation (13.4.7), which expresses the relation between the spectral estimate P_k at a discrete frequency and the actual underlying continuous spectrum $P(f)$ at nearby frequencies. In general, the spectral

power in one “bin” k contains leakage from frequency components that are actually s bins away, where s is the independent variable in equation (13.4.7). There is, as we pointed out, quite substantial leakage even from moderately large values of s .

When we select a run of N sampled points for periodogram spectral estimation, we are in effect multiplying an infinite run of sampled data c_j by a window function in time, one that is zero except during the total sampling time $N\Delta$, and is unity during that time. In other words, the data are windowed by a square window function. By the convolution theorem (12.0.9; but interchanging the roles of f and t), the Fourier transform of the product of the data with this square window function is equal to the convolution of the data’s Fourier transform with the window’s Fourier transform. In fact, we determined equation (13.4.7) as nothing more than the square of the discrete Fourier transform of the unity window function.

$$W(s) = \frac{1}{N^2} \left[\frac{\sin(\pi s)}{\sin(\pi s/N)} \right]^2 = \frac{1}{N^2} \left| \sum_{k=0}^{N-1} e^{2\pi i sk/N} \right|^2 \quad (13.4.8)$$

The reason for the leakage at large values of s , is that the square window function turns on and off so rapidly. Its Fourier transform has substantial components at high frequencies. To remedy this situation, we can multiply the input data c_j , $j = 0, \dots, N - 1$ by a window function w_j that changes more gradually from zero to a maximum and then back to zero as j ranges from 0 to N . In this case, the equations for the periodogram estimator (13.4.4–13.4.5) become

$$D_k \equiv \sum_{j=0}^{N-1} c_j w_j e^{2\pi i j k / N} \quad k = 0, \dots, N - 1 \quad (13.4.9)$$

$$\begin{aligned} P(0) &= P(f_0) = \frac{1}{W_{ss}} |D_0|^2 \\ P(f_k) &= \frac{1}{W_{ss}} \left[|D_k|^2 + |D_{N-k}|^2 \right] \quad k = 1, 2, \dots, \left(\frac{N}{2} - 1 \right) \\ P(f_c) &= P(f_{N/2}) = \frac{1}{W_{ss}} |D_{N/2}|^2 \end{aligned} \quad (13.4.10)$$

where W_{ss} stands for “window squared and summed,”

$$W_{ss} \equiv N \sum_{j=0}^{N-1} w_j^2 \quad (13.4.11)$$

and f_k is given by (13.4.6). The more general form of (13.4.7) can now be written in terms of the window function w_j as

$$\begin{aligned} W(s) &= \frac{1}{W_{ss}} \left| \sum_{k=0}^{N-1} e^{2\pi i sk/N} w_k \right|^2 \\ &\approx \frac{1}{W_{ss}} \left| \int_{-N/2}^{N/2} \cos(2\pi sk/N) w(k - N/2) dk \right|^2 \end{aligned} \quad (13.4.12)$$

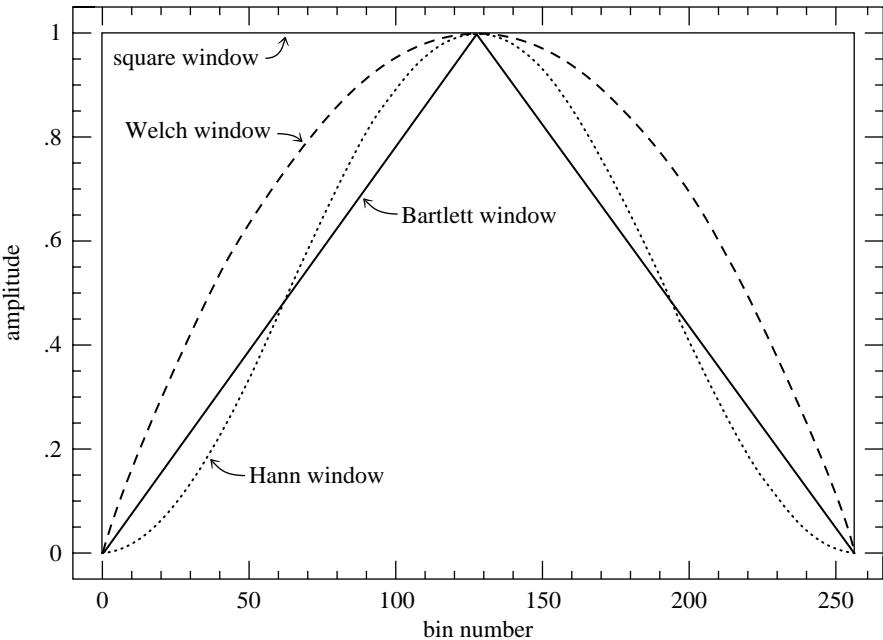

Figure 13.4.1. Window functions commonly used in FFT power spectral estimation. The data segment, here of length 256, is multiplied (bin by bin) by the window function before the FFT is computed. The square window, which is equivalent to no windowing, is least recommended. The Welch and Bartlett windows are good choices.

Here the approximate equality is useful for practical estimates, and holds for any window that is left-right symmetric (the usual case), and for $s \ll N$ (the case of interest for estimating leakage into nearby bins). The continuous function $w(k - N/2)$ in the integral is meant to be some smooth function that passes through the points w_k .

There is a lot of perhaps unnecessary lore about choice of a window function, and practically every function that rises from zero to a peak and then falls again has been named after someone. A few of the more common (also shown in Figure 13.4.1) are:

$$w_j = 1 - \left| \frac{j - \frac{1}{2}N}{\frac{1}{2}N} \right| \equiv \text{"Bartlett window"} \quad (13.4.13)$$

(The “Parzen window” is very similar to this.)

$$w_j = \frac{1}{2} \left[1 - \cos \left(\frac{2\pi j}{N} \right) \right] \equiv \text{"Hann window"} \quad (13.4.14)$$

(The “Hamming window” is similar but does not go exactly to zero at the ends.)

$$w_j = 1 - \left(\frac{j - \frac{1}{2}N}{\frac{1}{2}N} \right)^2 \equiv \text{"Welch window"} \quad (13.4.15)$$

We are inclined to follow Welch in recommending that you use either (13.4.13) or (13.4.15) in practical work. However, at the level of this book, there is effectively

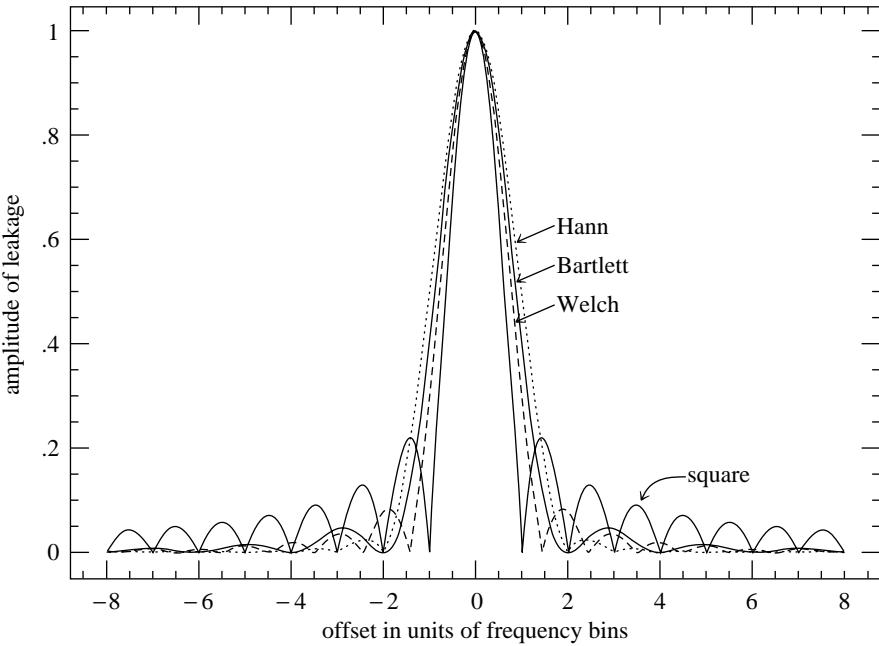

Figure 13.4.2. Leakage functions for the window functions of Figure 13.4.1. A signal whose frequency is actually located at zero offset “leaks” into neighboring bins with the amplitude shown. The purpose of windowing is to reduce the leakage at large offsets, where square (no) windowing has large sidelobes. Offset can have a fractional value, since the actual signal frequency can be located between two frequency bins of the FFT.

no difference between any of these (or similar) window functions. Their difference lies in subtle trade-offs among the various figures of merit that can be used to describe the narrowness or peakedness of the spectral leakage functions computed by (13.4.12). These figures of merit have such names as: *highest sidelobe level (dB)*, *sidelobe fall-off (dB per octave)*, *equivalent noise bandwidth (bins)*, *3-dB bandwidth (bins)*, *scalloped loss (dB)*, *worst case process loss (dB)*. Roughly speaking, the principal trade-off is between making the central peak as narrow as possible versus making the tails of the distribution fall off as rapidly as possible. For details, see (e.g.) [2]. Figure 13.4.2 plots the leakage amplitudes for several windows already discussed.

There is particularly a lore about window functions that rise smoothly from zero to unity in the first small fraction (say 10 percent) of the data, then stay at unity until the last small fraction (again say 10 percent) of the data, during which the window function falls smoothly back to zero. These windows will squeeze a little bit of extra narrowness out of the main lobe of the leakage function (never as much as a factor of two, however), but trade this off by widening the leakage tail by a significant factor (e.g., the reciprocal of 10 percent, a factor of ten). If we distinguish between the *width* of a window (number of samples for which it is at its maximum value) and its *rise/fall time* (number of samples during which it rises and falls); and if we distinguish between the *FWHM* (full width to half maximum value) of the leakage function’s main lobe and the *leakage width* (full width that contains half of the spectral power that is not contained in the main lobe); then these

quantities are related roughly by

$$(\text{FWHM in bins}) \approx \frac{N}{(\text{window width})} \quad (13.4.16)$$

$$(\text{leakage width in bins}) \approx \frac{N}{(\text{window rise/fall time})} \quad (13.4.17)$$

For the windows given above in (13.4.13)–(13.4.15), the effective window widths and the effective window rise/fall times are both of order $\frac{1}{2}N$. Generally speaking, we feel that the advantages of windows whose rise and fall times are only small fractions of the data length are minor or nonexistent, and we avoid using them. One sometimes hears it said that flat-topped windows “throw away less of the data,” but we will now show you a better way of dealing with that problem by use of overlapping data segments.

Let us now suppose that we have chosen a window function, and that we are ready to segment the data into K segments of $N = 2M$ points. Each segment will be FFT’d, and the resulting K periodograms will be averaged together to obtain a PSD estimate at $M + 1$ frequency values from 0 to f_c . We must now distinguish between two possible situations. We might want to obtain the smallest variance from a fixed amount of computation, without regard to the number of data points used. This will generally be the goal when the data are being gathered in real time, with the data-reduction being computer-limited. Alternatively, we might want to obtain the smallest variance from a fixed number of available sampled data points. This will generally be the goal in cases where the data are already recorded and we are analyzing it after the fact.

In the first situation (smallest spectral variance per computer operation), it is best to segment the data without any overlapping. The first $2M$ data points constitute segment number 1; the next $2M$ data points constitute segment number 2; and so on, up to segment number K , for a total of $2KM$ sampled points. The variance in this case, relative to a single segment, is reduced by a factor K .

In the second situation (smallest spectral variance per data point), it turns out to be optimal, or very nearly optimal, to overlap the segments by one half of their length. The first and second sets of M points are segment number 1; the second and third sets of M points are segment number 2; and so on, up to segment number K , which is made of the K th and $K + 1$ st sets of M points. The total number of sampled points is therefore $(K + 1)M$, just over half as many as with nonoverlapping segments. The reduction in the variance is not a full factor of K , since the segments are not statistically independent. It can be shown that the variance is instead reduced by a factor of about $9K/11$ (see the paper by Welch in [3]). This is, however, significantly better than the reduction of about $K/2$ that would have resulted if the same *number* of data points were segmented without overlapping.

We can now codify these ideas into a routine for spectral estimation. While we generally avoid input/output coding, we make an exception here to show how data are read sequentially in one pass through a data file (here FORTRAN Unit 9). Only a small fraction of the data is in memory at any one time. Note that `spctrm` returns the power at M , not $M + 1$, frequencies, omitting the component $P(f_c)$ at the Nyquist frequency. It would also be straightforward to include that component.

```

SUBROUTINE spctrm(p,m,k,ovrlap,w1,w2)
INTEGER k,m
REAL p(m),w1(4*m),w2(m)
LOGICAL ovrlap
C USES four1
      True for overlapping segments, false otherwise.
      Reads data from input unit 9 and returns as p(j) the data's power (mean square amplitude)
      at frequency  $(j-1)/(2*m)$  cycles per gridpoint, for  $j=1, 2, \dots, m$ , based on  $(2*k+1)*m$ 
      data points (if ovrlap is set .true.) or  $4*k*m$  data points (if ovrlap is set .false.).
      The number of segments of the data is  $2*k$  in both cases: The routine calls four1 k
      times, each call with 2 partitions each of  $2*m$  real data points. w1(1:4*m) and w2(1:m)
      are user-supplied workspaces.
      INTEGER j,j2,joff,joffn,kk,m4,m43,mm
      REAL den,facm,facp,sumw,w,window
      window(j)=(1.-abs(((j-1)-facm)*facp)) Statement function defines Bartlett window.
      C window(j)=1. Alternative for square window.
      C window(j)=(1.-(((j-1)-facm)*facp)**2) Alternative for Welch window.
      mm=m+m
      m4=mm+mm
      m44=m4+4
      m43=m4+3
      den=0.
      facm=m Factors used by the window statement function.
      facp=1./m
      sumw=0.
      do 11 j=1,mm Accumulate the squared sum of the weights.
      sumw=sumw+window(j)**2
      enddo 11
      do 12 j=1,m Initialize the spectrum to zero.
      p(j)=0.
      enddo 12
      if(ovrlap)then Initialize the "save" half-buffer.
      read (9,*) (w2(j),j=1,m)
      endif
      do 18 kk=1,k Loop over data set segments in groups of two.
      do 15 joff=-1,0,1 Get two complete segments into workspace.
      if (ovrlap) then
          do 13 j=1,m
              w1(joff+j+j)=w2(j)
          enddo 13
          read (9,*) (w2(j),j=1,m)
          joffn=joff+mm
          do 14 j=1,m
              w1(joffn+j+j)=w2(j)
          enddo 14
      else
          read (9,*) (w1(j),j=joff+2,m4,2)
      endif
      enddo 15
      do 16 j=1,mm Apply the window to the data.
      j2=j+j
      w=window(j)
      w1(j2)=w1(j2)*w
      w1(j2-1)=w1(j2-1)*w
      enddo 16
      call four1(w1,mm,1) Fourier transform the windowed data.
      p(1)=p(1)+w1(1)**2+w1(2)**2 Sum results into previous segments.
      do 17 j=2,m
          j2=j+j
          p(j)=p(j)+w1(j2)**2+w1(j2-1)**2
          +w1(m44-j2)**2+w1(m43-j2)**2
      enddo 17
      den=den+sumw
      enddo 18
      den=m4*den Correct normalization.

```

```

do 19 j=1,m
      p(j)=p(j)/den
  enddo 19
  return
END

```

Normalize the output.

13.5 Digital Filtering in the Time Domain

Suppose that you have a signal that you want to filter digitally. For example, perhaps you want to apply *high-pass* or *low-pass* filtering, to eliminate noise at low or high frequencies respectively; or perhaps the interesting part of your signal lies only in a certain frequency band, so that you need a *bandpass* filter. Or, if your measurements are contaminated by 60 Hz power-line interference, you may need a *notch filter* to remove only a narrow band around that frequency. This section speaks particularly about the case in which you have chosen to do such filtering in the time domain.

Before continuing, we hope you will reconsider this choice. Remember how convenient it is to filter in the Fourier domain. You just take your whole data record, FFT it, multiply the FFT output by a filter function $\mathcal{H}(f)$, and then do an inverse FFT to get back a filtered data set in time domain. Here is some additional background on the Fourier technique that you will want to take into account.

- Remember that you must define your filter function $\mathcal{H}(f)$ for both positive and negative frequencies, and that the magnitude of the frequency extremes is always the Nyquist frequency $1/(2\Delta)$, where Δ is the sampling interval. The magnitude of the smallest nonzero frequencies in the FFT is $\pm 1/(N\Delta)$, where N is the number of (complex) points in the FFT. The positive and negative frequencies to which this filter are applied are arranged in wrap-around order.
- If the measured data are real, and you want the filtered output also to be real, then your arbitrary filter function should obey $\mathcal{H}(-f) = \mathcal{H}(f)^*$. You can arrange this most easily by picking an \mathcal{H} that is real and even in f .
- If your chosen $\mathcal{H}(f)$ has sharp vertical edges in it, then the *impulse response* of your filter (the output arising from a short impulse as input) will have damped “ringing” at frequencies corresponding to these edges. There is nothing wrong with this, but if you don’t like it, then pick a smoother $\mathcal{H}(f)$. To get a first-hand look at the impulse response of your filter, just take the inverse FFT of your $\mathcal{H}(f)$. If you smooth all edges of the filter function over some number k of points, then the impulse response function of your filter will have a span on the order of a fraction $1/k$ of the whole data record.

13.5 Digital Filtering in the Time Domain

Suppose that you have a signal that you want to filter digitally. For example, perhaps you want to apply *high-pass* or *low-pass* filtering, to eliminate noise at low or high frequencies respectively; or perhaps the interesting part of your signal lies only in a certain frequency band, so that you need a *bandpass* filter. Or, if your measurements are contaminated by 60 Hz power-line interference, you may need a *notch filter* to remove only a narrow band around that frequency. This section speaks particularly about the case in which you have chosen to do such filtering in the time domain.

Before continuing, we hope you will reconsider this choice. Remember how convenient it is to filter in the Fourier domain. You just take your whole data record, FFT it, multiply the FFT output by a filter function $\mathcal{H}(f)$, and then do an inverse FFT to get back a filtered data set in time domain. Here is some additional background on the Fourier technique that you will want to take into account.

- Remember that you must define your filter function $\mathcal{H}(f)$ for both positive and negative frequencies, and that the magnitude of the frequency extremes is always the Nyquist frequency $1/(2\Delta)$, where Δ is the sampling interval. The magnitude of the smallest nonzero frequencies in the FFT is $\pm 1/(N\Delta)$, where N is the number of (complex) points in the FFT. The positive and negative frequencies to which this filter are applied are arranged in wrap-around order.
- If the measured data are real, and you want the filtered output also to be real, then your arbitrary filter function should obey $\mathcal{H}(-f) = \mathcal{H}(f)^*$. You can arrange this most easily by picking an \mathcal{H} that is real and even in f .
- If your chosen $\mathcal{H}(f)$ has sharp vertical edges in it, then the *impulse response* of your filter (the output arising from a short impulse as input) will have damped “ringing” at frequencies corresponding to these edges. There is nothing wrong with this, but if you don’t like it, then pick a smoother $\mathcal{H}(f)$. To get a first-hand look at the impulse response of your filter, just take the inverse FFT of your $\mathcal{H}(f)$. If you smooth all edges of the filter function over some number k of points, then the impulse response function of your filter will have a span on the order of a fraction $1/k$ of the whole data record.

- If your data set is too long to FFT all at once, then break it up into segments of any convenient size, as long as they are much longer than the impulse response function of the filter. Use zero-padding, if necessary.
- You should probably remove any trend from the data, by subtracting from it a straight line through the first and last points (i.e., make the first and last points equal to zero). If you are segmenting the data, then you can pick overlapping segments and use only the middle section of each, comfortably distant from edge effects.
- A digital filter is said to be *causal* or *physically realizable* if its output for a particular time-step depends only on inputs at that particular time-step or earlier. It is said to be *acausal* if its output can depend on both earlier and later inputs. Filtering in the Fourier domain is, in general, acausal, since the data are processed “in a batch,” without regard to time ordering. Don’t let this bother you! Acausal filters can generally give superior performance (e.g., less dispersion of phases, sharper edges, less asymmetric impulse response functions). People use causal filters not because they are better, but because some situations just don’t allow access to out-of-time-order data. Time domain filters can, in principle, be either causal or acausal, but they are most often used in applications where physical realizability is a constraint. For this reason we will restrict ourselves to the causal case in what follows.

If you are still favoring time-domain filtering after all we have said, it is probably because you have a real-time application, for which you must process a continuous data stream and wish to output filtered values at the same rate as you receive raw data. Otherwise, it may be that the quantity of data to be processed is so large that you can afford only a very small number of floating operations on each data point and cannot afford even a modest-sized FFT (with a number of floating operations per data point several times the logarithm of the number of points in the data set or segment).

Linear Filters

The most general linear filter takes a sequence x_k of input points and produces a sequence y_n of output points by the formula

$$y_n = \sum_{k=0}^M c_k x_{n-k} + \sum_{j=1}^N d_j y_{n-j} \quad (13.5.1)$$

Here the $M + 1$ coefficients c_k and the N coefficients d_j are fixed and define the filter response. The filter (13.5.1) produces each new output value from the current and M previous input values, and from its own N previous output values. If $N = 0$, so that there is no second sum in (13.5.1), then the filter is called *nonrecursive* or *finite impulse response (FIR)*. If $N \neq 0$, then it is called *recursive* or *infinite impulse response (IIR)*. (The term “IIR” connotes only that such filters are *capable* of having infinitely long impulse responses, not that their impulse response is necessarily long in a particular application. Typically the response of an IIR filter will drop off exponentially at late times, rapidly becoming negligible.)

The relation between the c_k ’s and d_j ’s and the filter response function $\mathcal{H}(f)$ is

$$\mathcal{H}(f) = \frac{\sum_{k=0}^M c_k e^{-2\pi i k(f\Delta)}}{1 - \sum_{j=1}^N d_j e^{-2\pi i j(f\Delta)}} \quad (13.5.2)$$

where Δ is, as usual, the sampling interval. The Nyquist interval corresponds to $f\Delta$ between $-1/2$ and $1/2$. For FIR filters the denominator of (13.5.2) is just unity.

Equation (13.5.2) tells how to determine $\mathcal{H}(f)$ from the c ’s and d ’s. To design a filter, though, we need a way of doing the inverse, getting a suitable set of c ’s and d ’s — as small a set as possible, to minimize the computational burden — from a desired $\mathcal{H}(f)$. Entire books are devoted to this issue. Like many other “inverse problems,” it has no all-purpose

solution. One clearly has to make compromises, since $\mathcal{H}(f)$ is a full continuous function, while the short list of c 's and d 's represents only a few adjustable parameters. The subject of digital filter design concerns itself with the various ways of making these compromises. We cannot hope to give any sort of complete treatment of the subject. We can, however, sketch a couple of basic techniques to get you started. For further details, you will have to consult some specialized books (see references).

FIR (Nonrecursive) Filters

When the denominator in (13.5.2) is unity, the right-hand side is just a discrete Fourier transform. The transform is easily invertible, giving the desired small number of c_k coefficients in terms of the same small number of values of $\mathcal{H}(f_i)$ at some discrete frequencies f_i . This fact, however, is not very useful. The reason is that, for values of c_k computed in this way, $\mathcal{H}(f)$ will tend to oscillate wildly in between the discrete frequencies where it is pinned down to specific values.

A better strategy, and one which is the basis of several formal methods in the literature, is this: Start by pretending that you are willing to have a relatively large number of filter coefficients, that is, a relatively large value of M . Then $\mathcal{H}(f)$ can be fixed to desired values on a relatively fine mesh, and the M coefficients c_k , $k = 0, \dots, M - 1$ can be found by an FFT. Next, truncate (set to zero) most of the c_k 's, leaving nonzero only the first, say, K , $(c_0, c_1, \dots, c_{K-1})$ and last $K - 1$, $(c_{M-K+1}, \dots, c_{M-1})$. The last few c_k 's are filter coefficients at *negative lag*, because of the wrap-around property of the FFT. But we don't want coefficients at negative lag. Therefore we cyclically shift the array of c_k 's, to bring everything to positive lag. (This corresponds to introducing a time-delay into the filter.) Do this by copying the c_k 's into a new array of length M in the following order:

$$(c_{M-K+1}, \dots, c_{M-1}, c_0, c_1, \dots, c_{K-1}, 0, 0, \dots, 0) \quad (13.5.3)$$

To see if your truncation is acceptable, take the FFT of the array (13.5.3), giving an approximation to your original $\mathcal{H}(f)$. You will generally want to compare the *modulus* $|\mathcal{H}(f)|$ to your original function, since the time-delay will have introduced complex phases into the filter response.

If the new filter function is acceptable, then you are done and have a set of $2K - 1$ filter coefficients. If it is not acceptable, then you can either (i) increase K and try again, or (ii) do something fancier to improve the acceptability for the same K . An example of something fancier is to modify the magnitudes (but not the phases) of the unacceptable $\mathcal{H}(f)$ to bring it more in line with your ideal, and then to FFT to get new c_k 's. Once again set to zero all but the first $2K - 1$ values of these (no need to cyclically shift since you have preserved the time-delays), then inverse transform to get a new $\mathcal{H}(f)$, which will often be more acceptable. You can iterate this procedure. Note, however, that the procedure will not converge if your requirements for acceptability are more stringent than your $2K - 1$ coefficients can handle.

The key idea, in other words, is to iterate between the space of coefficients and the space of functions $\mathcal{H}(f)$, until a Fourier conjugate pair that satisfies the imposed constraints *in both spaces* is found. A more formal technique for this kind of iteration is the *Remes Exchange Algorithm* which produces the best Chebyshev approximation to a given desired frequency response with a fixed number of filter coefficients (cf. §5.13).

IIR (Recursive) Filters

Recursive filters, whose output at a given time depends both on the current and previous inputs and on previous outputs, can generally have performance that is superior to nonrecursive filters with the same total number of coefficients (or same number of floating operations per input point). The reason is fairly clear by inspection of (13.5.2): A nonrecursive filter has a frequency response that is a polynomial in the variable $1/z$, where

$$z \equiv e^{2\pi i(f\Delta)} \quad (13.5.4)$$

By contrast, a recursive filter's frequency response is a *rational function* in $1/z$. The class of rational functions is especially good at fitting functions with sharp edges or narrow features, and most desired filter functions are in this category.

Nonrecursive filters are always stable. If you turn off the sequence of incoming x_i 's, then after no more than M steps the sequence of y_j 's produced by (13.5.1) will also turn off. Recursive filters, feeding as they do on their own output, are not necessarily stable. If the coefficients d_j are badly chosen, a recursive filter can have exponentially growing, so-called *homogeneous*, modes, which become huge even after the input sequence has been turned off. This is not good. The problem of designing recursive filters, therefore, is not just an inverse problem; it is an inverse problem with an additional stability constraint.

How do you tell if the filter (13.5.1) is stable for a given set of c_k and d_j coefficients? Stability depends only on the d_j 's. The filter is stable if and only if all N complex roots of the *characteristic polynomial* equation

$$z^N - \sum_{j=1}^N d_j z^{N-j} = 0 \quad (13.5.5)$$

are inside the unit circle, i.e., satisfy

$$|z| \leq 1 \quad (13.5.6)$$

The various methods for constructing stable recursive filters again form a subject area for which you will need more specialized books. One very useful technique, however, is the *bilinear transformation method*. For this topic we define a new variable w that reparametrizes the frequency f ,

$$w \equiv \tan[\pi(f\Delta)] = i \left(\frac{1 - e^{2\pi i(f\Delta)}}{1 + e^{2\pi i(f\Delta)}} \right) = i \left(\frac{1 - z}{1 + z} \right) \quad (13.5.7)$$

Don't be fooled by the i 's in (13.5.7). This equation maps real frequencies f into real values of w . In fact, it maps the Nyquist interval $-\frac{1}{2} < f\Delta < \frac{1}{2}$ onto the real w axis $-\infty < w < +\infty$. The inverse equation to (13.5.7) is

$$z = e^{2\pi i(f\Delta)} = \frac{1 + iw}{1 - iw} \quad (13.5.8)$$

In reparametrizing f , w also reparametrizes z , of course. Therefore, the condition for stability (13.5.5)–(13.5.6) can be rephrased in terms of w : If the filter response $\mathcal{H}(f)$ is written as a function of w , then the filter is stable if and only if the poles of the filter function (zeros of its denominator) are all in the upper half complex plane,

$$\text{Im}(w) \geq 0 \quad (13.5.9)$$

The idea of the bilinear transformation method is that instead of specifying your desired $\mathcal{H}(f)$, you specify only its desired modulus square, $|\mathcal{H}(f)|^2 = \mathcal{H}(f)\mathcal{H}(f)^* = \mathcal{H}(f)\mathcal{H}(-f)$. Pick this to be approximated by some rational function in w^2 . Then find all the poles of this function in the w complex plane. Every pole in the lower half-plane will have a corresponding pole in the upper half-plane, by symmetry. The idea is to form a product only of the factors with good poles, ones in the upper half-plane. This product is your *stably realizable* $\mathcal{H}(f)$. Now substitute equation (13.5.7) to write the function as a rational function in z , and compare with equation (13.5.2) to read off the c 's and d 's.

The procedure becomes clearer when we go through an example. Suppose we want to design a simple bandpass filter, whose lower cutoff frequency corresponds to a value $w = a$, and whose upper cutoff frequency corresponds to a value $w = b$, with a and b both positive numbers. A simple rational function that accomplishes this is

$$|\mathcal{H}(f)|^2 = \left(\frac{w^2}{w^2 + a^2} \right) \left(\frac{b^2}{w^2 + b^2} \right) \quad (13.5.10)$$

This function does not have a very sharp cutoff, but it is illustrative of the more general case. To obtain sharper edges, one could take the function (13.5.10) to some positive integer

power, or, equivalently, run the data sequentially through some number of copies of the filter that we will obtain from (13.5.10).

The poles of (13.5.10) are evidently at $w = \pm ia$ and $w = \pm ib$. Therefore the stably realizable $\mathcal{H}(f)$ is

$$\mathcal{H}(f) = \left(\frac{w}{w - ia} \right) \left(\frac{ib}{w - ib} \right) = \frac{\left(\frac{1-z}{1+z} \right) b}{\left[\left(\frac{1-z}{1+z} \right) - a \right] \left[\left(\frac{1-z}{1+z} \right) - b \right]} \quad (13.5.11)$$

We put the i in the numerator of the second factor in order to end up with real-valued coefficients. If we multiply out all the denominators, (13.5.11) can be rewritten in the form

$$\mathcal{H}(f) = \frac{-\frac{b}{(1+a)(1+b)} + \frac{b}{(1+a)(1+b)} z^{-2}}{1 - \frac{(1+a)(1-b)+(1-a)(1+b)}{(1+a)(1+b)} z^{-1} + \frac{(1-a)(1-b)}{(1+a)(1+b)} z^{-2}} \quad (13.5.12)$$

from which one reads off the filter coefficients for equation (13.5.1),

$$\begin{aligned} c_0 &= -\frac{b}{(1+a)(1+b)} \\ c_1 &= 0 \\ c_2 &= \frac{b}{(1+a)(1+b)} \\ d_1 &= \frac{(1+a)(1-b)+(1-a)(1+b)}{(1+a)(1+b)} \\ d_2 &= -\frac{(1-a)(1-b)}{(1+a)(1+b)} \end{aligned} \quad (13.5.13)$$

This completes the design of the bandpass filter.

Sometimes you can figure out how to construct directly a rational function in w for $\mathcal{H}(f)$, rather than having to start with its modulus square. The function that you construct has to have its poles only in the upper half-plane, for stability. It should also have the property of going into its own complex conjugate if you substitute $-w$ for w , so that the filter coefficients will be real.

For example, here is a function for a notch filter, designed to remove only a narrow frequency band around some fiducial frequency $w = w_0$, where w_0 is a positive number,

$$\begin{aligned} \mathcal{H}(f) &= \left(\frac{w - w_0}{w - w_0 - i\epsilon w_0} \right) \left(\frac{w + w_0}{w + w_0 - i\epsilon w_0} \right) \\ &= \frac{w^2 - w_0^2}{(w - i\epsilon w_0)^2 - w_0^2} \end{aligned} \quad (13.5.14)$$

In (13.5.14) the parameter ϵ is a small positive number that is the desired width of the notch, as a fraction of w_0 . Going through the arithmetic of substituting z for w gives the filter coefficients

$$\begin{aligned} c_0 &= \frac{1 + w_0^2}{(1 + \epsilon w_0)^2 + w_0^2} \\ c_1 &= -2 \frac{1 - w_0^2}{(1 + \epsilon w_0)^2 + w_0^2} \\ c_2 &= \frac{1 + w_0^2}{(1 + \epsilon w_0)^2 + w_0^2} \\ d_1 &= 2 \frac{1 - \epsilon^2 w_0^2 - w_0^2}{(1 + \epsilon w_0)^2 + w_0^2} \\ d_2 &= -\frac{(1 - \epsilon w_0)^2 + w_0^2}{(1 + \epsilon w_0)^2 + w_0^2} \end{aligned} \quad (13.5.15)$$

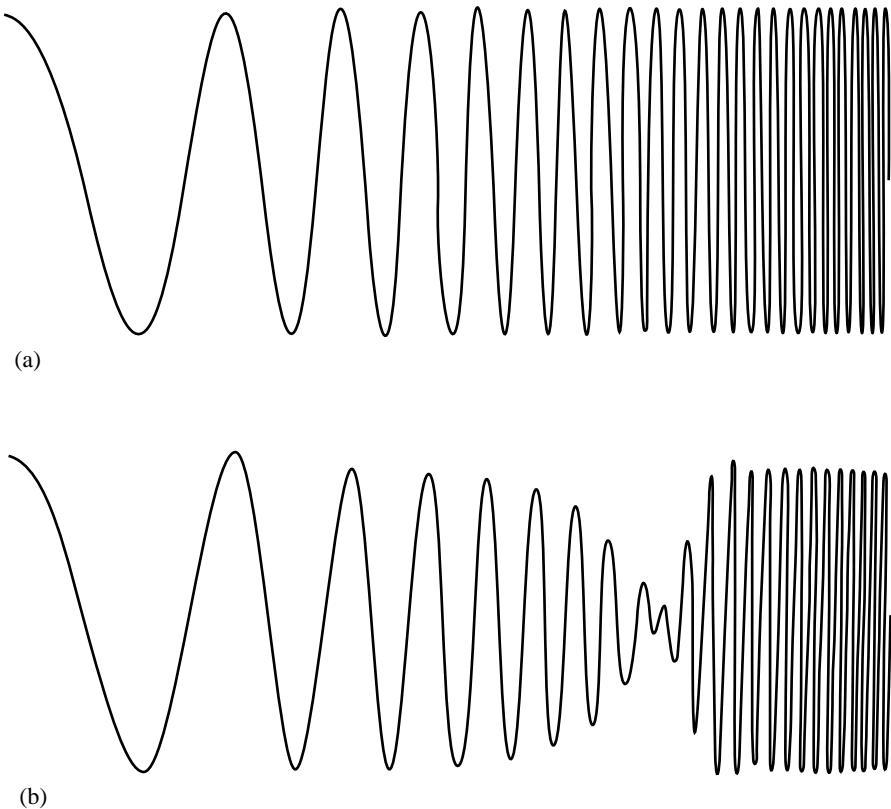

Figure 13.5.1. (a) A “chirp,” or signal whose frequency increases continuously with time. (b) Same signal after it has passed through the notch filter (13.5.15). The parameter ϵ is here 0.2.

Figure 13.5.1 shows the results of using a filter of the form (13.5.15) on a “chirp” input signal, one that glides upwards in frequency, crossing the notch frequency along the way.

While the bilinear transformation may seem very general, its applications are limited by some features of the resulting filters. The method is good at getting the general shape of the desired filter, and good where “flatness” is a desired goal. However, the nonlinear mapping between w and f makes it difficult to design to a desired shape for a cutoff, and may move cutoff frequencies (defined by a certain number of dB) from their desired places. Consequently, practitioners of the art of digital filter design reserve the bilinear transformation for specific situations, and arm themselves with a variety of other tricks. We suggest that you do likewise, as your projects demand.

13.6 Linear Prediction and Linear Predictive Coding

We begin with a very general formulation that will allow us to make connections to various special cases. Let $\{y'_\alpha\}$ be a set of measured values for some underlying set of true values of a quantity y , denoted $\{y_\alpha\}$, related to these true values by the addition of random noise,

$$y'_\alpha = y_\alpha + n_\alpha \quad (13.6.1)$$

(compare equation 13.3.2, with a somewhat different notation). Our use of a Greek subscript to index the members of the set is meant to indicate that the data points are not necessarily equally spaced along a line, or even ordered: they might be “random” points in three-dimensional space, for example. Now, suppose we want to construct the “best” estimate of the true value of some particular point y_* as a linear combination of the known, noisy, values. Writing

$$y_* = \sum_\alpha d_{*\alpha} y'_\alpha + x_* \quad (13.6.2)$$

we want to find coefficients $d_{*\alpha}$ that minimize, in some way, the *discrepancy* x_* . The coefficients $d_{*\alpha}$ have a “star” subscript to indicate that they depend on the choice of point y_* . Later, we might want to let y_* be one of the existing y_α ’s. In that case, our problem becomes one of optimal filtering or estimation, closely related to the discussion in §13.3. On the other hand, we might want y_* to be a completely new point. In that case, our problem will be one of *linear prediction*.

A natural way to minimize the discrepancy x_* is in the statistical mean square sense. If angle brackets denote statistical averages, then we seek $d_{*\alpha}$ ’s that minimize

$$\begin{aligned} \langle x_*^2 \rangle &= \left\langle \left[\sum_\alpha d_{*\alpha} (y'_\alpha - y_*) \right]^2 \right\rangle \\ &= \sum_{\alpha\beta} (\langle y_\alpha y_\beta \rangle + \langle n_\alpha n_\beta \rangle) d_{*\alpha} d_{*\beta} - 2 \sum_\alpha \langle y_* y_\alpha \rangle d_{*\alpha} + \langle y_*^2 \rangle \end{aligned} \quad (13.6.3)$$

Here we have used the fact that noise is uncorrelated with signal, e.g., $\langle n_\alpha y_\beta \rangle = 0$. The quantities $\langle y_\alpha y_\beta \rangle$ and $\langle y_* y_\alpha \rangle$ describe the autocorrelation structure of the underlying data. We have already seen an analogous expression, (13.2.2), for the case of equally spaced data points on a line; we will meet correlation several times again in its statistical sense in Chapters 14 and 15. The quantities $\langle n_\alpha n_\beta \rangle$ describe the autocorrelation properties of the noise. Often, for point-to-point uncorrelated noise, we have $\langle n_\alpha n_\beta \rangle = \langle n_\alpha^2 \rangle \delta_{\alpha\beta}$. It is convenient to think of the various correlation quantities as comprising matrices and vectors,

$$\phi_{\alpha\beta} \equiv \langle y_\alpha y_\beta \rangle \quad \phi_{*\alpha} \equiv \langle y_* y_\alpha \rangle \quad \eta_{\alpha\beta} \equiv \langle n_\alpha n_\beta \rangle \quad \text{or} \quad \langle n_\alpha^2 \rangle \delta_{\alpha\beta} \quad (13.6.4)$$

Setting the derivative of equation (13.6.3) with respect to the $d_{*\alpha}$ ’s equal to zero, one readily obtains the set of linear equations,

$$\sum_\beta [\phi_{\alpha\beta} + \eta_{\alpha\beta}] d_{*\beta} = \phi_{*\alpha} \quad (13.6.5)$$

13.6 Linear Prediction and Linear Predictive Coding

We begin with a very general formulation that will allow us to make connections to various special cases. Let $\{y'_\alpha\}$ be a set of measured values for some underlying set of true values of a quantity y , denoted $\{y_\alpha\}$, related to these true values by the addition of random noise,

$$y'_\alpha = y_\alpha + n_\alpha \quad (13.6.1)$$

(compare equation 13.3.2, with a somewhat different notation). Our use of a Greek subscript to index the members of the set is meant to indicate that the data points are not necessarily equally spaced along a line, or even ordered: they might be “random” points in three-dimensional space, for example. Now, suppose we want to construct the “best” estimate of the true value of some particular point y_* as a linear combination of the known, noisy, values. Writing

$$y_* = \sum_\alpha d_{*\alpha} y'_\alpha + x_* \quad (13.6.2)$$

we want to find coefficients $d_{*\alpha}$ that minimize, in some way, the *discrepancy* x_* . The coefficients $d_{*\alpha}$ have a “star” subscript to indicate that they depend on the choice of point y_* . Later, we might want to let y_* be one of the existing y_α ’s. In that case, our problem becomes one of optimal filtering or estimation, closely related to the discussion in §13.3. On the other hand, we might want y_* to be a completely new point. In that case, our problem will be one of *linear prediction*.

A natural way to minimize the discrepancy x_* is in the statistical mean square sense. If angle brackets denote statistical averages, then we seek $d_{*\alpha}$ ’s that minimize

$$\begin{aligned} \langle x_*^2 \rangle &= \left\langle \left[\sum_\alpha d_{*\alpha} (y'_\alpha - y_*) \right]^2 \right\rangle \\ &= \sum_{\alpha\beta} (\langle y_\alpha y_\beta \rangle + \langle n_\alpha n_\beta \rangle) d_{*\alpha} d_{*\beta} - 2 \sum_\alpha \langle y_* y_\alpha \rangle d_{*\alpha} + \langle y_*^2 \rangle \end{aligned} \quad (13.6.3)$$

Here we have used the fact that noise is uncorrelated with signal, e.g., $\langle n_\alpha y_\beta \rangle = 0$. The quantities $\langle y_\alpha y_\beta \rangle$ and $\langle y_* y_\alpha \rangle$ describe the autocorrelation structure of the underlying data. We have already seen an analogous expression, (13.2.2), for the case of equally spaced data points on a line; we will meet correlation several times again in its statistical sense in Chapters 14 and 15. The quantities $\langle n_\alpha n_\beta \rangle$ describe the autocorrelation properties of the noise. Often, for point-to-point uncorrelated noise, we have $\langle n_\alpha n_\beta \rangle = \langle n_\alpha^2 \rangle \delta_{\alpha\beta}$. It is convenient to think of the various correlation quantities as comprising matrices and vectors,

$$\phi_{\alpha\beta} \equiv \langle y_\alpha y_\beta \rangle \quad \phi_{*\alpha} \equiv \langle y_* y_\alpha \rangle \quad \eta_{\alpha\beta} \equiv \langle n_\alpha n_\beta \rangle \quad \text{or} \quad \langle n_\alpha^2 \rangle \delta_{\alpha\beta} \quad (13.6.4)$$

Setting the derivative of equation (13.6.3) with respect to the $d_{*\alpha}$ ’s equal to zero, one readily obtains the set of linear equations,

$$\sum_\beta [\phi_{\alpha\beta} + \eta_{\alpha\beta}] d_{*\beta} = \phi_{*\alpha} \quad (13.6.5)$$

If we write the solution as a matrix inverse, then the estimation equation (13.6.2) becomes, omitting the minimized discrepancy x_* ,

$$y_* \approx \sum_{\alpha\beta} \phi_{*\alpha} [\phi_{\mu\nu} + \eta_{\mu\nu}]_{\alpha\beta}^{-1} y'_\beta \quad (13.6.6)$$

From equations (13.6.3) and (13.6.5) one can also calculate the expected mean square value of the discrepancy at its minimum, denoted $\langle x_*^2 \rangle_0$,

$$\langle x_*^2 \rangle_0 = \langle y_*^2 \rangle - \sum_\beta d_{*\beta} \phi_{*\beta} = \langle y_*^2 \rangle - \sum_{\alpha\beta} \phi_{*\alpha} [\phi_{\mu\nu} + \eta_{\mu\nu}]_{\alpha\beta}^{-1} \phi_{*\beta} \quad (13.6.7)$$

A final general result tells how much the mean square discrepancy $\langle x_*^2 \rangle$ is increased if we use the estimation equation (13.6.2) not with the best values $d_{*\beta}$, but with some other values $\hat{d}_{*\beta}$. The above equations then imply

$$\langle x_*^2 \rangle = \langle x_*^2 \rangle_0 + \sum_{\alpha\beta} (\hat{d}_{*\alpha} - d_{*\alpha}) [\phi_{\alpha\beta} + \eta_{\alpha\beta}] (\hat{d}_{*\beta} - d_{*\beta}) \quad (13.6.8)$$

Since the second term is a pure quadratic form, we see that the increase in the discrepancy is only second order in any error made in estimating the $d_{*\beta}$'s.

Connection to Optimal Filtering

If we change “star” to a Greek index, say γ , then the above formulas describe optimal filtering, generalizing the discussion of §13.3. One sees, for example, that if the noise amplitudes n_α go to zero, so likewise do the noise autocorrelations $\eta_{\alpha\beta}$, and, canceling a matrix times its inverse, equation (13.6.6) simply becomes $y_\gamma = y'_\gamma$. Another special case occurs if the matrices $\phi_{\alpha\beta}$ and $\eta_{\alpha\beta}$ are diagonal. In that case, equation (13.6.6) becomes

$$y_\gamma = \frac{\phi_{\gamma\gamma}}{\phi_{\gamma\gamma} + \eta_{\gamma\gamma}} y'_\gamma \quad (13.6.9)$$

which is readily recognizable as equation (13.3.6) with $S^2 \rightarrow \phi_{\gamma\gamma}$, $N^2 \rightarrow \eta_{\gamma\gamma}$. What is going on is this: For the case of equally spaced data points, and in the Fourier domain, autocorrelations become simply squares of Fourier amplitudes (Wiener-Kinchin theorem, equation 12.0.12), and the optimal filter can be constructed algebraically, as equation (13.6.9), without inverting any matrix.

More generally, in the time domain, or any other domain, an optimal filter (one that minimizes the square of the discrepancy from the underlying true value in the presence of measurement noise) can be constructed by estimating the autocorrelation matrices $\phi_{\alpha\beta}$ and $\eta_{\alpha\beta}$, and applying equation (13.6.6) with $*$ \rightarrow γ . (Equation 13.6.8 is in fact the basis for the §13.3's statement that even crude optimal filtering can be quite effective.)

Linear Prediction

Classical *linear prediction* specializes to the case where the data points y_β are equally spaced along a line, $y_i, i = 1, 2, \dots, N$, and we want to use M consecutive values of y_i to predict an $M + 1$ st. Stationarity is assumed. That is, the autocorrelation $\langle y_j y_k \rangle$ is assumed to depend only on the difference $|j - k|$, and not on j or k individually, so that the autocorrelation ϕ has only a single index,

$$\phi_j \equiv \langle y_i y_{i+j} \rangle \approx \frac{1}{N-j} \sum_{i=1}^{N-j} y_i y_{i+j} \quad (13.6.10)$$

Here, the approximate equality shows one way to use the actual data set values to estimate the autocorrelation components. (In fact, there is a better way to make these estimates; see below.) In the situation described, the estimation equation (13.6.2) is

$$y_n = \sum_{j=1}^M d_j y_{n-j} + x_n \quad (13.6.11)$$

(compare equation 13.5.1) and equation (13.6.5) becomes the set of M equations for the M unknown d_j 's, now called the *linear prediction (LP) coefficients*,

$$\sum_{j=1}^M \phi_{|j-k|} d_j = \phi_k \quad (k = 1, \dots, M) \quad (13.6.12)$$

Notice that while noise is not explicitly included in the equations, it is properly accounted for, if it is point-to-point uncorrelated: ϕ_0 , as estimated by equation (13.6.10) using *measured* values y'_i , actually estimates the diagonal part of $\phi_{\alpha\alpha} + \eta_{\alpha\alpha}$, above. The mean square discrepancy $\langle x_n^2 \rangle$ is estimated by equation (13.6.7) as

$$\langle x_n^2 \rangle = \phi_0 - \phi_1 d_1 - \phi_2 d_2 - \dots - \phi_M d_M \quad (13.6.13)$$

To use linear prediction, we first compute the d_j 's, using equations (13.6.10) and (13.6.12). We then calculate equation (13.6.13) or, more concretely, apply (13.6.11) to the known record to get an idea of how large are the discrepancies x_i . If the discrepancies are small, then we can continue applying (13.6.11) right on into the future, imagining the unknown “future” discrepancies x_i to be zero. In this application, (13.6.11) is a kind of extrapolation formula. In many situations, this extrapolation turns out to be vastly more powerful than any kind of simple polynomial extrapolation. (By the way, you should not confuse the terms “linear prediction” and “linear extrapolation”; the general functional form used by linear prediction is *much* more complex than a straight line, or even a low-order polynomial!)

However, to achieve its full usefulness, linear prediction must be constrained in one additional respect: One must take additional measures to guarantee its *stability*. Equation (13.6.11) is a special case of the general linear filter (13.5.1). The condition that (13.6.11) be stable as a linear predictor is precisely that given in equations (13.5.5) and (13.5.6), namely that the characteristic polynomial

$$z^N - \sum_{j=1}^N d_j z^{N-j} = 0 \quad (13.6.14)$$

have all N of its roots inside the unit circle,

$$|z| \leq 1 \quad (13.6.15)$$

There is no guarantee that the coefficients produced by equation (13.6.12) will have this property. If the data contain many oscillations without any particular trend towards increasing or decreasing amplitude, then the complex roots of (13.6.14) will generally all be rather close to the unit circle. The finite length of the data set will cause some of these roots to be inside the unit circle, others outside. In some applications, where the resulting instabilities are slowly growing and the linear prediction is not pushed too far, it is best to use the “unmassaged” LP coefficients that come directly out of (13.6.12). For example, one might be extrapolating to fill a short gap in a data set; then one might extrapolate both forwards across the gap and backwards from the data beyond the gap. If the two extrapolations agree tolerably well, then instability is not a problem.

When instability *is* a problem, you have to “massage” the LP coefficients. You do this by (i) solving (numerically) equation (13.6.14) for its N complex roots; (ii) moving the roots to where you think they ought to be inside or on the unit circle; (iii) reconstituting the now-modified LP coefficients. You may think that step (ii) sounds a little vague. It is. There is no “best” procedure. If you think that your signal is truly a sum of undamped sine and cosine waves (perhaps with incommensurate periods), then you will want simply to move each root z_i onto the unit circle,

$$z_i \rightarrow z_i / |z_i| \quad (13.6.16)$$

In other circumstances it may seem appropriate to reflect a bad root across the unit circle

$$z_i \rightarrow 1/z_i^* \quad (13.6.17)$$

This alternative has the property that it preserves the amplitude of the output of (13.6.11) when it is driven by a sinusoidal set of x_i ’s. It assumes that (13.6.12) has correctly identified the spectral width of a resonance, but only slipped up on identifying its time sense so that signals that should be damped as time proceeds end up growing in amplitude. The choice between (13.6.16) and (13.6.17) sometimes might as well be based on voodoo. We prefer (13.6.17).

Also magical is the choice of M , the number of LP coefficients to use. You should choose M to be as small as works for you, that is, you should choose it by experimenting with your data. Try $M = 5, 10, 20, 40$. If you need larger M ’s than this, be aware that the procedure of “massaging” all those complex roots is quite sensitive to roundoff error. Use double precision.

Linear prediction is especially successful at extrapolating signals that are smooth and oscillatory, though not necessarily periodic. In such cases, linear prediction often extrapolates accurately through *many cycles* of the signal. By contrast, polynomial extrapolation in general becomes seriously inaccurate after at most a cycle or two. A prototypical example of a signal that can successfully be linearly predicted is the height of ocean tides, for which the fundamental 12-hour period is modulated in phase and amplitude over the course of the month and year, and for which local

hydrodynamic effects may make even one cycle of the curve look rather different in shape from a sine wave.

We already remarked that equation (13.6.10) is not necessarily the best way to estimate the covariances ϕ_k from the data set. In fact, results obtained from linear prediction are remarkably sensitive to exactly how the ϕ_k 's are estimated. One particularly good method is due to Burg [1], and involves a recursive procedure for increasing the order M by one unit at a time, at each stage re-estimating the coefficients d_j , $j = 1, \dots, M$ so as to minimize the residual in equation (13.6.13). Although further discussion of the Burg method is beyond our scope here, the method is implemented in the following routine [1,2] for estimating the LP coefficients d_j of a data set.

```
SUBROUTINE memcof(data,n,m,xms,d)
INTEGER m,n,MMAX,NMAX
REAL xms,d(m),data(n)
PARAMETER (MMAX=60,NMAX=2000)
      Given a real vector of data(1:n), and given m, this routine returns m linear prediction
      coefficients as d(1:m), and returns the mean square discrepancy as xms.
INTEGER i,j,k
REAL denom,p,pneum,wk1(NMAX),wk2(NMAX),wkm(MMAX)
if (m.gt.MMAX.or.n.gt.NMAX) pause 'workspace too small in memcof'
p=0.
do 11 j=1,n
  p=p+data(j)**2
enddo 11
xms=p/n
wk1(1)=data(1)
wk2(n-1)=data(n)
do 12 j=2,n-1
  wk1(j)=data(j)
  wk2(j-1)=data(j)
enddo 12
do 13 k=1,m
  pneum=0.
  denom=0.
  do 14 j=1,n-k
    pneum=pneum+wk1(j)*wk2(j)
    denom=denom+wk1(j)**2+wk2(j)**2
  enddo 14
  d(k)=2.*pneum/denom
  xms=xms*(1.-d(k)**2)
  do 15 i=1,k-1
    d(i)=wkm(i)-d(k)*wkm(k-i)
  enddo 15
enddo 13
      The algorithm is recursive, building up the answer for larger and larger values of m until
      the desired value is reached. At this point in the algorithm, one could return the vector
      d and scalar xms for a set of LP coefficients with k (rather than m) terms.
if(k.eq.m)return
do 16 i=1,k
  wkm(i)=d(i)
enddo 16
do 17 j=1,n-k-1
  wk1(j)=wk1(j)-wkm(k)*wk2(j)
  wk2(j)=wk2(j+1)-wkm(k)*wk1(j+1)
enddo 17
endo 17
pause 'never get here in memcof'
END
```

Here are procedures for rendering the LP coefficients stable (if you choose to do so), and for extrapolating a data set by linear prediction, using the original or massaged LP coefficients. The routine `zroots` (§9.5) is used to find all complex roots of a polynomial.

```

SUBROUTINE fixrts(d,m)
INTEGER m,MMAX
REAL d(m)
PARAMETER (MMAX=100)           Largest expected value of m.
C USES zroots
      Given the LP coefficients d(1:m), this routine finds all roots of the characteristic polynomial
      (13.6.14), reflects any roots that are outside the unit circle back inside, and then returns
      a modified set of coefficients d(1:m).
      INTEGER i,j
      LOGICAL polish
      COMPLEX a(MMAX),roots(MMAX)
      a(m+1)=cmplx(1.,0.)
      do 11 j=m,1,-1             Set up complex coefficients for polynomial root finder.
          a(j)=cmplx(-d(m+1-j),0.)
      enddo 11
      polish=.true.
      call zroots(a,m,roots,polish)      Find all the roots.
      do 12 j=1,m                  Look for a...
          if(abs(roots(j)).gt.1.)then   root outside the unit circle,
              roots(j)=1./conjg(roots(j))  and reflect it back inside.
          endif
      enddo 12
      a(1)=-roots(1)                Now reconstruct the polynomial coefficients,
      a(2)=cmplx(1.,0.)
      do 14 j=2,m                  by looping over the roots
          a(j+1)=cmplx(1.,0.)
          do 13 i=j,2,-1            and synthetically multiplying.
              a(i)=a(i-1)-roots(j)*a(i)
          enddo 13
          a(1)=-roots(j)*a(1)
      enddo 14
      do 15 j=1,m                  The polynomial coefficients are guaranteed to be real,
          d(m+1-j)=-real(a(j))    so we need only return the real part as new LP coefficients.
      enddo 15
      return
END

```

```

SUBROUTINE predic(data,ndata,d,m,future,nfut)
INTEGER ndata,nfut,m,MMAX
REAL d(m),data(ndata),future(nfut)
PARAMETER (MMAX=100)
      Given data(1:ndata), and given the data's LP coefficients d(1:m), this routine applies
      equation (13.6.11) to predict the next nfut data points, which it returns in the array
      future(1:nfut). Note that the routine references only the last m values of data, as
      initial values for the prediction.
      Parameter: MMAX is the largest expected value of m.
      INTEGER j,k
      REAL discrp,sum,reg(MMAX)
      do 11 j=1,m
          reg(j)=data(ndata+1-j)
      enddo 11
      do 14 j=1,nfut
          discrp=0.
          sum=discrp
          do 12 k=1,m

```

This is where you would put in a known discrepancy if you
were reconstructing a function by linear predictive coding
rather than extrapolating a function by linear prediction.
See text.

```

        sum=sum+d(k)*reg(k)
enddo 12
do 13 k=m,2,-1           [If you want to implement circular arrays, you can avoid this
    reg(k)=reg(k-1)          shifting of coefficients!]
enddo 13
reg(1)=sum
future(j)=sum
endo 14
return
END

```

Removing the Bias in Linear Prediction

You might expect that the sum of the d_j 's in equation (13.6.11) (or, more generally, in equation 13.6.2) should be 1, so that (e.g.) adding a constant to all the data points y_i yields a prediction that is increased by the same constant. However, the d_j 's do not sum to 1 but, in general, to a value slightly less than one. This fact reveals a subtle point, that the estimator of classical linear prediction is not *unbiased*, even though it does minimize the mean square discrepancy. At any place where the measured autocorrelation does not imply a better estimate, the equations of linear prediction tend to predict a value that tends towards zero.

Sometimes, that is just what you want. If the process that generates the y_i 's in fact has zero mean, then zero is the best guess absent other information. At other times, however, this behavior is unwarranted. If you have data that show only small variations around a positive value, you don't want linear predictions that droop towards zero.

Often it is a workable approximation to subtract the mean off your data set, perform the linear prediction, and then add the mean back. This procedure contains the germ of the correct solution; but the simple arithmetic mean is not quite the correct constant to subtract. In fact, an unbiased estimator is obtained by subtracting from every data point an autocorrelation-weighted mean defined by [3,4]

$$\bar{y} \equiv \sum_{\beta} [\phi_{\mu\nu} + \eta_{\mu\nu}]_{\alpha\beta}^{-1} y_{\beta} / \sum_{\alpha\beta} [\phi_{\mu\nu} + \eta_{\mu\nu}]_{\alpha\beta}^{-1} \quad (13.6.18)$$

With this subtraction, the sum of the LP coefficients should be unity, up to roundoff and differences in how the ϕ_k 's are estimated.

Linear Predictive Coding (LPC)

A different, though related, method to which the formalism above can be applied is the “compression” of a sampled signal so that it can be stored more compactly. The original form should be *exactly* recoverable from the compressed version. Obviously, compression can be accomplished only if there is redundancy in the signal. Equation (13.6.11) describes one kind of redundancy: It says that the signal, except for a small discrepancy, is predictable from its previous values and from a small number of LP coefficients. Compression of a signal by the use of (13.6.11) is thus called *linear predictive coding*, or *LPC*.

The basic idea of LPC (in its simplest form) is to record as a compressed file (i) the number of LP coefficients M , (ii) their M values, e.g., as obtained by `memcof`,

(iii) the first M data points, and then (iv) for each subsequent data point only its residual discrepancy x_i (equation 13.6.1). When you are creating the compressed file, you find the residual by applying (13.6.1) to the previous M points, subtracting the sum from the actual value of the current point. When you are reconstructing the original file, you add the residual back in, at the point indicated in the routine `predic`.

It may not be obvious why there is any compression at all in this scheme. After all, we are storing one value of residual per data point! Why not just store the original data point? The answer depends on the relative sizes of the numbers involved. The residual is obtained by subtracting two very nearly equal numbers (the data and the linear prediction). Therefore, the discrepancy typically has only a very small number of nonzero bits. These can be stored in a compressed file. How do you do it in a high-level language? Here is one way: Scale your data to have integer values, say between +1000000 and -1000000 (supposing that you need six significant figures). Modify equation (13.6.1) by enclosing the sum term in an “integer part of” operator. The discrepancy will now, by definition, be an integer. Experiment with different values of M , to find LP coefficients that make the range of the discrepancy as small as you can. If you can get to within a range of ± 127 (and in our experience this is not at all difficult) then you can write it to a file as a single byte. This is a compression factor of 4, compared to 4-byte integer or floating formats.

Notice that the LP coefficients are computed using the *quantized* data, and that the discrepancy is also quantized, i.e., quantization is done both outside and inside the LPC loop. If you are careful in following this prescription, then, apart from the initial quantization of the data, you will not introduce even a single bit of roundoff error into the compression-reconstruction process: While the evaluation of the sum in (13.6.11) may have roundoff errors, the residual that you store is the value which, when added back to the sum, gives *exactly* the original (quantized) data value. Notice also that you do not need to massage the LP coefficients for stability; by adding the residual back in to each point, you never depart from the original data, so instabilities cannot grow. There is therefore no need for `fixrts`, above.

Look at §20.4 to learn about *Huffman coding*, which will further compress the residuals by taking advantage of the fact that smaller values of discrepancy will occur more often than larger values. A very primitive version of Huffman coding would be this: If most of the discrepancies are in the range ± 127 , but an occasional one is outside, then reserve the value 127 to mean “out of range,” and then record on the file (immediately following the 127) a full-word value of the out-of-range discrepancy. §20.4 explains how to do much better.

There are many variant procedures that all fall under the rubric of LPC.

- If the spectral character of the data is time-variable, then it is best not to use a single set of LP coefficients for the whole data set, but rather to partition the data into segments, computing and storing different LP coefficients for each segment.
- If the data are really well characterized by their LP coefficients, and you can tolerate some small amount of error, then don’t bother storing all of the residuals. Just do linear prediction until you are outside of tolerances, then reinitialize (using M sequential stored residuals) and continue predicting.
- In some applications, most notably speech synthesis, one cares only about the spectral content of the reconstructed signal, not the relative phases. In this case, one need not store any starting values at all, but only the

LP coefficients for each segment of the data. The output is reconstructed by driving these coefficients with initial conditions consisting of all zeros except for one nonzero spike. A speech synthesizer chip may have of order 10 LP coefficients, which change perhaps 20 to 50 times per second.

- Some people believe that it is interesting to analyze a signal by LPC, even when the residuals x_i are *not* small. The x_i 's are then interpreted as the underlying “input signal” which, when filtered through the all-poles filter defined by the LP coefficients (see §13.7), produces the observed “output signal.” LPC reveals simultaneously, it is said, the nature of the filter *and* the particular input that is driving it. We are skeptical of these applications; the literature, however, is full of extravagant claims.

13.7 Power Spectrum Estimation by the Maximum Entropy (All Poles) Method

The FFT is not the only way to estimate the power spectrum of a process, nor is it necessarily the best way for all purposes. To see how one might devise another method, let us enlarge our view for a moment, so that it includes not only real frequencies in the Nyquist interval $-f_c < f < f_c$, but also the entire complex frequency plane. From that vantage point, let us transform the complex f -plane to a new plane, called the *z-transform plane* or *z-plane*, by the relation

$$z \equiv e^{2\pi i f \Delta} \quad (13.7.1)$$

where Δ is, as usual, the sampling interval in the time domain. Notice that the Nyquist interval on the real axis of the f -plane maps one-to-one onto the unit circle in the complex z -plane.

If we now compare (13.7.1) to equations (13.4.4) and (13.4.6), we see that the FFT power spectrum estimate (13.4.5) for any real sampled function $c_k \equiv c(t_k)$ can be written, except for normalization convention, as

$$P(f) = \left| \sum_{k=-N/2}^{N/2-1} c_k z^k \right|^2 \quad (13.7.2)$$

Of course, (13.7.2) is not the *true* power spectrum of the underlying function $c(t)$, but only an estimate. We can see in two related ways why the estimate is not likely to be exact. First, in the time domain, the estimate is based on only a finite range of the function $c(t)$ which may, for all we know, have continued from $t = -\infty$ to ∞ . Second, in the z -plane of equation (13.7.2), the finite Laurent series offers, in general, only an approximation to a general analytic function of z . In fact, a formal expression for representing “true” power spectra (up to normalization) is

$$P(f) = \left| \sum_{k=-\infty}^{\infty} c_k z^k \right|^2 \quad (13.7.3)$$

LP coefficients for each segment of the data. The output is reconstructed by driving these coefficients with initial conditions consisting of all zeros except for one nonzero spike. A speech synthesizer chip may have of order 10 LP coefficients, which change perhaps 20 to 50 times per second.

- Some people believe that it is interesting to analyze a signal by LPC, even when the residuals x_i are *not* small. The x_i 's are then interpreted as the underlying “input signal” which, when filtered through the all-poles filter defined by the LP coefficients (see §13.7), produces the observed “output signal.” LPC reveals simultaneously, it is said, the nature of the filter *and* the particular input that is driving it. We are skeptical of these applications; the literature, however, is full of extravagant claims.

13.7 Power Spectrum Estimation by the Maximum Entropy (All Poles) Method

The FFT is not the only way to estimate the power spectrum of a process, nor is it necessarily the best way for all purposes. To see how one might devise another method, let us enlarge our view for a moment, so that it includes not only real frequencies in the Nyquist interval $-f_c < f < f_c$, but also the entire complex frequency plane. From that vantage point, let us transform the complex f -plane to a new plane, called the *z-transform plane* or *z-plane*, by the relation

$$z \equiv e^{2\pi i f \Delta} \quad (13.7.1)$$

where Δ is, as usual, the sampling interval in the time domain. Notice that the Nyquist interval on the real axis of the f -plane maps one-to-one onto the unit circle in the complex z -plane.

If we now compare (13.7.1) to equations (13.4.4) and (13.4.6), we see that the FFT power spectrum estimate (13.4.5) for any real sampled function $c_k \equiv c(t_k)$ can be written, except for normalization convention, as

$$P(f) = \left| \sum_{k=-N/2}^{N/2-1} c_k z^k \right|^2 \quad (13.7.2)$$

Of course, (13.7.2) is not the *true* power spectrum of the underlying function $c(t)$, but only an estimate. We can see in two related ways why the estimate is not likely to be exact. First, in the time domain, the estimate is based on only a finite range of the function $c(t)$ which may, for all we know, have continued from $t = -\infty$ to ∞ . Second, in the z -plane of equation (13.7.2), the finite Laurent series offers, in general, only an approximation to a general analytic function of z . In fact, a formal expression for representing “true” power spectra (up to normalization) is

$$P(f) = \left| \sum_{k=-\infty}^{\infty} c_k z^k \right|^2 \quad (13.7.3)$$

This is an infinite Laurent series which depends on an infinite number of values c_k . Equation (13.7.2) is just one kind of analytic approximation to the analytic function of z represented by (13.7.3); the kind, in fact, that is implicit in the use of FFTs to estimate power spectra by periodogram methods. It goes under several names, including *direct method*, *all-zero model*, and *moving average (MA) model*. The term “all-zero” in particular refers to the fact that the model spectrum can have zeros in the z -plane, but not poles.

If we look at the problem of approximating (13.7.3) more generally it seems clear that we could do a better job with a rational function, one with a series of type (13.7.2) in both the numerator and the denominator. Less obviously, it turns out that there are some advantages in an approximation whose free parameters all lie in the *denominator*, namely,

$$P(f) \approx \frac{1}{\left| \sum_{k=-M/2}^{M/2} b_k z^k \right|^2} = \frac{a_0}{\left| 1 + \sum_{k=1}^M a_k z^k \right|^2} \quad (13.7.4)$$

Here the second equality brings in a new set of coefficients a_k 's, which can be determined from the b_k 's using the fact that z lies on the unit circle. The b_k 's can be thought of as being determined by the condition that power series expansion of (13.7.4) agree with the first $M + 1$ terms of (13.7.3). In practice, as we shall see, one determines the b_k 's or a_k 's by another method.

The differences between the approximations (13.7.2) and (13.7.4) are not just cosmetic. They are approximations with very different character. Most notable is the fact that (13.7.4) can have *poles*, corresponding to infinite power spectral density, on the unit z -circle, i.e., at real frequencies in the Nyquist interval. Such poles can provide an accurate representation for underlying power spectra that have sharp, discrete “lines” or delta-functions. By contrast, (13.7.2) can have only zeros, not poles, at real frequencies in the Nyquist interval, and must thus attempt to fit sharp spectral features with, essentially, a polynomial. The approximation (13.7.4) goes under several names: *all-poles model*, *maximum entropy method (MEM)*, *autoregressive model (AR)*. We need only find out how to compute the coefficients a_0 and the a_k 's from a data set, so that we can actually use (13.7.4) to obtain spectral estimates.

A pleasant surprise is that we already know how! Look at equation (13.6.11) for linear prediction. Compare it with linear filter equations (13.5.1) and (13.5.2), and you will see that, viewed as a filter that takes input x 's into output y 's, linear prediction has a filter function

$$\mathcal{H}(f) = \frac{1}{1 - \sum_{j=1}^N d_j z^{-j}} \quad (13.7.5)$$

Thus, the power spectrum of the y 's should be equal to the power spectrum of the x 's multiplied by $|\mathcal{H}(f)|^2$. Now let us think about what the spectrum of the input x 's is, when they are residual discrepancies from linear prediction. Although we will not prove it formally, it is intuitively believable that the x 's are independently random and therefore have a flat (white noise) spectrum. (Roughly speaking, any residual correlations left in the x 's would have allowed a more accurate linear prediction, and would have been removed.) The overall normalization of this flat spectrum is just the mean square amplitude of the x 's. But this is exactly the quantity computed in equation (13.6.13) and returned by the routine `memcof` as `xms`. Thus, the coefficients a_0 and a_k in equation (13.7.4) are related to the LP coefficients returned by `memcof` simply by

$$a_0 = \text{xms} \quad a_k = -d(k), \quad k = 1, \dots, M \quad (13.7.6)$$

There is also another way to describe the relation between the a_k 's and the autocorrelation components ϕ_k . The Wiener-Khinchin theorem (12.0.12) says that the Fourier transform of the autocorrelation is equal to the power spectrum. In z -transform language, this Fourier transform is just a Laurent series in z . The equation that is to be satisfied by the coefficients in equation (13.7.4) is thus

$$\frac{a_0}{\left| 1 + \sum_{k=1}^M a_k z^k \right|^2} \approx \sum_{j=-M}^M \phi_j z^j \quad (13.7.7)$$

The approximately equal sign in (13.7.7) has a somewhat special interpretation. It means that the series expansion of the left-hand side is supposed to agree with the right-hand side term by term from z^{-M} to z^M . Outside this range of terms, the right-hand side is obviously zero, while the left-hand side will still have nonzero terms. Notice that M , the number of coefficients in the approximation on the left-hand side, can be any integer up to N , the total number of autocorrelations available. (In practice, one often chooses M much smaller than N .) M is called the *order or number of poles* of the approximation.

Whatever the chosen value of M , the series expansion of the left-hand side of (13.7.7) defines a certain sort of *extrapolation* of the autocorrelation function to lags larger than M , in fact even to lags larger than N , i.e., *larger than the run of data can actually measure*. It turns out that this particular extrapolation can be shown to have, among all possible extrapolations, the maximum *entropy* in a definable information-theoretic sense. Hence the name *maximum entropy method*, or MEM. The maximum entropy property has caused MEM to acquire a certain “cult” popularity; one sometimes hears that it gives an intrinsically “better” estimate than is given by other methods. Don’t believe it. MEM has the very cute property of being able to fit sharp spectral features, but there is nothing else magical about its power spectrum estimates.

The operations count in `memcof` scales as the product of N (the number of data points) and M (the desired order of the MEM approximation). If M were chosen to be as large as N , then the method would be much slower than the $N \log N$ FFT methods of the previous section. In practice, however, one usually wants to limit the order (or number of poles) of the MEM approximation to a few times the number of sharp spectral features that one desires it to fit. With this restricted number of poles, the method will smooth the spectrum somewhat, but this is often a desirable property. While exact values depend on the application, one might take $M = 10$ or 20 or 50 for $N = 1000$ or 10000 . In that case MEM estimation is not much slower than FFT estimation.

We feel obliged to warn you that `memcof` can be a bit quirky at times. If the number of poles or number of data points is too large, roundoff error can be a problem, even in double precision. With “peaky” data (i.e., data with extremely sharp spectral features), the algorithm may suggest split peaks even at modest orders, and the peaks may shift with the phase of the sine wave. Also, with noisy input functions, if you choose too high an order, you will find spurious peaks galore! Some experts recommend the use of this algorithm in conjunction with more conservative methods, like periodograms, to help choose the correct model order, and to avoid getting too fooled by spurious spectral features. MEM can be finicky, but it can also do remarkable things. We recommend that you try it out, cautiously, on your own problems. We now turn to the evaluation of the MEM spectral estimate from its coefficients.

The MEM estimation (13.7.4) is a function of continuously varying frequency f . There is no special significance to specific equally spaced frequencies as there was in the FFT case. In fact, since the MEM estimate may have very sharp spectral features, one wants to be able to evaluate it on a very fine mesh near to those features, but perhaps only more coarsely farther away from them. Here is a subroutine which, given the coefficients already computed, evaluates (13.7.4) and returns the estimated power spectrum as a function of $f\Delta$ (the frequency times the sampling interval). Of course, $f\Delta$ should lie in the Nyquist range between $-1/2$ and $1/2$.

```

FUNCTION evlmem(fdt,d,m,xms)
INTEGER m
REAL evlmem,fdt,xms,d(m)
      Given d, m, xms as returned by memcof, this function returns the power spectrum estimate
      P(f) as a function of fdt = fΔ.
INTEGER i
REAL sumi,sumr
DOUBLE PRECISION theta,wi,wpi,wpr,wr,wtemp           Trigonometric recurrences in double
theta=6.28318530717959d0*fdt                         precision.
wpr=cos(theta)                                         Set up for recurrence relations.
wpi=sin(theta)
wr=1.d0
wi=0.d0
sumr=1.                                              These will accumulate the denominator of (13.7.4).

```

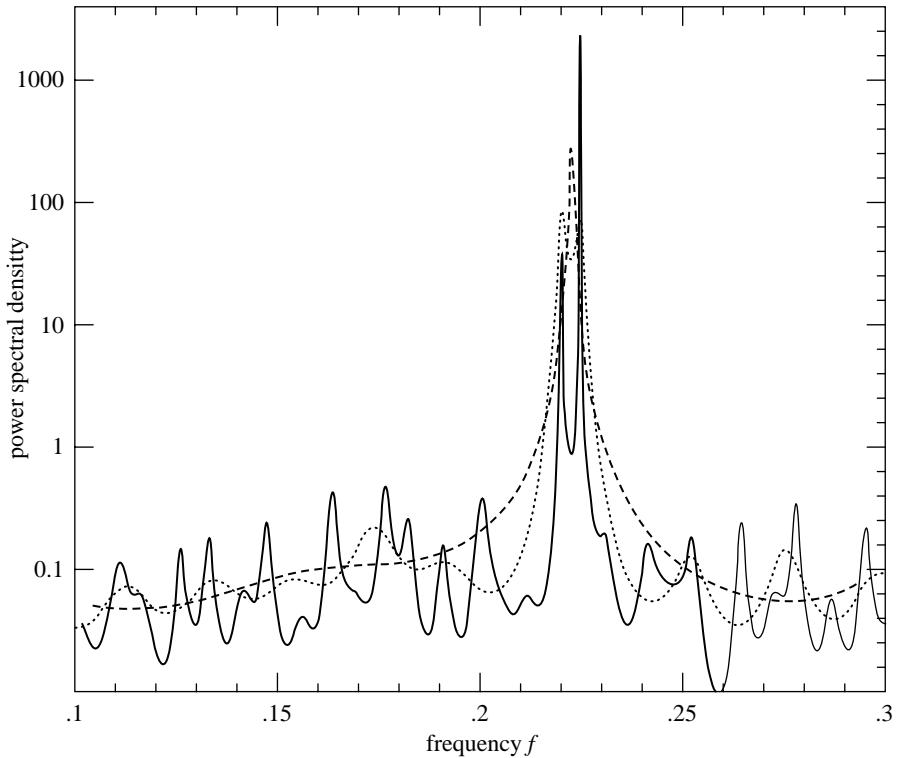

Figure 13.7.1. Sample output of maximum entropy spectral estimation. The input signal consists of 512 samples of the sum of two sinusoids of very nearly the same frequency, plus white noise with about equal power. Shown is an expanded portion of the full Nyquist frequency interval (which would extend from zero to 0.5). The dashed spectral estimate uses 20 poles; the dotted, 40; the solid, 150. With the larger number of poles, the method can resolve the distinct sinusoids; but the flat noise background is beginning to show spurious peaks. (Note logarithmic scale.)

```

sumi=0.
do ii i=1,m                         Loop over the terms in the sum.
    wtemp=wr
    wr=wr*wpr-wi*wpi
    wi=wi*wpr+wtemp*wpi
    sumr=sumr-d(i)*sngl(wr)
    sumi=sumi-d(i)*sngl(wi)
enddo ii
evlmem=xms/(sumr**2+sumi**2)          Equation (13.7.4).
return
END

```

Be sure to evaluate $P(f)$ on a fine enough grid to *find* any narrow features that may be there! Such narrow features, if present, can contain virtually all of the power in the data. You might also wish to know how the $P(f)$ produced by the routines `mempcof` and `evlmem` is normalized with respect to the mean square value of the input data vector. The answer is

$$\int_{-1/2}^{1/2} P(f\Delta) d(f\Delta) = 2 \int_0^{1/2} P(f\Delta) d(f\Delta) = \text{mean square value of data} \quad (13.7.8)$$

Sample spectra produced by the routines `mempcof` and `evlmem` are shown in Figure 13.7.1.

13.8 Spectral Analysis of Unevenly Sampled Data

Thus far, we have been dealing exclusively with evenly sampled data,

$$h_n = h(n\Delta) \quad n = \dots, -3, -2, -1, 0, 1, 2, 3, \dots \quad (13.8.1)$$

where Δ is the sampling interval, whose reciprocal is the sampling rate. Recall also (§12.1) the significance of the Nyquist critical frequency

$$f_c \equiv \frac{1}{2\Delta} \quad (13.8.2)$$

as codified by the sampling theorem: A sampled data set like equation (13.8.1) contains *complete* information about all spectral components in a signal $h(t)$ up to the Nyquist frequency, and scrambled or *aliased* information about any signal components at frequencies larger than the Nyquist frequency. The sampling theorem thus defines both the attractiveness, and the limitation, of any analysis of an evenly spaced data set.

There are situations, however, where evenly spaced data cannot be obtained. A common case is where instrumental drop-outs occur, so that data is obtained only on a (not consecutive integer) subset of equation (13.8.1), the so-called *missing data* problem. Another case, common in observational sciences like astronomy, is that the observer cannot completely control the time of the observations, but must simply accept a certain dictated set of t_i 's.

There are some obvious ways to get from unevenly spaced t_i 's to evenly spaced ones, as in equation (13.8.1). Interpolation is one way: lay down a grid of evenly spaced times on your data and interpolate values onto that grid; then use FFT methods. In the missing data problem, you only have to interpolate on missing data points. If a lot of consecutive points are missing, you might as well just set them to zero, or perhaps “clamp” the value at the last measured point. However, the experience of practitioners of such interpolation techniques is *not reassuring*. Generally speaking, such techniques perform poorly. Long gaps in the data, for example, often produce a spurious bulge of power at low frequencies (wavelengths comparable to gaps).

A completely different method of spectral analysis for unevenly sampled data, one that mitigates these difficulties and has some other very desirable properties, was developed by Lomb [1], based in part on earlier work by Barnard [2] and Vaníček [3], and additionally elaborated by Scargle [4]. The Lomb method (as we will call it) evaluates data, and sines and cosines, only at times t_i that are actually measured. Suppose that there are N data points $h_i \equiv h(t_i)$, $i = 1, \dots, N$. Then first find the mean and variance of the data by the usual formulas,

$$\bar{h} \equiv \frac{1}{N} \sum_1^N h_i \quad \sigma^2 \equiv \frac{1}{N-1} \sum_1^N (h_i - \bar{h})^2 \quad (13.8.3)$$

Now, the Lomb *normalized periodogram* (spectral power as a function of angular frequency $\omega \equiv 2\pi f > 0$) is defined by

$$P_N(\omega) \equiv \frac{1}{2\sigma^2} \left\{ \frac{\left[\sum_j (h_j - \bar{h}) \cos \omega(t_j - \tau) \right]^2}{\sum_j \cos^2 \omega(t_j - \tau)} + \frac{\left[\sum_j (h_j - \bar{h}) \sin \omega(t_j - \tau) \right]^2}{\sum_j \sin^2 \omega(t_j - \tau)} \right\} \quad (13.8.4)$$

13.8 Spectral Analysis of Unevenly Sampled Data

Thus far, we have been dealing exclusively with evenly sampled data,

$$h_n = h(n\Delta) \quad n = \dots, -3, -2, -1, 0, 1, 2, 3, \dots \quad (13.8.1)$$

where Δ is the sampling interval, whose reciprocal is the sampling rate. Recall also (§12.1) the significance of the Nyquist critical frequency

$$f_c \equiv \frac{1}{2\Delta} \quad (13.8.2)$$

as codified by the sampling theorem: A sampled data set like equation (13.8.1) contains *complete* information about all spectral components in a signal $h(t)$ up to the Nyquist frequency, and scrambled or *aliased* information about any signal components at frequencies larger than the Nyquist frequency. The sampling theorem thus defines both the attractiveness, and the limitation, of any analysis of an evenly spaced data set.

There are situations, however, where evenly spaced data cannot be obtained. A common case is where instrumental drop-outs occur, so that data is obtained only on a (not consecutive integer) subset of equation (13.8.1), the so-called *missing data* problem. Another case, common in observational sciences like astronomy, is that the observer cannot completely control the time of the observations, but must simply accept a certain dictated set of t_i 's.

There are some obvious ways to get from unevenly spaced t_i 's to evenly spaced ones, as in equation (13.8.1). Interpolation is one way: lay down a grid of evenly spaced times on your data and interpolate values onto that grid; then use FFT methods. In the missing data problem, you only have to interpolate on missing data points. If a lot of consecutive points are missing, you might as well just set them to zero, or perhaps “clamp” the value at the last measured point. However, the experience of practitioners of such interpolation techniques is *not reassuring*. Generally speaking, such techniques perform poorly. Long gaps in the data, for example, often produce a spurious bulge of power at low frequencies (wavelengths comparable to gaps).

A completely different method of spectral analysis for unevenly sampled data, one that mitigates these difficulties and has some other very desirable properties, was developed by Lomb [1], based in part on earlier work by Barnard [2] and Vaníček [3], and additionally elaborated by Scargle [4]. The Lomb method (as we will call it) evaluates data, and sines and cosines, only at times t_i that are actually measured. Suppose that there are N data points $h_i \equiv h(t_i)$, $i = 1, \dots, N$. Then first find the mean and variance of the data by the usual formulas,

$$\bar{h} \equiv \frac{1}{N} \sum_1^N h_i \quad \sigma^2 \equiv \frac{1}{N-1} \sum_1^N (h_i - \bar{h})^2 \quad (13.8.3)$$

Now, the Lomb *normalized periodogram* (spectral power as a function of angular frequency $\omega \equiv 2\pi f > 0$) is defined by

$$P_N(\omega) \equiv \frac{1}{2\sigma^2} \left\{ \frac{\left[\sum_j (h_j - \bar{h}) \cos \omega(t_j - \tau) \right]^2}{\sum_j \cos^2 \omega(t_j - \tau)} + \frac{\left[\sum_j (h_j - \bar{h}) \sin \omega(t_j - \tau) \right]^2}{\sum_j \sin^2 \omega(t_j - \tau)} \right\} \quad (13.8.4)$$

Here τ is defined by the relation

$$\tan(2\omega\tau) = \frac{\sum_j \sin 2\omega t_j}{\sum_j \cos 2\omega t_j} \quad (13.8.5)$$

The constant τ is a kind of offset that makes $P_N(\omega)$ completely independent of shifting all the t_i 's by any constant. Lomb shows that this particular choice of offset has another, deeper, effect: It makes equation (13.8.4) identical to the equation that one would obtain if one estimated the harmonic content of a data set, at a given frequency ω , by linear least-squares fitting to the model

$$h(t) = A \cos \omega t + B \sin \omega t \quad (13.8.6)$$

This fact gives some insight into why the method can give results superior to FFT methods: It weights the data on a “per point” basis instead of on a “per time interval” basis, when uneven sampling can render the latter seriously in error.

A very common occurrence is that the measured data points h_i are the sum of a periodic signal and independent (white) Gaussian noise. If we are trying to determine the presence or absence of such a periodic signal, we want to be able to give a quantitative answer to the question, “How significant is a peak in the spectrum $P_N(\omega)$?”. In this question, the null hypothesis is that the data values are independent Gaussian random values. A very nice property of the Lomb normalized periodogram is that the viability of the null hypothesis can be tested fairly rigorously, as we now discuss.

The word “normalized” refers to the factor σ^2 in the denominator of equation (13.8.4). Scargle [4] shows that with this normalization, at any particular ω and *in the case of the null hypothesis*, $P_N(\omega)$ has an exponential probability distribution with unit mean. In other words, the probability that $P_N(\omega)$ will be between some positive z and $z + dz$ is $\exp(-z)dz$. It readily follows that, if we scan some M independent frequencies, the probability that none give values larger than z is $(1 - e^{-z})^M$. So

$$P(>z) \equiv 1 - (1 - e^{-z})^M \quad (13.8.7)$$

is the false-alarm probability of the null hypothesis, that is, the *significance level* of any peak in $P_N(\omega)$ that we do see. A small value for the false-alarm probability indicates a highly significant periodic signal.

To evaluate this significance, we need to know M . After all, the more frequencies we look at, the less significant is some one modest bump in the spectrum. (Look long enough, find anything!) A typical procedure will be to plot $P_N(\omega)$ as a function of many closely spaced frequencies in some large frequency range. How many of these are independent?

Before answering, let us first see how accurately we need to know M . The interesting region is where the significance is a small (significant) number, $\ll 1$. There, equation (13.8.7) can be series expanded to give

$$P(>z) \approx Me^{-z} \quad (13.8.8)$$

We see that the significance scales linearly with M . Practical significance levels are numbers like 0.05, 0.01, 0.001, etc. An error of even $\pm 50\%$ in the estimated significance is often tolerable, since quoted significance levels are typically spaced apart by factors of 5 or 10. So our estimate of M need not be very accurate.

Horne and Baliunas [5] give results from extensive Monte Carlo experiments for determining M in various cases. In general M depends on the number of frequencies sampled, the number of data points N , and their detailed spacing. It turns out that M is very nearly equal to N when the data points are approximately equally spaced, and when the sampled frequencies “fill” (oversample) the frequency range from 0 to the Nyquist frequency f_c (equation 13.8.2). Further, the value of M is not importantly different for random spacing of the data points than for equal spacing. When a larger frequency range than the Nyquist range is sampled, M increases proportionally. About the only case where M differs significantly from the case of evenly spaced points is when the points are closely clumped, say into groups of 3; then (as one would expect) the number of independent frequencies is reduced by a factor of about 3.

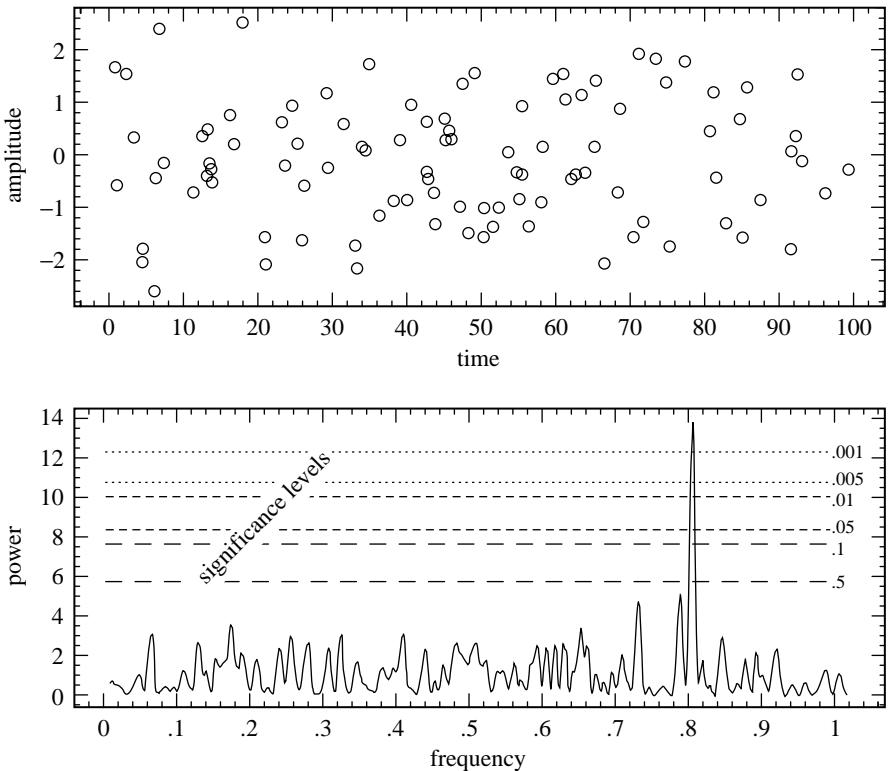

Figure 13.8.1. Example of the Lomb algorithm in action. The 100 data points (upper figure) are at random times between 0 and 100. Their sinusoidal component is readily uncovered (lower figure) by the algorithm, at a significance level better than 0.001. If the 100 data points had been evenly spaced at unit interval, the Nyquist critical frequency would have been 0.5. Note that, for these unevenly spaced points, there is no visible aliasing into the Nyquist range.

The program `period`, below, calculates an effective value for M based on the above rough-and-ready rules and assumes that there is no important clumping. This will be adequate for most purposes. In any particular case, if it really matters, it is not too difficult to compute a better value of M by simple Monte Carlo: Holding fixed the number of data points and their locations t_i , generate synthetic data sets of Gaussian (normal) deviates, find the largest values of $P_N(\omega)$ for each such data set (using the accompanying program), and fit the resulting distribution for M in equation (13.8.7).

Figure 13.8.1 shows the results of applying the method as discussed so far. In the upper figure, the data points are plotted against time. Their number is $N = 100$, and their distribution in t is Poisson random. There is certainly no sinusoidal signal evident to the eye. The lower figure plots $P_N(\omega)$ against frequency $f = \omega/2\pi$. The Nyquist critical frequency that would obtain if the points were evenly spaced is at $f = f_c = 0.5$. Since we have searched up to about twice that frequency, and oversampled the f 's to the point where successive values of $P_N(\omega)$ vary smoothly, we take $M = 2N$. The horizontal dashed and dotted lines are (respectively from bottom to top) significance levels 0.5, 0.1, 0.05, 0.01, 0.005, and 0.001. One sees a highly significant peak at a frequency of 0.81. That is in fact the frequency of the sine wave that is present in the data. (You will have to take our word for this!)

Note that two other peaks approach, but do not exceed the 50% significance level; that is about what one might expect by chance. It is also worth commenting on the fact that the significant peak was found (correctly) *above the Nyquist frequency* and without any significant aliasing down into the Nyquist interval! That would not be possible for evenly spaced data. It is possible here because the randomly spaced data has *some* points spaced much closer than

the “average” sampling rate, and these remove ambiguity from any aliasing.

Implementation of the normalized periodogram in code is straightforward, with, however, a few points to be kept in mind. We are dealing with a *slow* algorithm. Typically, for N data points, we may wish to examine on the order of $2N$ or $4N$ frequencies. Each combination of frequency and data point has, in equations (13.8.4) and (13.8.5), not just a few adds or multiplies, but four calls to trigonometric functions; the operations count can easily reach several hundred times N^2 . It is highly desirable — in fact results in a factor 4 speedup — to replace these trigonometric calls by recurrences. That is possible only if the sequence of frequencies examined is a linear sequence. Since such a sequence is probably what most users would want anyway, we have built this into the implementation.

At the end of this section we describe a way to evaluate equations (13.8.4) and (13.8.5) — approximately, but to any desired degree of approximation — by a fast method [6] whose operation count goes only as $N \log N$. This faster method should be used for long data sets.

The lowest independent frequency f to be examined is the inverse of the span of the input data, $\max_i(t_i) - \min_i(t_i) \equiv T$. This is the frequency such that the data can include one complete cycle. In subtracting off the data’s mean, equation (13.8.4) already assumed that you are not interested in the data’s zero-frequency piece — which is just that mean value. In an FFT method, higher independent frequencies would be integer multiples of $1/T$. Because we are interested in the statistical significance of any peak that may occur, however, we had better (over-) sample more finely than at interval $1/T$, so that sample points lie close to the top of any peak. Thus, the accompanying program includes an oversampling parameter, called *ofac*; a value *ofac* $\gtrsim 4$ might be typical in use. We also want to specify how high in frequency to go, say f_{hi} . One guide to choosing f_{hi} is to compare it with the Nyquist frequency f_c which would obtain if the N data points were evenly spaced over the same span T , that is $f_c = N/(2T)$. The accompanying program includes an input parameter *hifac*, defined as f_{hi}/f_c . The number of different frequencies N_P returned by the program is then given by

$$N_P = \frac{\text{ofac} \times \text{hifac}}{2} N \quad (13.8.9)$$

(You have to remember to dimension the output arrays to at least this size.)

The code does the trigonometric recurrences in double precision and embodies a few tricks with trigonometric identities, to decrease roundoff errors. If you are an aficionado of such things you can puzzle it out. A final detail is that equation (13.8.7) will fail because of roundoff error if z is too large; but equation (13.8.8) is fine in this regime.

```
SUBROUTINE period(x,y,n,ofac,hifac,px,py,np,nout,jmax,prob)
INTEGER jmax,n,nout,np,NMAX
REAL hifac,ofac,prob,px(np),py(np),x(n),y(n)
PARAMETER (NMAX=2000)                                Maximum expected value of n.
C USES avevar
Given n data points with abscissas x(1:n) (which need not be equally spaced) and ordinates y(1:n), and given a desired oversampling factor ofac (a typical value being 4 or larger), this routine fills array px with an increasing sequence of frequencies (not angular frequencies) up to hifac times the “average” Nyquist frequency, and fills array py with the values of the Lomb normalized periodogram at those frequencies. The arrays x and y are not altered.
np, the dimension of px and py, must be large enough to contain the output, or an error (pause) results. The routine also returns jmax such that py(jmax) is the maximum element in py, and prob, an estimate of the significance of that maximum against the hypothesis of random noise. A small value of prob indicates that a significant periodic signal is present.

Fast Computation of the Lomb Periodogram

We here show how equations (13.8.4) and (13.8.5) can be calculated — approximately, but to any desired precision — with an operation count only of order $N_P \log N_P$. The method uses the FFT, but it is in no sense an FFT periodogram of the data. It is an actual evaluation of equations (13.8.4) and (13.8.5), the Lomb normalized periodogram, with exactly that method's strengths and weaknesses. This fast algorithm, due to Press and Rybicki [6], makes feasible the application of the Lomb method to data sets at least as large as 10^6 points; it is already faster than straightforward evaluation of equations (13.8.4) and (13.8.5) for data sets as small as 60 or 100 points.

Notice that the trigonometric sums that occur in equations (13.8.5) and (13.8.4) can be reduced to four simpler sums. If we define

$$S_h \equiv \sum_{j=1}^N (h_j - \bar{h}) \sin(\omega t_j) \quad C_h \equiv \sum_{j=1}^N (h_j - \bar{h}) \cos(\omega t_j) \quad (13.8.10)$$

and

$$S_2 \equiv \sum_{j=1}^N \sin(2\omega t_j) \quad C_2 \equiv \sum_{j=1}^N \cos(2\omega t_j) \quad (13.8.11)$$

then

$$\begin{aligned} \sum_{j=1}^N (h_j - \bar{h}) \cos \omega(t_j - \tau) &= C_h \cos \omega\tau + S_h \sin \omega\tau \\ \sum_{j=1}^N (h_j - \bar{h}) \sin \omega(t_j - \tau) &= S_h \cos \omega\tau - C_h \sin \omega\tau \\ \sum_{j=1}^N \cos^2 \omega(t_j - \tau) &= \frac{N}{2} + \frac{1}{2} C_2 \cos(2\omega\tau) + \frac{1}{2} S_2 \sin(2\omega\tau) \\ \sum_{j=1}^N \sin^2 \omega(t_j - \tau) &= \frac{N}{2} - \frac{1}{2} C_2 \cos(2\omega\tau) - \frac{1}{2} S_2 \sin(2\omega\tau) \end{aligned} \quad (13.8.12)$$

Now notice that if the t_j s were evenly spaced, then the four quantities S_h , C_h , S_2 , and C_2 could be evaluated by two complex FFTs, and the results could then be substituted back through equation (13.8.12) to evaluate equations (13.8.5) and (13.8.4). The problem is therefore only to evaluate equations (13.8.10) and (13.8.11) for unevenly spaced data.

Interpolation, or rather reverse interpolation — we will here call it *extirpolation* — provides the key. Interpolation, as classically understood, uses several function values on a regular mesh to construct an accurate approximation at an arbitrary point. Extirpolation, just the opposite, replaces a function value at an arbitrary point by several function values on a regular mesh, doing this in such a way that sums over the mesh are an accurate approximation to sums over the original arbitrary point.

It is not hard to see that the weight functions for extirpolation are identical to those for interpolation. Suppose that the function $h(t)$ to be extirpolated is known only at the discrete (unevenly spaced) points $h(t_i) \equiv h_i$, and that the function $g(t)$ (which will be, e.g., $\cos \omega t$) can be evaluated anywhere. Let \hat{t}_k be a sequence of evenly spaced points on a regular mesh. Then Lagrange interpolation (§3.1) gives an approximation of the form

$$g(t) \approx \sum_k w_k(t) g(\hat{t}_k) \quad (13.8.13)$$

where $w_k(t)$ are interpolation weights. Now let us evaluate a sum of interest by the following scheme:

$$\sum_{j=1}^N h_j g(t_j) \approx \sum_{j=1}^N h_j \left[\sum_k w_k(t_j) g(\hat{t}_k) \right] = \sum_k \left[\sum_{j=1}^N h_j w_k(t_j) \right] g(\hat{t}_k) \equiv \sum_k \hat{h}_k g(\hat{t}_k) \quad (13.8.14)$$

Here $\hat{h}_k \equiv \sum_j h_j w_k(t_j)$. Notice that equation (13.8.14) replaces the original sum by one on the regular mesh. Notice also that the accuracy of equation (13.8.13) depends only on the fineness of the mesh with respect to the function g and has nothing to do with the spacing of the points t_j or the function h ; therefore the accuracy of equation (13.8.14) also has this property.

The general outline of the fast evaluation method is therefore this: (i) Choose a mesh size large enough to accommodate some desired oversampling factor, and large enough to have several extirpolation points per half-wavelength of the highest frequency of interest. (ii) Extirpolate the values h_i onto the mesh and take the FFT; this gives S_h and C_h in equation (13.8.10). (iii) Extirpolate the constant values 1 onto another mesh, and take its FFT; this, with some manipulation, gives S_2 and C_2 in equation (13.8.11). (iv) Evaluate equations (13.8.12), (13.8.5), and (13.8.4), in that order.

There are several other tricks involved in implementing this algorithm efficiently. You can figure most out from the code, but we will mention the following points: (a) A nice way to get transform values at frequencies 2ω instead of ω is to stretch the time-domain data by a factor 2, and then wrap it to double-cover the original length. (This trick goes back to Tukey.) In the program, this appears as a modulo function. (b) Trigonometric identities are used to get from the left-hand side of equation (13.8.5) to the various needed trigonometric functions of $\omega\tau$. FORTRAN identifiers like (e.g.) `cwt` and `hs2wt` represent quantities like (e.g.) $\cos \omega\tau$ and $\frac{1}{2} \sin(2\omega\tau)$. (c) The subroutine `spread` does extirpolation onto the M most nearly centered mesh points around an arbitrary point; its turgid code evaluates coefficients of the Lagrange interpolating polynomials, in an efficient manner.

```

SUBROUTINE fasper(x,y,n,ofac,hifac,wk1,wk2,nout,jmax,prob)
INTEGER jmax,n,nout,nwk,MACC
REAL hifac,ofac,prob,wk1(nwk),wk2(nwk),x(n),y(n)
PARAMETER (MACC=4)           Number of interpolation points per 1/4 cycle of highest fre-
C USES avevar,realfft,spread      quency.
Given n data points with abscissas x (which need not be equally spaced) and ordinates y,
and given a desired oversampling factor ofac (a typical value being 4 or larger), this routine
fills array wk1 with a sequence of nout increasing frequencies (not angular frequencies) up
to hifac times the "average" Nyquist frequency, and fills array wk2 with the values of the
Lomb normalized periodogram at those frequencies. The arrays x and y are not altered.
nwk, the dimension of wk1 and wk2, must be large enough for intermediate work space,
or an error (pause) results. The routine also returns jmax such that wk2(jmax) is the
maximum element in wk2, and prob, an estimate of the significance of that maximum
against the hypothesis of random noise. A small value of prob indicates that a significant
periodic signal is present.

13.9 Computing Fourier Integrals Using the FFT

Not uncommonly, one wants to calculate accurate numerical values for integrals of the form

$$I = \int_a^b e^{i\omega t} h(t) dt , \quad (13.9.1)$$

or the equivalent real and imaginary parts

$$I_c = \int_a^b \cos(\omega t) h(t) dt \quad I_s = \int_a^b \sin(\omega t) h(t) dt , \quad (13.9.2)$$

and one wants to evaluate this integral for many different values of ω . In cases of interest, $h(t)$ is often a smooth function, but it is not necessarily periodic in $[a, b]$, nor does it necessarily go to zero at a or b . While it seems intuitively obvious that the *force majeure* of the FFT ought to be applicable to this problem, doing so turns out to be a surprisingly subtle matter, as we will now see.

Let us first approach the problem naively, to see where the difficulty lies. Divide the interval $[a, b]$ into M subintervals, where M is a large integer, and define

$$\Delta \equiv \frac{b-a}{M} , \quad t_j \equiv a + j\Delta , \quad h_j \equiv h(t_j) , \quad j = 0, \dots, M \quad (13.9.3)$$

Notice that $h_0 = h(a)$ and $h_M = h(b)$, and that there are $M + 1$ values h_j . We can approximate the integral I by a sum,

$$I \approx \Delta \sum_{j=0}^{M-1} h_j \exp(i\omega t_j) \quad (13.9.4)$$

which is at any rate first-order accurate. (If we centered the h_j 's and the t_j 's in the intervals, we could be accurate to second order.) Now for certain values of ω and M , the sum in equation (13.9.4) can be made into a discrete Fourier transform, or DFT, and evaluated by the fast Fourier transform (FFT) algorithm. In particular, we can choose M to be an integer power of 2, and define a set of special ω 's by

$$\omega_m \Delta \equiv \frac{2\pi m}{M} \quad (13.9.5)$$

```

    yy(j)=yy(j)+y*fac/(nden*(x-j))

$$\Delta \equiv \frac{b-a}{M} , \quad t_j \equiv a + j\Delta , \quad h_j \equiv h(t_j) , \quad j = 0, \dots, M \quad (13.9.3)$$

Notice that $h_0 = h(a)$ and $h_M = h(b)$, and that there are $M + 1$ values h_j . We can approximate the integral I by a sum,

$$I \approx \Delta \sum_{j=0}^{M-1} h_j \exp(i\omega t_j) \quad (13.9.4)$$

which is at any rate first-order accurate. (If we centered the h_j 's and the t_j 's in the intervals, we could be accurate to second order.) Now for certain values of ω and M , the sum in equation (13.9.4) can be made into a discrete Fourier transform, or DFT, and evaluated by the fast Fourier transform (FFT) algorithm. In particular, we can choose M to be an integer power of 2, and define a set of special ω 's by

$$\omega_m \Delta \equiv \frac{2\pi m}{M} \quad (13.9.5)$$

where m has the values $m = 0, 1, \dots, M/2 - 1$. Then equation (13.9.4) becomes

$$I(\omega_m) \approx \Delta e^{i\omega_m a} \sum_{j=0}^{M-1} h_j e^{2\pi i m j / M} = \Delta e^{i\omega_m a} [\text{DFT}(h_0 \dots h_{M-1})]_m \quad (13.9.6)$$

Equation (13.9.6), while simple and clear, is emphatically *not recommended* for use: It is likely to give wrong answers!

The problem lies in the oscillatory nature of the integral (13.9.1). If $h(t)$ is at all smooth, and if ω is large enough to imply several cycles in the interval $[a, b]$ — in fact, ω_m in equation (13.9.5) gives exactly m cycles — then the value of I is typically very small, so small that it is easily swamped by first-order, or even (with centered values) second-order, truncation error. Furthermore, the characteristic “small parameter” that occurs in the error term is not $\Delta/(b-a) = 1/M$, as it would be if the integrand were not oscillatory, but $\omega\Delta$, which can be as large as π for ω 's within the Nyquist interval of the DFT (cf. equation 13.9.5). The result is that equation (13.9.6) becomes systematically inaccurate as ω increases.

It is a sobering exercise to implement equation (13.9.6) for an integral that can be done analytically, and to see just how bad it is. We recommend that you try it.

Let us therefore turn to a more sophisticated treatment. Given the sampled points h_j , we can approximate the function $h(t)$ everywhere in the interval $[a, b]$ by interpolation on nearby h_j 's. The simplest case is linear interpolation, using the two nearest h_j 's, one to the left and one to the right. A higher-order interpolation, e.g., would be cubic interpolation, using two points to the left and two to the right — except in the first and last subintervals, where we must interpolate with three h_j 's on one side, one on the other.

The formulas for such interpolation schemes are (piecewise) polynomial in the independent variable t , but with coefficients that are of course linear in the function values h_j . Although one does not usually think of it in this way, interpolation can be viewed as approximating a function by a sum of kernel functions (which depend only on the interpolation scheme) times sample values (which depend only on the function). Let us write

$$h(t) \approx \sum_{j=0}^M h_j \psi\left(\frac{t-t_j}{\Delta}\right) + \sum_{j=\text{endpoints}} h_j \varphi_j\left(\frac{t-t_j}{\Delta}\right) \quad (13.9.7)$$

Here $\psi(s)$ is the kernel function of an interior point: It is zero for s sufficiently negative or sufficiently positive, and becomes nonzero only when s is in the range where the h_j multiplying it is actually used in the interpolation. We always have $\psi(0) = 1$ and $\psi(m) = 0$, $m = \pm 1, \pm 2, \dots$, since interpolation right on a sample point should give the sampled function value. For linear interpolation $\psi(s)$ is piecewise linear, rises from 0 to 1 for s in $(-1, 0)$, and falls back to 0 for s in $(0, 1)$. For higher-order interpolation, $\psi(s)$ is made up piecewise of segments of Lagrange interpolation polynomials. It has discontinuous derivatives at integer values of s , where the pieces join, because the set of points used in the interpolation changes discretely.

As already remarked, the subintervals closest to a and b require different (noncentered) interpolation formulas. This is reflected in equation (13.9.7) by the second sum, with the special endpoint kernels $\varphi_j(s)$. Actually, for reasons that will become clearer below, we have included *all* the points in the *first* sum (with kernel ψ), so the φ_j 's are actually differences between true endpoint kernels and the interior kernel ψ . It is a tedious, but straightforward, exercise to write down all the $\varphi_j(s)$'s for any particular order of interpolation, each one consisting of differences of Lagrange interpolating polynomials spliced together piecewise.

Now apply the integral operator $\int_a^b dt \exp(i\omega t)$ to both sides of equation (13.9.7), interchange the sums and integral, and make the changes of variable $s = (t - t_j)/\Delta$ in the first sum, $s = (t - a)/\Delta$ in the second sum. The result is

$$I \approx \Delta e^{i\omega a} \left[W(\theta) \sum_{j=0}^M h_j e^{ij\theta} + \sum_{j=\text{endpoints}} h_j \alpha_j(\theta) \right] \quad (13.9.8)$$

Here $\theta \equiv \omega\Delta$, and the functions $W(\theta)$ and $\alpha_j(\theta)$ are defined by

$$W(\theta) \equiv \int_{-\infty}^{\infty} ds e^{i\theta s} \psi(s) \quad (13.9.9)$$

$$\alpha_j(\theta) \equiv \int_{-\infty}^{\infty} ds e^{i\theta s} \varphi_j(s - j) \quad (13.9.10)$$

The key point is that equations (13.9.9) and (13.9.10) can be evaluated, analytically, once and for all, for any given interpolation scheme. Then equation (13.9.8) is an algorithm for applying “endpoint corrections” to a sum which (as we will see) can be done using the FFT, giving a result with high-order accuracy.

We will consider only interpolations that are left-right symmetric. Then symmetry implies

$$\varphi_{M-j}(s) = \varphi_j(-s) \quad \alpha_{M-j}(\theta) = e^{i\theta M} \alpha_j^*(\theta) = e^{i\omega(b-a)} \alpha_j^*(\theta) \quad (13.9.11)$$

where $*$ denotes complex conjugation. Also, $\psi(s) = \psi(-s)$ implies that $W(\theta)$ is real.

Turn now to the first sum in equation (13.9.8), which we want to do by FFT methods. To do so, choose some N that is an integer power of 2 with $N \geq M + 1$. (Note that M need not be a power of two, so $M = N - 1$ is allowed.) If $N > M + 1$, define $h_j \equiv 0$, $M + 1 < j \leq N - 1$, i.e., “zero pad” the array of h_j ’s so that j takes on the range $0 \leq j \leq N - 1$. Then the sum can be done as a DFT for the special values $\omega = \omega_n$ given by

$$\omega_n \Delta \equiv \frac{2\pi n}{N} \equiv \theta \quad n = 0, 1, \dots, \frac{N}{2} - 1 \quad (13.9.12)$$

For fixed M , the larger N is chosen, the finer the sampling in frequency space. The value M , on the other hand, determines the *highest* frequency sampled, since Δ decreases with increasing M (equation 13.9.3), and the largest value of $\omega \Delta$ is always just under π (equation 13.9.12). In general it is advantageous to oversample by *at least* a factor of 4, i.e., $N > 4M$ (see below). We can now rewrite equation (13.9.8) in its final form as

$$\begin{aligned} I(\omega_n) = \Delta e^{i\omega_n a} & \left\{ W(\theta) [\text{DFT}(h_0 \dots h_{N-1})]_n \right. \\ & + \alpha_0(\theta) h_0 + \alpha_1(\theta) h_1 + \alpha_2(\theta) h_2 + \alpha_3(\theta) h_3 + \dots \\ & \left. + e^{i\omega(b-a)} [\alpha_0^*(\theta) h_M + \alpha_1^*(\theta) h_{M-1} + \alpha_2^*(\theta) h_{M-2} + \alpha_3^*(\theta) h_{M-3} + \dots] \right\} \end{aligned} \quad (13.9.13)$$

For cubic (or lower) polynomial interpolation, at most the terms explicitly shown above are nonzero; the ellipses (\dots) can therefore be ignored, and we need explicit forms only for the functions W , α_0 , α_1 , α_2 , α_3 , calculated with equations (13.9.9) and (13.9.10). We have worked these out for you, in the trapezoidal (second-order) and cubic (fourth-order) cases. Here are the results, along with the first few terms of their power series expansions for small θ :

Trapezoidal order:

$$W(\theta) = \frac{2(1 - \cos \theta)}{\theta^2} \approx 1 - \frac{1}{12}\theta^2 + \frac{1}{360}\theta^4 - \frac{1}{20160}\theta^6$$

$$\begin{aligned} \alpha_0(\theta) &= -\frac{(1 - \cos \theta)}{\theta^2} + i \frac{(\theta - \sin \theta)}{\theta^2} \\ &\approx -\frac{1}{2} + \frac{1}{24}\theta^2 - \frac{1}{720}\theta^4 + \frac{1}{40320}\theta^6 + i\theta \left(\frac{1}{6} - \frac{1}{120}\theta^2 + \frac{1}{5040}\theta^4 - \frac{1}{362880}\theta^6 \right) \end{aligned}$$

$$\alpha_1 = \alpha_2 = \alpha_3 = 0$$

Cubic order:

$$W(\theta) = \left(\frac{6 + \theta^2}{3\theta^4} \right) (3 - 4 \cos \theta + \cos 2\theta) \approx 1 - \frac{11}{720} \theta^4 + \frac{23}{15120} \theta^6$$

$$\alpha_0(\theta) = \frac{(-42 + 5\theta^2) + (6 + \theta^2)(8 \cos \theta - \cos 2\theta)}{6\theta^4} + i \frac{(-12\theta + 6\theta^3) + (6 + \theta^2) \sin 2\theta}{6\theta^4}$$

$$\approx -\frac{2}{3} + \frac{1}{45} \theta^2 + \frac{103}{15120} \theta^4 - \frac{169}{226800} \theta^6 + i\theta \left(\frac{2}{45} + \frac{2}{105} \theta^2 - \frac{8}{2835} \theta^4 + \frac{86}{467775} \theta^6 \right)$$

$$\alpha_1(\theta) = \frac{14(3 - \theta^2) - 7(6 + \theta^2) \cos \theta}{6\theta^4} + i \frac{30\theta - 5(6 + \theta^2) \sin \theta}{6\theta^4}$$

$$\approx \frac{7}{24} - \frac{7}{180} \theta^2 + \frac{5}{3456} \theta^4 - \frac{7}{259200} \theta^6 + i\theta \left(\frac{7}{72} - \frac{1}{168} \theta^2 + \frac{11}{72576} \theta^4 - \frac{13}{5987520} \theta^6 \right)$$

$$\alpha_2(\theta) = \frac{-4(3 - \theta^2) + 2(6 + \theta^2) \cos \theta}{3\theta^4} + i \frac{-12\theta + 2(6 + \theta^2) \sin \theta}{3\theta^4}$$

$$\approx -\frac{1}{6} + \frac{1}{45} \theta^2 - \frac{5}{6048} \theta^4 + \frac{1}{64800} \theta^6 + i\theta \left(-\frac{7}{90} + \frac{1}{210} \theta^2 - \frac{11}{90720} \theta^4 + \frac{13}{7484400} \theta^6 \right)$$

$$\alpha_3(\theta) = \frac{2(3 - \theta^2) - (6 + \theta^2) \cos \theta}{6\theta^4} + i \frac{6\theta - (6 + \theta^2) \sin \theta}{6\theta^4}$$

$$\approx \frac{1}{24} - \frac{1}{180} \theta^2 + \frac{5}{24192} \theta^4 - \frac{1}{259200} \theta^6 + i\theta \left(\frac{7}{360} - \frac{1}{840} \theta^2 + \frac{11}{362880} \theta^4 - \frac{13}{29937600} \theta^6 \right)$$

The program `dftcor`, below, implements the endpoint corrections for the cubic case. Given input values of ω , Δ , a , b , and an array with the eight values $h_0, \dots, h_3, h_{M-3}, \dots, h_M$, it returns the real and imaginary parts of the endpoint corrections in equation (13.9.13), and the factor $W(\theta)$. The code is turgid, but only because the formulas above are complicated. The formulas have cancellations to high powers of θ . It is therefore necessary to compute the right-hand sides in double precision, even when the corrections are desired only to single precision. It is also necessary to use the series expansion for small values of θ . The optimal cross-over value of θ depends on your machine's wordlength, but you can always find it experimentally as the largest value where the two methods give identical results to machine precision.

```
SUBROUTINE dftcor(w,delta,a,b,endpts,corre,corim,corfac)
REAL a,b,corfac,corim,corre,delta,w,endpts(8)
```

For an integral approximated by a discrete Fourier transform, this routine computes the correction factor that multiplies the DFT and the endpoint correction to be added. Input is the angular frequency w , stepsize δ , lower and upper limits of the integral a and b , while the array `endpts` contains the first 4 and last 4 function values. The correction factor $W(\theta)$ is returned as `corfac`, while the real and imaginary parts of the endpoint correction are returned as `corre` and `corim`.

Since the use of `dftcor` can be confusing, we also give an illustrative program `dftint` which uses `dftcor` to compute equation (13.9.1) for general a, b, ω , and $h(t)$. Several points within this program bear mentioning: The parameters `M` and `NDFT` correspond to M and N in the above discussion. On successive calls, we recompute the Fourier transform only if a or b has changed. (We should also recompute if $h(t)$ has changed, but FORTRAN doesn't provide a way for us to test this.)

Since `dftint` is designed to work for any value of ω satisfying $\omega\Delta < \pi$, not just the special values returned by the DFT (equation 13.9.12), we do polynomial interpolation of degree `MPOL` on the DFT spectrum. You should be warned that a large factor of oversampling ($N \gg M$) is required for this interpolation to be accurate. After interpolation, we add the endpoint corrections from `dftcor`, which can be evaluated for any ω .

While `dftcor` is good at what it does, `dftint` is illustrative only. It is not a general purpose program, because it does not adapt its parameters `M`, `NDFT`, `MPOL`, or its interpolation scheme, to any particular function $h(t)$. You will have to experiment with your own application.

```

SUBROUTINE dftint(func,a,b,w,cosint,sinint)
INTEGER M,NDFT,MPOL
REAL a,b,cosint,sinint,w,func,TWOP
PARAMETER (M=64,NDFT=1024,MPOL=6,TWOP=2.*3.14159265)
EXTERNAL func
C   USES dftcor,func,polint,realft

```

Example program illustrating how to use the routine `dftcor`. The user supplies an external function `func` that returns the quantity $h(t)$. The routine then returns $\int_a^b \cos(\omega t)h(t) dt$ as `cosint` and $\int_a^b \sin(\omega t)h(t) dt$ as `sinint`.

Parameters: The values of `M`, `NDFT`, and `MPOL` are merely illustrative and should be optimized for your particular application. `M` is the number of subintervals, `NDFT` is the length of the FFT (a power of 2), and `MPOL` is the degree of polynomial interpolation used to obtain the desired frequency from the FFT.

```

Sometimes one is interested only in the discrete frequencies ω_m of equation (13.9.5), the ones that have integral numbers of periods in the interval $[a, b]$. For smooth $h(t)$, the value of I tends to be much smaller in magnitude at these ω 's than at values in between, since the integral half-periods tend to cancel precisely. (That is why one must oversample for interpolation to be accurate: $I(\omega)$ is oscillatory with small magnitude near the ω_m 's.) If you want these ω_m 's without messy (and possibly inaccurate) interpolation, you have to set N to

a multiple of M (compare equations 13.9.5 and 13.9.12). In the method implemented above, however, N must be at least $M + 1$, so the smallest such multiple is $2M$, resulting in a factor ~ 2 unnecessary computing. Alternatively, one can derive a formula like equation (13.9.13), but with the last sample function $h_M = h(b)$ omitted from the DFT, but included entirely in the endpoint correction for h_M . Then one can set $M = N$ (an integer power of 2) and get the special frequencies of equation (13.9.5) with no additional overhead. The modified formula is

$$\begin{aligned} I(\omega_m) = \Delta e^{i\omega_m a} & \left\{ W(\theta)[\text{DFT}(h_0 \dots h_{M-1})]_m \right. \\ & + \alpha_0(\theta)h_0 + \alpha_1(\theta)h_1 + \alpha_2(\theta)h_2 + \alpha_3(\theta)h_3 \\ & \left. + e^{i\omega(b-a)} [A(\theta)h_M + \alpha_1^*(\theta)h_{M-1} + \alpha_2^*(\theta)h_{M-2} + \alpha_3^*(\theta)h_{M-3}] \right\} \end{aligned} \quad (13.9.14)$$

where $\theta \equiv \omega_m \Delta$ and $A(\theta)$ is given by

$$A(\theta) = -\alpha_0(\theta) \quad (13.9.15)$$

for the trapezoidal case, or

$$\begin{aligned} A(\theta) &= \frac{(-6 + 11\theta^2) + (6 + \theta^2) \cos 2\theta}{6\theta^4} - i \operatorname{Im}[\alpha_0(\theta)] \\ &\approx \frac{1}{3} + \frac{1}{45}\theta^2 - \frac{8}{945}\theta^4 + \frac{11}{14175}\theta^6 - i \operatorname{Im}[\alpha_0(\theta)] \end{aligned} \quad (13.9.16)$$

for the cubic case.

Factors like $W(\theta)$ arise naturally whenever one calculates Fourier coefficients of smooth functions, and they are sometimes called attenuation factors [1]. However, the endpoint corrections are equally important in obtaining accurate values of integrals. Narasimhan and Karthikeyan [2] have given a formula that is algebraically equivalent to our trapezoidal formula. However, their formula requires the evaluation of *two* FFTs, which is unnecessary. The basic idea used here goes back at least to Filon [3] in 1928 (before the FFT!). He used Simpson's rule (quadratic interpolation). Since this interpolation is not left-right symmetric, two Fourier transforms are required. An alternative algorithm for equation (13.9.14) has been given by Lyness in [4]; for related references, see [5]. To our knowledge, the cubic-order formulas derived here have not previously appeared in the literature.

Calculating Fourier transforms when the range of integration is $(-\infty, \infty)$ can be tricky. If the function falls off reasonably quickly at infinity, you can split the integral at a large enough value of t . For example, the integration to $+\infty$ can be written

$$\begin{aligned} \int_a^\infty e^{i\omega t} h(t) dt &= \int_a^b e^{i\omega t} h(t) dt + \int_b^\infty e^{i\omega t} h(t) dt \\ &= \int_a^b e^{i\omega t} h(t) dt - \frac{h(b)e^{i\omega b}}{i\omega} + \frac{h'(b)e^{i\omega b}}{(i\omega)^2} - \dots \end{aligned} \quad (13.9.17)$$

The splitting point b must be chosen large enough that the remaining integral over (b, ∞) is small. Successive terms in its asymptotic expansion are found by integrating by parts. The integral over (a, b) can be done using `dftint`. You keep as many terms in the asymptotic expansion as you can easily compute. See [6] for some examples of this idea. More powerful methods, which work well for long-tailed functions but which do not use the FFT, are described in [7-9].

13.10 Wavelet Transforms

Like the fast Fourier transform (FFT), the discrete wavelet transform (DWT) is a fast, linear operation that operates on a data vector whose length is an integer power of two, transforming it into a numerically different vector of the same length. Also like the FFT, the wavelet transform is invertible and in fact orthogonal — the inverse transform, when viewed as a big matrix, is simply the transpose of the transform. Both FFT and DWT, therefore, can be viewed as a rotation in function space, from the input space (or time) domain, where the basis functions are the unit vectors \mathbf{e}_i , or Dirac delta functions in the continuum limit, to a different domain. For the FFT, this new domain has basis functions that are the familiar sines and cosines. In the wavelet domain, the basis functions are somewhat more complicated and have the fanciful names “mother functions” and “wavelets.”

Of course there are an infinity of possible bases for function space, almost all of them uninteresting! What makes the wavelet basis interesting is that, *unlike* sines and cosines, individual wavelet functions are quite localized in space; simultaneously, *like* sines and cosines, individual wavelet functions are quite localized in frequency or (more precisely) characteristic scale. As we will see below, the particular kind of dual localization achieved by wavelets renders large classes of functions and operators sparse, or sparse to some high accuracy, when transformed into the wavelet domain. Analogously with the Fourier domain, where a class of computations, like convolutions, become computationally fast, there is a large class of computations — those that can take advantage of sparsity — that become computationally fast in the wavelet domain [1].

Unlike sines and cosines, which define a unique Fourier transform, there is not one single unique set of wavelets; in fact, there are infinitely many possible sets. Roughly, the different sets of wavelets make different trade-offs between how compactly they are localized in space and how smooth they are. (There are further fine distinctions.)

Daubechies Wavelet Filter Coefficients

A particular set of wavelets is specified by a particular set of numbers, called *wavelet filter coefficients*. Here, we will largely restrict ourselves to wavelet filters in a class discovered by Daubechies [2]. This class includes members ranging from highly localized to highly smooth. The simplest (and most localized) member, often called *DAUB4*, has only four coefficients, c_0, \dots, c_3 . For the moment we specialize to this case for ease of notation.

13.10 Wavelet Transforms

Like the fast Fourier transform (FFT), the discrete wavelet transform (DWT) is a fast, linear operation that operates on a data vector whose length is an integer power of two, transforming it into a numerically different vector of the same length. Also like the FFT, the wavelet transform is invertible and in fact orthogonal — the inverse transform, when viewed as a big matrix, is simply the transpose of the transform. Both FFT and DWT, therefore, can be viewed as a rotation in function space, from the input space (or time) domain, where the basis functions are the unit vectors \mathbf{e}_i , or Dirac delta functions in the continuum limit, to a different domain. For the FFT, this new domain has basis functions that are the familiar sines and cosines. In the wavelet domain, the basis functions are somewhat more complicated and have the fanciful names “mother functions” and “wavelets.”

Of course there are an infinity of possible bases for function space, almost all of them uninteresting! What makes the wavelet basis interesting is that, *unlike* sines and cosines, individual wavelet functions are quite localized in space; simultaneously, *like* sines and cosines, individual wavelet functions are quite localized in frequency or (more precisely) characteristic scale. As we will see below, the particular kind of dual localization achieved by wavelets renders large classes of functions and operators sparse, or sparse to some high accuracy, when transformed into the wavelet domain. Analogously with the Fourier domain, where a class of computations, like convolutions, become computationally fast, there is a large class of computations — those that can take advantage of sparsity — that become computationally fast in the wavelet domain [1].

Unlike sines and cosines, which define a unique Fourier transform, there is not one single unique set of wavelets; in fact, there are infinitely many possible sets. Roughly, the different sets of wavelets make different trade-offs between how compactly they are localized in space and how smooth they are. (There are further fine distinctions.)

Daubechies Wavelet Filter Coefficients

A particular set of wavelets is specified by a particular set of numbers, called *wavelet filter coefficients*. Here, we will largely restrict ourselves to wavelet filters in a class discovered by Daubechies [2]. This class includes members ranging from highly localized to highly smooth. The simplest (and most localized) member, often called *DAUB4*, has only four coefficients, c_0, \dots, c_3 . For the moment we specialize to this case for ease of notation.

Consider the following transformation matrix acting on a column vector of data to its right:

$$\begin{bmatrix} c_0 & c_1 & c_2 & c_3 \\ c_3 & -c_2 & c_1 & -c_0 \\ & c_0 & c_1 & c_2 & c_3 \\ & c_3 & -c_2 & c_1 & -c_0 \\ \vdots & \vdots & & & \ddots \\ & & & c_0 & c_1 & c_2 & c_3 \\ & & & c_3 & -c_2 & c_1 & -c_0 \\ c_2 & c_3 & & & & c_0 & c_1 \\ c_1 & -c_0 & & & & c_3 & -c_2 \end{bmatrix} \quad (13.10.1)$$

Here blank entries signify zeroes. Note the structure of this matrix. The first row generates one component of the data convolved with the filter coefficients c_0, \dots, c_3 . Likewise the third, fifth, and other odd rows. If the even rows followed this pattern, offset by one, then the matrix would be a circulant, that is, an ordinary convolution that could be done by FFT methods. (Note how the last two rows wrap around like convolutions with periodic boundary conditions.) Instead of convolving with c_0, \dots, c_3 , however, the even rows perform a different convolution, with coefficients $c_3, -c_2, c_1, -c_0$. The action of the matrix, overall, is thus to perform two related convolutions, then to decimate each of them by half (throw away half the values), and interleave the remaining halves.

It is useful to think of the filter c_0, \dots, c_3 as being a smoothing filter, call it H , something like a moving average of four points. Then, because of the minus signs, the filter $c_3, -c_2, c_1, -c_0$, call it G , is *not* a smoothing filter. (In signal processing contexts, H and G are called *quadrature mirror filters* [3].) In fact, the c 's are chosen so as to make G yield, insofar as possible, a *zero* response to a sufficiently smooth data vector. This is done by requiring the sequence $c_3, -c_2, c_1, -c_0$ to have a certain number of vanishing moments. When this is the case for p moments (starting with the zeroth), a set of wavelets is said to satisfy an “approximation condition of order p .” This results in the output of H , decimated by half, accurately representing the data’s “smooth” information. The output of G , also decimated, is referred to as the data’s “detail” information [4].

For such a characterization to be useful, it must be possible to reconstruct the original data vector of length N from its $N/2$ smooth or s-components and its $N/2$ detail or d-components. That is effected by requiring the matrix (13.10.1) to be orthogonal, so that its inverse is just the transposed matrix

$$\begin{bmatrix} c_0 & c_3 & & \cdots & & c_2 & c_1 \\ c_1 & -c_2 & & \cdots & & c_3 & -c_0 \\ c_2 & c_1 & c_0 & c_3 & & & \\ c_3 & -c_0 & c_1 & -c_2 & & & \\ & & & & \ddots & & \\ & & & & c_2 & c_1 & c_0 & c_3 \\ & & & & c_3 & -c_0 & c_1 & -c_2 \\ & & & & & c_2 & c_1 & c_0 & c_3 \\ & & & & & c_3 & -c_0 & c_1 & -c_2 \end{bmatrix} \quad (13.10.2)$$

One sees immediately that matrix (13.10.2) is inverse to matrix (13.10.1) if and only if these two equations hold,

$$\begin{aligned} c_0^2 + c_1^2 + c_2^2 + c_3^2 &= 1 \\ c_2 c_0 + c_3 c_1 &= 0 \end{aligned} \quad (13.10.3)$$

If additionally we require the approximation condition of order $p = 2$, then two additional relations are required,

$$\begin{aligned} c_3 - c_2 + c_1 - c_0 &= 0 \\ 0c_3 - 1c_2 + 2c_1 - 3c_0 &= 0 \end{aligned} \quad (13.10.4)$$

Equations (13.10.3) and (13.10.4) are 4 equations for the 4 unknowns c_0, \dots, c_3 , first recognized and solved by Daubechies. The unique solution (up to a left-right reversal) is

$$\begin{aligned} c_0 &= (1 + \sqrt{3})/4\sqrt{2} & c_1 &= (3 + \sqrt{3})/4\sqrt{2} \\ c_2 &= (3 - \sqrt{3})/4\sqrt{2} & c_3 &= (1 - \sqrt{3})/4\sqrt{2} \end{aligned} \quad (13.10.5)$$

In fact, DAUB4 is only the most compact of a sequence of wavelet sets: If we had six coefficients instead of four, there would be three orthogonality requirements in equation (13.10.3) (with offsets of zero, two, and four), and we could require the vanishing of $p = 3$ moments in equation (13.10.4). In this case, DAUB6, the solution coefficients can also be expressed in closed form,

$$\begin{aligned} c_0 &= (1 + \sqrt{10} + \sqrt{5 + 2\sqrt{10}})/16\sqrt{2} & c_1 &= (5 + \sqrt{10} + 3\sqrt{5 + 2\sqrt{10}})/16\sqrt{2} \\ c_2 &= (10 - 2\sqrt{10} + 2\sqrt{5 + 2\sqrt{10}})/16\sqrt{2} & c_3 &= (10 - 2\sqrt{10} - 2\sqrt{5 + 2\sqrt{10}})/16\sqrt{2} \\ c_4 &= (5 + \sqrt{10} - 3\sqrt{5 + 2\sqrt{10}})/16\sqrt{2} & c_5 &= (1 + \sqrt{10} - \sqrt{5 + 2\sqrt{10}})/16\sqrt{2} \end{aligned} \quad (13.10.6)$$

For higher p , up to 10, Daubechies [2] has tabulated the coefficients numerically. The number of coefficients increases by two each time p is increased by one.

Discrete Wavelet Transform

We have not yet defined the discrete wavelet transform (DWT), but we are almost there: The DWT consists of applying a wavelet coefficient matrix like (13.10.1) *hierarchically*, first to the full data vector of length N , then to the “smooth” vector of length $N/2$, then to the “smooth-smooth” vector of length $N/4$, and so on until only a trivial number of “smooth-...-smooth” components (usually 2) remain. The procedure is sometimes called a *pyramidal algorithm* [4], for obvious reasons. The output of the DWT consists of these remaining components and all the “detail” components that were accumulated along the way. A diagram should make the procedure clear:

$$\begin{array}{c}
 \left[\begin{array}{c} y_1 \\ y_2 \\ y_3 \\ y_4 \\ y_5 \\ y_6 \\ y_7 \\ y_8 \\ y_9 \\ y_{10} \\ y_{11} \\ y_{12} \\ y_{13} \\ y_{14} \\ y_{15} \\ y_{16} \end{array} \right] \xrightarrow{\text{13.10.1}} \left[\begin{array}{c} s_1 \\ d_1 \\ s_2 \\ d_2 \\ s_3 \\ d_3 \\ s_4 \\ d_4 \\ s_5 \\ d_5 \\ s_6 \\ d_6 \\ s_7 \\ d_7 \\ s_8 \\ d_8 \end{array} \right] \xrightarrow{\text{permute}} \left[\begin{array}{c} s_1 \\ s_2 \\ s_3 \\ s_4 \\ D_1 \\ D_2 \\ S_2 \\ S_3 \\ D_3 \\ S_4 \\ D_4 \\ d_1 \\ d_2 \\ d_3 \\ d_4 \\ d_5 \\ d_6 \\ d_7 \\ d_8 \end{array} \right] \xrightarrow{\text{13.10.1}} \left[\begin{array}{c} S_1 \\ D_1 \\ S_2 \\ D_2 \\ S_3 \\ D_3 \\ S_4 \\ D_4 \\ \frac{S_1}{D_1} \\ \frac{S_2}{D_1} \\ \frac{S_3}{D_2} \\ \frac{D_2}{D_1} \\ \frac{D_3}{D_2} \\ \frac{D_4}{D_3} \\ \frac{d_1}{a_1} \\ \frac{d_2}{a_2} \\ \frac{d_3}{a_3} \\ \frac{d_4}{a_4} \\ \frac{d_5}{a_5} \\ \frac{d_6}{a_6} \\ \frac{d_7}{a_7} \\ \frac{d_8}{a_8} \end{array} \right] \xrightarrow{\text{permute}} \left[\begin{array}{c} S_1 \\ S_2 \\ \frac{S_3}{D_1} \\ \frac{D_2}{D_1} \\ \frac{D_3}{D_2} \\ \frac{D_4}{D_3} \\ \frac{D_4}{D_1} \\ \frac{d_1}{a_1} \\ \frac{d_2}{a_2} \\ \frac{d_3}{a_3} \\ \frac{d_4}{a_4} \\ \frac{d_5}{a_5} \\ \frac{d_6}{a_6} \\ \frac{d_7}{a_7} \\ \frac{d_8}{a_8} \end{array} \right] \xrightarrow{\text{etc.}} \left[\begin{array}{c} S_1 \\ S_2 \\ \frac{D_1}{D_1} \\ \frac{D_2}{D_1} \\ \frac{D_3}{D_2} \\ \frac{D_4}{D_3} \\ \frac{D_4}{D_1} \\ \frac{d_1}{a_1} \\ \frac{d_2}{a_2} \\ \frac{d_3}{a_3} \\ \frac{d_4}{a_4} \\ \frac{d_5}{a_5} \\ \frac{d_6}{a_6} \\ \frac{d_7}{a_7} \\ \frac{d_8}{a_8} \end{array} \right]
 \end{array} \tag{13.10.7}$$

If the length of the data vector were a higher power of two, there would be more stages of applying (13.10.1) (or any other wavelet coefficients) and permuting. The endpoint will always be a vector with two S 's and a hierarchy of D 's, D 's, d 's, etc. Notice that once d 's are generated, they simply propagate through to all subsequent stages.

A value d_i of any level is termed a “wavelet coefficient” of the original data vector; the final values S_1, S_2 should strictly be called “mother-function coefficients,” although the term “wavelet coefficients” is often used loosely for both d 's and final S 's. Since the full procedure is a composition of orthogonal linear operations, the whole DWT is itself an orthogonal linear operator.

To invert the DWT, one simply reverses the procedure, starting with the smallest level of the hierarchy and working (in equation 13.10.7) from right to left. The inverse matrix (13.10.2) is of course used instead of the matrix (13.10.1).

As already noted, the matrices (13.10.1) and (13.10.2) embody periodic (“wrap-around”) boundary conditions on the data vector. One normally accepts this as a minor inconvenience: the last few wavelet coefficients at each level of the hierarchy are affected by data from both ends of the data vector. By circularly shifting the matrix (13.10.1) $N/2$ columns to the left, one can symmetrize the wrap-around; but this does not eliminate it. It is in fact possible to eliminate the wrap-around completely by altering the coefficients in the first and last N rows of (13.10.1), giving an orthogonal matrix that is purely band-diagonal [5]. This variant, beyond our scope here, is useful when, e.g., the data varies by many orders of magnitude from one end of the data vector to the other.

Here is a routine, `wt1`, that performs the pyramidal algorithm (or its inverse if `isign` is negative) on some data vector `a(1:n)`. Successive applications of the wavelet filter, and accompanying permutations, are done by an assumed routine `wtstep`, which must be provided. (We give examples of several different `wtstep` routines just below.)

```

SUBROUTINE wt1(a,n,isign,wtstep)
INTEGER isign,n
REAL a(n)
EXTERNAL wtstep
C USES wtstep

```

One-dimensional discrete wavelet transform. This routine implements the pyramid algorithm, replacing `a(1:n)` by its wavelet transform (for `isign=1`), or performing the inverse operation (for `isign=-1`). Note that `n` MUST be an integer power of 2. The subroutine

`wtstep`, whose actual name must be supplied in calling this routine, is the underlying wavelet filter. Examples of `wtstep` are `daub4` and (preceded by `pwtset`) `pwt`.

```

INTEGER nn
if (n.lt.4) return
if (isign.ge.0) then
    nn=n                               Wavelet transform.
    if (nn.ge.4) then                  Start at largest hierarchy,
        call wtstep(a,nn,isign)
        nn=nn/2
    goto 1
    endif
else
    nn=4                               Inverse wavelet transform.
    if (nn.le.n) then                 Start at smallest hierarchy,
        call wtstep(a,nn,isign)
        nn=nn*2
    goto 2
    endif
endif
return
END
```

Here, as a specific instance of `wtstep`, is a routine for the DAUB4 wavelets:

```

SUBROUTINE daub4(a,n,isign)
INTEGER n,isign,NMAX           NMAX is the maximum allowed value of n.
REAL a(n),C3,C2,C1,C0
PARAMETER (C0=0.4829629131445341,C1=0.8365163037378079,
*          C2=0.2241438680420134,C3=-0.1294095225512604,NMAX=1024)
          Applies the Daubechies 4-coefficient wavelet filter to data vector a(1:n) (for isign=1) or
          applies its transpose (for isign=-1). Used hierarchically by routines wt1 and wtn.
REAL wksp(NMAX)
INTEGER nh,nh1,i,j
if(n.lt.4) return
if(n.gt.NMAX) pause 'wksp too small in daub4'
nh=n/2
nh1=nh+1
if (isign.ge.0) then           Apply filter.
    i=1
    do 11 j=1,n-3,2
        wksp(i)=C0*a(j)+C1*a(j+1)+C2*a(j+2)+C3*a(j+3)
        wksp(i+nh)=C3*a(j)-C2*a(j+1)+C1*a(j+2)-C0*a(j+3)
        i=i+1
    enddo 11
    wksp(i)=C0*a(n-1)+C1*a(n)+C2*a(1)+C3*a(2)
    wksp(i+nh)=C3*a(n-1)-C2*a(n)+C1*a(1)-C0*a(2)
else                           Apply transpose filter.
    wksp(1)=C2*a(nh)+C1*a(n)+C0*a(1)+C3*a(nh1)
    wksp(2)=C3*a(nh)-C0*a(n)+C1*a(1)-C2*a(nh1)
    j=3
    do 12 i=1,nh-1
        wksp(j)=C2*a(i)+C1*a(i+nh)+C0*a(i+1)+C3*a(i+nh1)
        wksp(j+1)=C3*a(i)-C0*a(i+nh)+C1*a(i+1)-C2*a(i+nh1)
        j=j+2
    enddo 12
endif
do 13 i=1,n
    a(i)=wksp(i)
enddo 13
return
END
```

For larger sets of wavelet coefficients, the wrap-around of the last rows or columns is a programming inconvenience. An efficient implementation would handle the wrap-arounds as special cases, outside of the main loop. Here, we will content ourselves with a more general scheme involving some extra arithmetic at run time. The following routine sets up any particular wavelet coefficients whose values you happen to know.

```
SUBROUTINE pwtset(n)
INTEGER n,NCMAX,ncof,ioff,joff
PARAMETER (NCMAX=50)           Maximum number of wavelet coefficients passed to pwt.
REAL cc(NCMAX),cr(NCMAX)
COMMON /pwtcom/ cc,cr,ncof,ioff,joff
      Initializing routine for pwt, here implementing the Daubechies wavelet filters with 4, 12,
      and 20 coefficients, as selected by the input value n. Further wavelet filters can be included
      in the obvious manner. This routine must be called (once) before the first use of pwt. (For
      the case n=4, the specific routine daub4 is considerably faster than pwt.)
      INTEGER k
      REAL sig,c4(4),c12(12),c20(20)
      SAVE c4,c12,c20,/pwtcom/
      DATA c4/0.4829629131445341, .8365163037378079,

      joff=-n/2
      return
END
These values center the "support" of the wavelets at each level.
Alternatively, the "peaks" of the wavelets can be approximately centered by the choices ioff=-2 and joff=-n+2.
Note that daub4 and pwtset with n=4 use different default centerings.
```

Once pwtset has been called, the following routine can be used as a specific instance of wtstep.

```
SUBROUTINE pwt(a,n,isign)
INTEGER isign,n,NMAX,NCMAX,ncof,ioff,joff
PARAMETER (NMAX=2048,NCMAX=50)
REAL a(n),wksp(NMAX),cc(NCMAX),cr(NCMAX)
COMMON /pwtcom/ cc,cr,ncof,ioff,joff
```

Partial wavelet transform: applies an arbitrary wavelet filter to data vector $a(1:n)$ (for $isign=1$) or applies its transpose (for $isign=-1$). Used hierarchically by routines `wt1` and `wtm`. The actual filter is determined by a preceding (and required) call to `pwtset`, which initializes the common block `pwtcom`.

```

INTEGER i,ii,j,jf,jr,k,n1,ni,nj,nh,nmod
REAL ai,ai1
SAVE /pwtcom/
if (n.lt.4) return
nmod=ncof*n                         A positive constant equal to zero mod n.
n1=n-1                                Mask of all bits, since n a power of 2.
nh=n/2
do 11 j=1,n
    wksp(j)=0.
enddo 11
if (isign.ge.0) then                  Apply filter.
    ii=1
    do 13 i=1,n,2
        ni=i+nmod+ioff                Pointer to be incremented and wrapped-around.
        nj=i+nmod+joff
        do 12 k=1,ncof
            jf=iand(n1,ni+k)          We use bitwise and to wrap-around the pointers.
            jr=iand(n1,nj+k)
            wksp(ii)=wksp(ii)+cc(k)*a(jf+1)
            wksp(ii+nh)=wksp(ii+nh)+cr(k)*a(jr+1)
        enddo 12
        ii=ii+1
    enddo 13
else                                   Apply transpose filter.
    ii=1
    do 15 i=1,n,2
        ai=a(ii)
        ai1=a(ii+nh)
        ni=i+nmod+ioff              See comments above.
        nj=i+nmod+joff
        do 14 k=1,ncof
            jf=iand(n1,ni+k)+1
            jr=iand(n1,nj+k)+1
            wksp(jf)=wksp(jf)+cc(k)*ai
            wksp(jr)=wksp(jr)+cr(k)*ai1
        enddo 14
        ii=ii+1
    enddo 15
endif
do 16 j=1,n                          Copy the results back from workspace.
    a(j)=wksp(j)
enddo 16
return
END

```

What Do Wavelets Look Like?

We are now in a position actually to see some wavelets. To do so, we simply run unit vectors through any of the above discrete wavelet transforms, with $isign$ negative so that the inverse transform is performed. Figure 13.10.1 shows the DAUB4 wavelet that is the inverse DWT of a unit vector in the 5th component of a vector of length 1024, and also the DAUB20 wavelet that is the inverse of the 22nd component. (One needs to go to a later hierarchical level for DAUB20, to avoid a wavelet with a wrapped-around tail.) Other unit vectors would give wavelets with the same shapes, but different positions and scales.

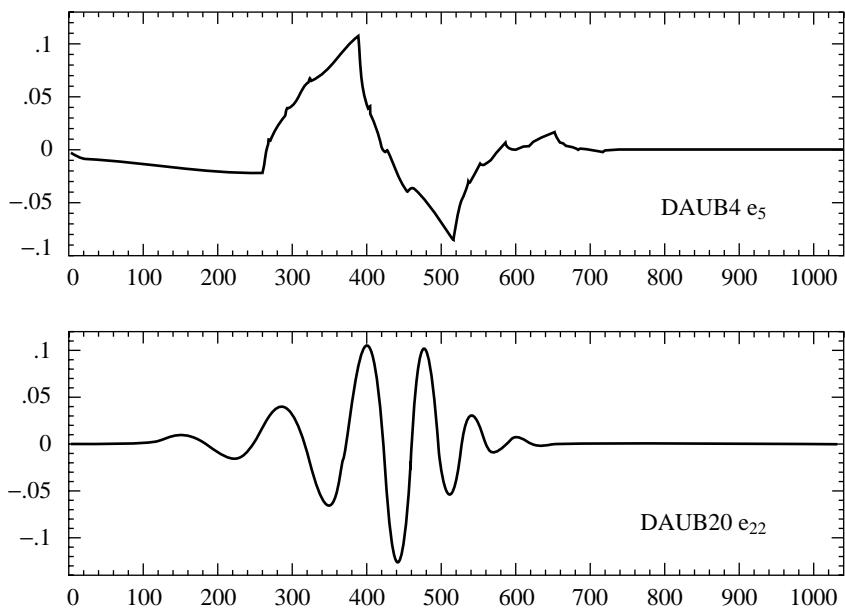

Figure 13.10.1. Wavelet functions, that is, single basis functions from the wavelet families DAUB4 and DAUB20. A complete, orthonormal wavelet basis consists of scalings and translations of either one of these functions. DAUB4 has an infinite number of cusps; DAUB20 would show similar behavior in a higher derivative.

One sees that both DAUB4 and DAUB20 have wavelets that are continuous. DAUB20 wavelets also have higher continuous derivatives. DAUB4 has the peculiar property that its derivative exists only *almost* everywhere. Examples of where it fails to exist are the points $p/2^n$, where p and n are integers; at such points, DAUB4 is left differentiable, but not right differentiable! This kind of discontinuity — at least in some derivative — is a necessary feature of wavelets with compact support, like the Daubechies series. For every increase in the number of wavelet coefficients by two, the Daubechies wavelets gain about *half* a derivative of continuity. (But not exactly half; the actual orders of regularity are irrational numbers!)

Note that the fact that wavelets are not smooth does not prevent their having exact representations for some smooth functions, as demanded by their approximation order p . The continuity of a wavelet is not the same as the continuity of functions that a set of wavelets can represent. For example, DAUB4 can represent (piecewise) linear functions of arbitrary slope: in the correct linear combinations, the cusps all cancel out. Every increase of two in the number of coefficients allows one higher order of polynomial to be exactly represented.

Figure 13.10.2 shows the result of performing the inverse DWT on the input vector $\mathbf{e}_{10} + \mathbf{e}_{58}$, again for the two different particular wavelets. Since 10 lies early in the hierarchical range of 9 – 16, that wavelet lies on the left side of the picture. Since 58 lies in a later (smaller-scale) hierarchy, it is a narrower wavelet; in the range of 33–64 it is towards the end, so it lies on the right side of the picture. Note that smaller-scale wavelets are taller, so as to have the same squared integral.

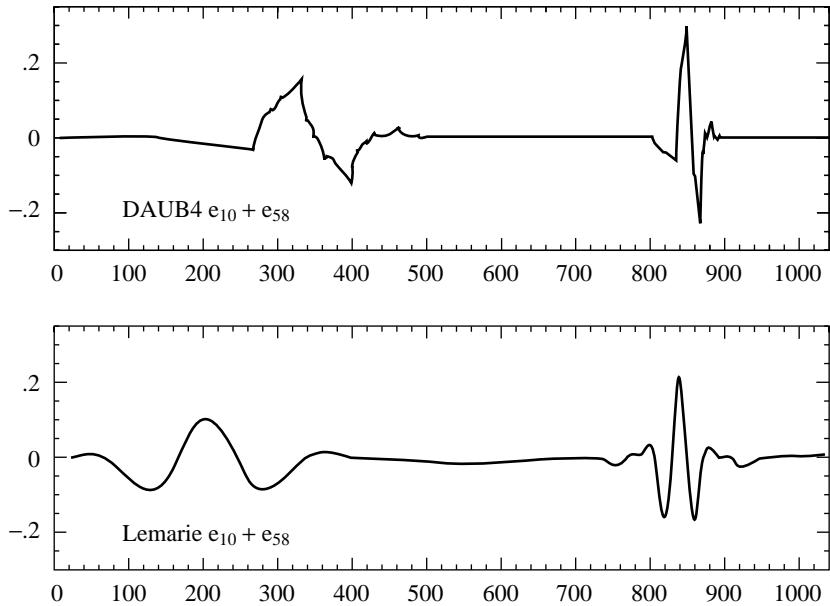

Figure 13.10.2. More wavelets, here generated from the sum of two unit vectors, $e_{10} + e_{58}$, which are in different hierarchical levels of scale, and also at different spatial positions. DAUB4 wavelets (a) are defined by a filter in coordinate space (equation 13.10.5), while Lemarie wavelets (b) are defined by a filter most easily written in Fourier space (equation 13.10.14).

Wavelet Filters in the Fourier Domain

The Fourier transform of a set of filter coefficients c_j is given by

$$H(\omega) = \sum_j c_j e^{ij\omega} \quad (13.10.8)$$

Here H is a function periodic in 2π , and it has the same meaning as before: It is the wavelet filter, now written in the Fourier domain. A very useful fact is that the orthogonality conditions for the c 's (e.g., equation 13.10.3 above) collapse to two simple relations in the Fourier domain,

$$\frac{1}{2}|H(0)|^2 = 1 \quad (13.10.9)$$

and

$$\frac{1}{2} [|H(\omega)|^2 + |H(\omega + \pi)|^2] = 1 \quad (13.10.10)$$

Likewise the approximation condition of order p (e.g., equation 13.10.4 above) has a simple formulation, requiring that $H(\omega)$ have a p th order zero at $\omega = \pi$, or (equivalently)

$$H^{(m)}(\pi) = 0 \quad m = 0, 1, \dots, p-1 \quad (13.10.11)$$

It is thus relatively straightforward to invent wavelet sets in the Fourier domain. You simply invent a function $H(\omega)$ satisfying equations (13.10.9)–(13.10.11). To find the actual c_j 's applicable to a data (or s -component) vector of length N , and with periodic wrap-around as in matrices (13.10.1) and (13.10.2), you invert equation (13.10.8) by the discrete Fourier transform

$$c_j = \frac{1}{N} \sum_{k=0}^{N-1} H\left(\frac{2\pi k}{N}\right) e^{-2\pi i j k / N} \quad (13.10.12)$$

The quadrature mirror filter G (reversed c_j 's with alternating signs), incidentally, has the Fourier representation

$$G(\omega) = e^{-i\omega} H^*(\omega + \pi) \quad (13.10.13)$$

where asterisk denotes complex conjugation.

In general the above procedure will *not* produce wavelet filters with compact support. In other words, all N of the c_j 's, $j = 0, \dots, N - 1$ will in general be nonzero (though they may be rapidly decreasing in magnitude). The Daubechies wavelets, or other wavelets with compact support, are specially chosen so that $H(\omega)$ is a trigonometric polynomial with only a small number of Fourier components, guaranteeing that there will be only a small number of nonzero c_j 's.

On the other hand, there is sometimes no particular reason to demand compact support. Giving it up in fact allows the ready construction of relatively smoother wavelets (higher values of p). Even without compact support, the convolutions implicit in the matrix (13.10.1) can be done efficiently by FFT methods.

Lemarie's wavelet (see [4]) has $p = 4$, does not have compact support, and is defined by the choice of $H(\omega)$,

$$H(\omega) = \left[2(1-u)^4 \frac{315 - 420u + 126u^2 - 4u^3}{315 - 420v + 126v^2 - 4v^3} \right]^{1/2} \quad (13.10.14)$$

where

$$u \equiv \sin^2 \frac{\omega}{2} \quad v \equiv \sin^2 \omega \quad (13.10.15)$$

It is beyond our scope to explain where equation (13.10.14) comes from. An informal description is that the quadrature mirror filter $G(\omega)$ deriving from equation (13.10.14) has the property that it gives identically zero when applied to any function whose odd-numbered samples are equal to the cubic spline interpolation of its even-numbered samples. Since this class of functions includes many very smooth members, it follows that $H(\omega)$ does a good job of truly selecting a function's smooth information content. Sample Lemarie wavelets are shown in Figure 13.10.2.

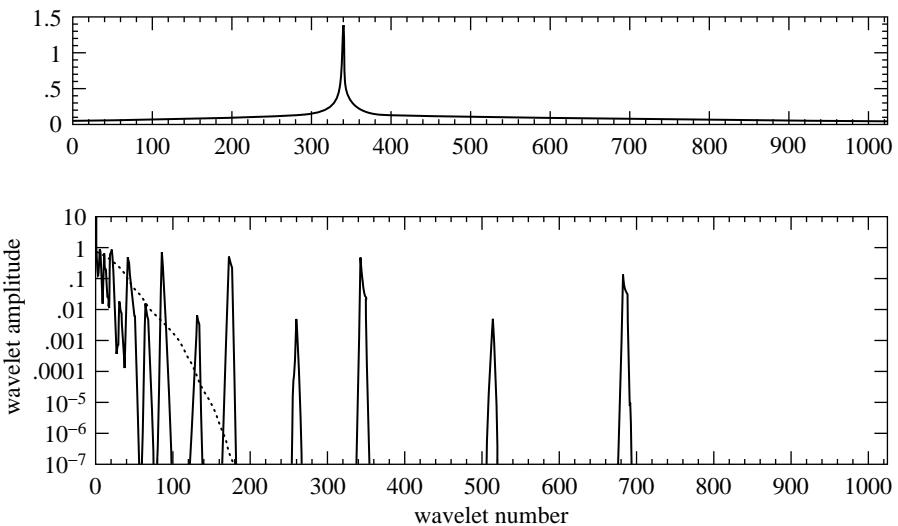

Figure 13.10.3. (a) Arbitrary test function, with cusp, sampled on a vector of length 1024. (b) Absolute value of the 1024 wavelet coefficients produced by the discrete wavelet transform of (a). Note log scale. The dotted curve plots the same amplitudes when sorted by decreasing size. One sees that only 130 out of 1024 coefficients are larger than 10^{-4} (or larger than about 10^{-5} times the largest coefficient, whose value is ~ 10).

Truncated Wavelet Approximations

Most of the usefulness of wavelets rests on the fact that wavelet transforms can usefully be severely truncated, that is, turned into sparse expansions. The case of Fourier transforms is different: FFTs are ordinarily used without truncation, to compute fast convolutions, for example. This works because the convolution operator is particularly simple in the Fourier basis. There are not, however, any standard mathematical operations that are especially simple in the wavelet basis.

To see how truncation works, consider the simple example shown in Figure 13.10.3. The upper panel shows an arbitrarily chosen test function, smooth except for a square-root cusp, sampled onto a vector of length 2^{10} . The bottom panel (solid curve) shows, on a log scale, the absolute value of the vector's components after it has been run through the DAUB4 discrete wavelet transform. One notes, from right to left, the different levels of hierarchy, 513–1024, 257–512, 129–256, etc. Within each level, the wavelet coefficients are non-negligible only very near the location of the cusp, or very near the left and right boundaries of the hierarchical range (edge effects).

The dotted curve in the lower panel of Figure 13.10.3 plots the same amplitudes as the solid curve, but sorted into decreasing order of size. One can read off, for example, that the 130th largest wavelet coefficient has an amplitude less than 10^{-5} of the largest coefficient, whose magnitude is ~ 10 (power or square integral ratio less than 10^{-10}). Thus, the example function can be represented quite accurately by only 130, rather than 1024, coefficients — the remaining ones being set to zero. Note that this kind of truncation makes the vector sparse, but not shorter than 1024. It is very important that vectors in wavelet space be truncated according to the *amplitude* of the components, not their position in the vector. Keeping the

first 256 components of the vector (all levels of the hierarchy except the last two) would give an extremely poor, and jagged, approximation to the function. When you compress a function with wavelets, you have to record both the values *and the positions* of the nonzero coefficients.

Generally, compact (and therefore unsmooth) wavelets are better for lower accuracy approximation and for functions with discontinuities (like edges), while smooth (and therefore noncompact) wavelets are better for achieving high numerical accuracy. This makes compact wavelets a good choice for image compression, for example, while it makes smooth wavelets best for fast solution of integral equations.

Wavelet Transform in Multidimensions

A wavelet transform of a d -dimensional array is most easily obtained by transforming the array sequentially on its first index (for all values of its other indices), then on its second, and so on. Each transformation corresponds to multiplication by an orthogonal matrix. By matrix associativity, the result is independent of the order in which the indices were transformed. The situation is exactly like that for multidimensional FFTs. A routine for effecting the multidimensional DWT can thus be modeled on a multidimensional FFT routine like `fourn`:

```
SUBROUTINE wtn(a,nn,ndim,isign,wtstep)
INTEGER isign,ndim,nn(ndim),NMAX
REAL a(*)
EXTERNAL wtstep
PARAMETER (NMAX=1024)
C USES wtstep
    Replaces a by its ndim-dimensional discrete wavelet transform, if isign is input as 1. nn
    is an integer array of length ndim, containing the lengths of each dimension (number of real
    values), which MUST all be powers of 2. a is a real array of length equal to the product
    of these lengths, in which the data are stored as in a multidimensional real FORTRAN array.
    If isign is input as -1, a is replaced by its inverse wavelet transform. The subroutine
    wtstep, whose actual name must be supplied in calling this routine, is the underlying
    wavelet filter. Examples of wtstep are daub4 and (preceded by pwtset) pwt.
    INTEGER i1,i2,i3,idim,k,n,nnew,npref,nt,ntot
    REAL wksp(NMAX)
    ntot=1
    do 11 idim=1,ndim
        ntot=ntot*nn(idim)
    enddo 11
    npref=1
    do 16 idim=1,ndim
        n=nn(idim)
        nnew=n*npref
        if (n.gt.4) then
            do 15 i2=0,ntot-1,nnew
                do 14 i1=1,npref
                    i3=i1+i2
                    do 12 k=1,n
                        wksp(k)=a(i3)
                        i3=i3+npref
                    enddo 12
                    if (isign.ge.0) then      Copy the relevant row or column or etc. into
                        nt=n                           workspace.
                    if (nt.ge.4) then
                        call wtstep(wksp,nt,isign)
                        nt=nt/2
                    goto 1
                    endif
                enddo 14
            enddo 15
        endif
    enddo 16
    Main loop over the dimensions.
1
    if (nt.ge.4) then
        call wtstep(wksp,nt,isign)
        nt=nt/2
        goto 1
        endif
```

```

        else                                Or inverse transform.
2
        nt=4
        if (nt.le.n) then
        call wtstep(wksp,nt,isign)
        nt=nt*2
        goto 2
        endif
        endiff
        i3=i1+i2
        do 13 k=1,n                         Copy back from workspace.
        a(i3)=wksp(k)
        i3=i3+nprev
      enddo 13
      enddo 14
    enddo 15
  endiff
  nprev=nnew
enddo 16
return
END

```

Here, as before, `wtstep` is an individual wavelet step, either `daub4` or `pwt`.

Compression of Images

An immediate application of the multidimensional transform `wt` is to image compression. The overall procedure is to take the wavelet transform of a digitized image, and then to “allocate bits” among the wavelet coefficients in some highly nonuniform, optimized, manner. In general, large wavelet coefficients get quantized accurately, while small coefficients are quantized coarsely with only a bit or two — or else are truncated completely. If the resulting quantization levels are still statistically nonuniform, they may then be further compressed by a technique like Huffman coding (§20.4).

While a more detailed description of the “back end” of this process, namely the quantization and coding of the image, is beyond our scope, it is quite straightforward to demonstrate the “front-end” wavelet encoding with a simple truncation: We keep (with full accuracy) all wavelet coefficients larger than some threshold, and we delete (set to zero) all smaller wavelet coefficients. We can then adjust the threshold to vary the fraction of preserved coefficients.

Figure 13.10.4 shows a sequence of images that differ in the number of wavelet coefficients that have been kept. The original picture (a), which is an official IEEE test image, has 256 by 256 pixels with an 8-bit grayscale. The two reproductions following are reconstructed with 23% (b) and 5.5% (c) of the 65536 wavelet coefficients. The latter image illustrates the kind of compromises made by the truncated wavelet representation. High-contrast edges (the model’s right cheek and hair highlights, e.g.) are maintained at a relatively high resolution, while low-contrast areas (the model’s left eye and cheek, e.g.) are washed out into what amounts to large constant pixels. Figure 13.10.4 (d) is the result of performing the identical procedure with Fourier, instead of wavelet, transforms: The figure is reconstructed from the 5.5% of 65536 real Fourier components having the largest magnitudes. One sees that, since sines and cosines are nonlocal, the resolution is uniformly poor across the picture; also, the deletion of any components produces a mottled “ringing” everywhere. (Practical Fourier image compression schemes therefore break up an

Figure 13.10.4. (a) IEEE test image, 256×256 pixels with 8-bit grayscale. (b) The image is transformed into the wavelet basis; 77% of its wavelet components are set to zero (those of smallest magnitude); it is then reconstructed from the remaining 23%. (c) Same as (b), but 94.5% of the wavelet components are deleted. (d) Same as (c), but the Fourier transform is used instead of the wavelet transform. Wavelet coefficients are better than the Fourier coefficients at preserving relevant details.

image into small blocks of pixels, 16×16 , say, and do rather elaborate smoothing across block boundaries when the image is reconstructed.)

Fast Solution of Linear Systems

One of the most interesting, and promising, wavelet applications is linear algebra. The basic idea [1] is to think of an integral operator (that is, a large matrix) as a digital image. Suppose that the operator compresses well under a two-dimensional wavelet transform, i.e., that a large fraction of its wavelet coefficients are so small as to be negligible. Then any linear system involving the operator becomes a sparse

system in the wavelet basis. In other words, to solve

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (13.10.16)$$

we first wavelet-transform the operator \mathbf{A} and the right-hand side \mathbf{b} by

$$\tilde{\mathbf{A}} \equiv \mathbf{W} \cdot \mathbf{A} \cdot \mathbf{W}^T, \quad \tilde{\mathbf{b}} \equiv \mathbf{W} \cdot \mathbf{b} \quad (13.10.17)$$

where \mathbf{W} represents the one-dimensional wavelet transform, then solve

$$\tilde{\mathbf{A}} \cdot \tilde{\mathbf{x}} = \tilde{\mathbf{b}} \quad (13.10.18)$$

and finally transform to the answer by the inverse wavelet transform

$$\mathbf{x} = \mathbf{W}^T \cdot \tilde{\mathbf{x}} \quad (13.10.19)$$

(Note that the routine `wtn` does the complete transformation of \mathbf{A} into $\tilde{\mathbf{A}}$.)

A typical integral operator that compresses well into wavelets has arbitrary (or even nearly singular) elements near to its main diagonal, but becomes smooth away from the diagonal. An example might be

$$A_{ij} = \begin{cases} -1 & \text{if } i = j \\ |i - j|^{-1/2} & \text{otherwise} \end{cases} \quad (13.10.20)$$

Figure 13.10.5 shows a graphical representation of the wavelet transform of this matrix, where i and j range over $1 \dots 256$, using the DAUB12 wavelets. Elements larger in magnitude than 10^{-3} times the maximum element are shown as black pixels, while elements between 10^{-3} and 10^{-6} are shown in gray. White pixels are $< 10^{-6}$. The indices i and j each number from the lower left.

In the figure, one sees the hierarchical decomposition into power-of-two sized blocks. At the edges or corners of the various blocks, one sees edge effects caused by the wrap-around wavelet boundary conditions. Apart from edge effects, within each block, the nonnegligible elements are concentrated along the block diagonals. This is a statement that, for this type of linear operator, a wavelet is coupled mainly to near neighbors in its own hierarchy (square blocks along the main diagonal) and near neighbors in other hierarchies (rectangular blocks off the diagonal).

The number of nonnegligible elements in a matrix like that in Figure 13.10.5 scales only as N , the linear size of the matrix; as a rough rule of thumb it is about $10N \log_{10}(1/\epsilon)$, where ϵ is the truncation level, e.g., 10^{-6} . For a 2000 by 2000 matrix, then, the matrix is sparse by a factor on the order of 30.

Various numerical schemes can be used to solve sparse linear systems of this “hierarchically band diagonal” form. Beylkin, Coifman, and Rokhlin [1] make the interesting observations that (1) the product of two such matrices is itself hierarchically band diagonal (truncating, of course, newly generated elements that are smaller than the predetermined threshold ϵ); and moreover that (2) the product can be formed in order N operations.

Fast matrix multiplication makes it possible to find the matrix inverse by Schultz’s (or Hotelling’s) method, see §2.5.

Figure 13.10.5. Wavelet transform of a 256×256 matrix, represented graphically. The original matrix has a discontinuous cusp along its diagonal, decaying smoothly away on both sides of the diagonal. In wavelet basis, the matrix becomes sparse: Components larger than 10^{-3} are shown as black, components larger than 10^{-6} as gray, and smaller-magnitude components are white. The matrix indices i and j number from the lower left.

Other schemes are also possible for fast solution of hierarchically band diagonal forms. For example, one can use the conjugate gradient method, implemented in §2.7 as `linbcg`.

13.11 Numerical Use of the Sampling Theorem

In §6.10 we implemented an approximating formula for Dawson's integral due to Rybicki. Now that we have become Fourier sophisticates, we can learn that the formula derives from *numerical* application of the sampling theorem (§12.1), normally considered to be a purely analytic tool. Our discussion is identical to Rybicki [1].

For present purposes, the sampling theorem is most conveniently stated as follows: Consider an arbitrary function $g(t)$ and the grid of sampling points $t_n = \alpha + nh$, where n ranges over the integers and α is a constant that allows an arbitrary shift of the sampling grid. We then write

$$g(t) = \sum_{n=-\infty}^{\infty} g(t_n) \operatorname{sinc} \frac{\pi}{h}(t - t_n) + e(t) \quad (13.11.1)$$

where $\operatorname{sinc} x \equiv \sin x/x$. The summation over the sampling points is called the *sampling representation* of $g(t)$, and $e(t)$ is its error term. The sampling theorem asserts that the sampling representation is exact, that is, $e(t) \equiv 0$, if the Fourier transform of $g(t)$,

$$G(\omega) = \int_{-\infty}^{\infty} g(t) e^{i\omega t} dt \quad (13.11.2)$$

vanishes identically for $|\omega| \geq \pi/h$.

When can sampling representations be used to advantage for the approximate numerical computation of functions? In order that the error term be small, the Fourier transform $G(\omega)$ must be sufficiently small for $|\omega| \geq \pi/h$. On the other hand, in order for the summation in (13.11.1) to be approximated by a reasonably small number of terms, the function $g(t)$ itself should be very small outside of a fairly limited range of values of t . Thus we are led to two conditions to be satisfied in order that (13.11.1) be useful numerically: Both the function $g(t)$ and its Fourier transform $G(\omega)$ must rapidly approach zero for large values of their respective arguments.

Unfortunately, these two conditions are mutually antagonistic — the Uncertainty Principle in quantum mechanics. There exist strict limits on how rapidly the simultaneous approach to zero can be in both arguments. According to a theorem of Hardy [2], if $g(t) = O(e^{-t^2})$ as $|t| \rightarrow \infty$ and $G(\omega) = O(e^{-\omega^2/4})$ as $|\omega| \rightarrow \infty$, then $g(t) \equiv Ce^{-t^2}$, where C is a constant. This can be interpreted as saying that of all functions the Gaussian is the most rapidly decaying in both t and ω , and in this sense is the “best” function to be expressed numerically as a sampling representation.

Let us then write for the Gaussian $g(t) = e^{-t^2}$,

$$e^{-t^2} = \sum_{n=-\infty}^{\infty} e^{-t_n^2} \operatorname{sinc} \frac{\pi}{h}(t - t_n) + e(t) \quad (13.11.3)$$

The error $e(t)$ depends on the parameters h and α as well as on t , but it is sufficient for the present purposes to state the bound,

$$|e(t)| < e^{-(\pi/2h)^2} \quad (13.11.4)$$

which can be understood simply as the order of magnitude of the Fourier transform of the Gaussian at the point where it “spills over” into the region $|\omega| > \pi/h$.

When the summation in (13.11.3) is approximated by one with finite limits, say from $N_0 - N$ to $N_0 + N$, where N_0 is the integer nearest to $-\alpha/h$, there is a further truncation error. However, if N is chosen so that $N > \pi/(2h^2)$, the truncation error in the summation is less than the bound given by (13.11.4), and, since this bound is an overestimate, we shall continue to use it for (13.11.3) as well. The truncated summation gives a remarkably accurate representation for the Gaussian even for moderate values of N . For example, $|e(t)| < 5 \times 10^{-5}$ for $h = 1/2$ and $N = 7$; $|e(t)| < 2 \times 10^{-10}$ for $h = 1/3$ and $N = 15$; and $|e(t)| < 7 \times 10^{-18}$ for $h = 1/4$ and $N = 25$.

13.11 Numerical Use of the Sampling Theorem

In §6.10 we implemented an approximating formula for Dawson's integral due to Rybicki. Now that we have become Fourier sophisticates, we can learn that the formula derives from *numerical* application of the sampling theorem (§12.1), normally considered to be a purely analytic tool. Our discussion is identical to Rybicki [1].

For present purposes, the sampling theorem is most conveniently stated as follows: Consider an arbitrary function $g(t)$ and the grid of sampling points $t_n = \alpha + nh$, where n ranges over the integers and α is a constant that allows an arbitrary shift of the sampling grid. We then write

$$g(t) = \sum_{n=-\infty}^{\infty} g(t_n) \operatorname{sinc} \frac{\pi}{h}(t - t_n) + e(t) \quad (13.11.1)$$

where $\operatorname{sinc} x \equiv \sin x/x$. The summation over the sampling points is called the *sampling representation* of $g(t)$, and $e(t)$ is its error term. The sampling theorem asserts that the sampling representation is exact, that is, $e(t) \equiv 0$, if the Fourier transform of $g(t)$,

$$G(\omega) = \int_{-\infty}^{\infty} g(t) e^{i\omega t} dt \quad (13.11.2)$$

vanishes identically for $|\omega| \geq \pi/h$.

When can sampling representations be used to advantage for the approximate numerical computation of functions? In order that the error term be small, the Fourier transform $G(\omega)$ must be sufficiently small for $|\omega| \geq \pi/h$. On the other hand, in order for the summation in (13.11.1) to be approximated by a reasonably small number of terms, the function $g(t)$ itself should be very small outside of a fairly limited range of values of t . Thus we are led to two conditions to be satisfied in order that (13.11.1) be useful numerically: Both the function $g(t)$ and its Fourier transform $G(\omega)$ must rapidly approach zero for large values of their respective arguments.

Unfortunately, these two conditions are mutually antagonistic — the Uncertainty Principle in quantum mechanics. There exist strict limits on how rapidly the simultaneous approach to zero can be in both arguments. According to a theorem of Hardy [2], if $g(t) = O(e^{-t^2})$ as $|t| \rightarrow \infty$ and $G(\omega) = O(e^{-\omega^2/4})$ as $|\omega| \rightarrow \infty$, then $g(t) \equiv Ce^{-t^2}$, where C is a constant. This can be interpreted as saying that of all functions the Gaussian is the most rapidly decaying in both t and ω , and in this sense is the “best” function to be expressed numerically as a sampling representation.

Let us then write for the Gaussian $g(t) = e^{-t^2}$,

$$e^{-t^2} = \sum_{n=-\infty}^{\infty} e^{-t_n^2} \operatorname{sinc} \frac{\pi}{h}(t - t_n) + e(t) \quad (13.11.3)$$

The error $e(t)$ depends on the parameters h and α as well as on t , but it is sufficient for the present purposes to state the bound,

$$|e(t)| < e^{-(\pi/2h)^2} \quad (13.11.4)$$

which can be understood simply as the order of magnitude of the Fourier transform of the Gaussian at the point where it “spills over” into the region $|\omega| > \pi/h$.

When the summation in (13.11.3) is approximated by one with finite limits, say from $N_0 - N$ to $N_0 + N$, where N_0 is the integer nearest to $-\alpha/h$, there is a further truncation error. However, if N is chosen so that $N > \pi/(2h^2)$, the truncation error in the summation is less than the bound given by (13.11.4), and, since this bound is an overestimate, we shall continue to use it for (13.11.3) as well. The truncated summation gives a remarkably accurate representation for the Gaussian even for moderate values of N . For example, $|e(t)| < 5 \times 10^{-5}$ for $h = 1/2$ and $N = 7$; $|e(t)| < 2 \times 10^{-10}$ for $h = 1/3$ and $N = 15$; and $|e(t)| < 7 \times 10^{-18}$ for $h = 1/4$ and $N = 25$.

One may ask, what is the point of such a numerical representation for the Gaussian, which can be computed so easily and quickly as an exponential? The answer is that many transcendental functions can be expressed as an integral involving the Gaussian, and by substituting (13.11.3) one can often find excellent approximations to the integrals as a sum over elementary functions.

Let us consider as an example the function $w(z)$ of the complex variable $z = x + iy$, related to the complex error function by

$$w(z) = e^{-z^2} \operatorname{erfc}(-iz) \quad (13.11.5)$$

having the integral representation

$$w(z) = \frac{1}{\pi i} \int_C \frac{e^{-t^2}}{t - z} dt \quad (13.11.6)$$

where the contour C extends from $-\infty$ to ∞ , passing below z (see, e.g., [3]). Many methods exist for the evaluation of this function (e.g., [4]). Substituting the sampling representation (13.11.3) into (13.11.6) and performing the resulting elementary contour integrals, we obtain

$$w(z) \approx \frac{1}{\pi i} \sum_{n=-\infty}^{\infty} h e^{-t_n^2} \frac{1 - (-1)^n e^{-\pi i(\alpha-z)/h}}{t_n - z} \quad (13.11.7)$$

where we now omit the error term. One should note that there is no singularity as $z \rightarrow t_m$ for some $n = m$, but a special treatment of the m th term will be required in this case (for example, by power series expansion).

An alternative form of equation (13.11.7) can be found by expressing the complex exponential in (13.11.7) in terms of trigonometric functions and using the sampling representation (13.11.3) with z replacing t . This yields

$$w(z) \approx e^{-z^2} + \frac{1}{\pi i} \sum_{n=-\infty}^{\infty} h e^{-t_n^2} \frac{1 - (-1)^n \cos \pi(\alpha - z)/h}{t_n - z} \quad (13.11.8)$$

This form is particularly useful in obtaining $\operatorname{Re} w(z)$ when $|y| \ll 1$. Note that in evaluating (13.11.7) the exponential inside the summation is a constant and needs to be evaluated only once; a similar comment holds for the cosine in (13.11.8).

There are a variety of formulas that can now be derived from either equation (13.11.7) or (13.11.8) by choosing particular values of α . Eight interesting choices are: $\alpha = 0, x, iy$, or z , plus the values obtained by adding $h/2$ to each of these. Since the error bound (13.11.3) assumed a real value of α , the choices involving a complex α are useful only if the imaginary part of z is not too large. This is not the place to catalog all sixteen possible formulas, and we give only two particular cases that show some of the important features.

First of all let $\alpha = 0$ in equation (13.11.8), which yields,

$$w(z) \approx e^{-z^2} + \frac{1}{\pi i} \sum_{n=-\infty}^{\infty} h e^{-(nh)^2} \frac{1 - (-1)^n \cos(\pi z/h)}{nh - z} \quad (13.11.9)$$

This approximation is good over the entire z -plane. As stated previously, one has to treat the case where one denominator becomes small by expansion in a power series. Formulas for the case $\alpha = 0$ were discussed briefly in [5]. They are similar, but not identical, to formulas derived by Chiarella and Reichel [6], using the method of Goodwin [7].

Next, let $\alpha = z$ in (13.11.7), which yields

$$w(z) \approx e^{-z^2} - \frac{2}{\pi i} \sum_{n \text{ odd}} \frac{e^{-(z-nh)^2}}{n} \quad (13.11.10)$$

the sum being over all odd integers (positive and negative). Note that we have made the substitution $n \rightarrow -n$ in the summation. This formula is simpler than (13.11.9) and contains half the number of terms, but its error is worse if y is large. Equation (13.11.10) is the source of the approximation formula (6.10.3) for Dawson's integral, used in §6.10.

Chapter 14. Statistical Description of Data

14.0 Introduction

In this chapter and the next, the concept of *data* enters the discussion more prominently than before.

Data consist of numbers, of course. But these numbers are fed into the computer, not produced by it. These are numbers to be treated with considerable respect, neither to be tampered with, nor subjected to a numerical process whose character you do not completely understand. You are well advised to acquire a reverence for data that is rather different from the “sporty” attitude that is sometimes allowable, or even commendable, in other numerical tasks.

The analysis of data inevitably involves some trafficking with the field of *statistics*, that gray area which is not quite a branch of mathematics — and just as surely not quite a branch of science. In the following sections, you will repeatedly encounter the following paradigm:

- apply some formula to the data to compute “a statistic”
- compute where the value of that statistic falls in a probability distribution that is computed on the basis of some “null hypothesis”
- if it falls in a very unlikely spot, way out on a tail of the distribution, conclude that the null hypothesis is *false* for your data set

If a statistic falls in a *reasonable* part of the distribution, you must not make the mistake of concluding that the null hypothesis is “verified” or “proved.” That is the curse of statistics, that it can never prove things, only disprove them! At best, you can substantiate a hypothesis by ruling out, statistically, a whole long list of competing hypotheses, every one that has ever been proposed. After a while your adversaries and competitors will give up trying to think of alternative hypotheses, or else they will grow old and die, and *then your hypothesis will become accepted*. Sounds crazy, we know, but that’s how science works!

In this book we make a somewhat arbitrary distinction between data analysis procedures that are *model-independent* and those that are *model-dependent*. In the former category, we include so-called *descriptive statistics* that characterize a data set in general terms: its mean, variance, and so on. We also include statistical tests that seek to establish the “sameness” or “differentness” of two or more data sets, or that seek to establish and measure a degree of *correlation* between two data sets. These subjects are discussed in this chapter.

In the other category, model-dependent statistics, we lump the whole subject of fitting data to a theory, parameter estimation, least-squares fits, and so on. Those subjects are introduced in Chapter 15.

Section 14.1 deals with so-called *measures of central tendency*, the moments of a distribution, the median and mode. In §14.2 we learn to test whether different data sets are drawn from distributions with different values of these measures of central tendency. This leads naturally, in §14.3, to the more general question of whether two distributions can be shown to be (significantly) different.

In §14.4–§14.7, we deal with *measures of association* for two distributions. We want to determine whether two variables are “correlated” or “dependent” on one another. If they are, we want to characterize the degree of correlation in some simple ways. The distinction between parametric and nonparametric (rank) methods is emphasized.

Section 14.8 introduces the concept of data smoothing, and discusses the particular case of Savitzky-Golay smoothing filters.

This chapter draws mathematically on the material on special functions that was presented in Chapter 6, especially §6.1–§6.4. You may wish, at this point, to review those sections.

14.1 Moments of a Distribution: Mean, Variance, Skewness, and So Forth

When a set of values has a sufficiently strong central tendency, that is, a tendency to cluster around some particular value, then it may be useful to characterize the set by a few numbers that are related to its *moments*, the sums of integer powers of the values.

Best known is the *mean* of the values x_1, \dots, x_N ,

$$\bar{x} = \frac{1}{N} \sum_{j=1}^N x_j \quad (14.1.1)$$

which estimates the value around which central clustering occurs. Note the use of an overbar to denote the mean; angle brackets are an equally common notation, e.g., $\langle x \rangle$. You should be aware that the mean is not the only available estimator of this

14.1 Moments of a Distribution: Mean, Variance, Skewness, and So Forth

When a set of values has a sufficiently strong central tendency, that is, a tendency to cluster around some particular value, then it may be useful to characterize the set by a few numbers that are related to its *moments*, the sums of integer powers of the values.

Best known is the *mean* of the values x_1, \dots, x_N ,

$$\bar{x} = \frac{1}{N} \sum_{j=1}^N x_j \quad (14.1.1)$$

which estimates the value around which central clustering occurs. Note the use of an overbar to denote the mean; angle brackets are an equally common notation, e.g., $\langle x \rangle$. You should be aware that the mean is not the only available estimator of this

quantity, nor is it necessarily the best one. For values drawn from a probability distribution with very broad “tails,” the mean may converge poorly, or not at all, as the number of sampled points is increased. Alternative estimators, the *median* and the *mode*, are mentioned at the end of this section.

Having characterized a distribution’s central value, one conventionally next characterizes its “width” or “variability” around that value. Here again, more than one measure is available. Most common is the *variance*,

$$\text{Var}(x_1 \dots x_N) = \frac{1}{N-1} \sum_{j=1}^N (x_j - \bar{x})^2 \quad (14.1.2)$$

or its square root, the *standard deviation*,

$$\sigma(x_1 \dots x_N) = \sqrt{\text{Var}(x_1 \dots x_N)} \quad (14.1.3)$$

Equation (14.1.2) estimates the mean squared deviation of x from its mean value. There is a long story about why the denominator of (14.1.2) is $N - 1$ instead of N . If you have never heard that story, you may consult any good statistics text. Here we will be content to note that the $N - 1$ *should* be changed to N if you are ever in the situation of measuring the variance of a distribution whose mean \bar{x} is known *a priori* rather than being estimated from the data. (We might also comment that if the difference between N and $N - 1$ ever matters to you, then you are probably up to no good anyway — e.g., trying to substantiate a questionable hypothesis with marginal data.)

As the mean depends on the first moment of the data, so do the variance and standard deviation depend on the second moment. It is not uncommon, in real life, to be dealing with a distribution whose second moment does not exist (i.e., is infinite). In this case, the variance or standard deviation is useless as a measure of the data’s width around its central value: The values obtained from equations (14.1.2) or (14.1.3) will not converge with increased numbers of points, nor show any consistency from data set to data set drawn from the same distribution. This can occur even when the width of the peak looks, by eye, perfectly finite. A more robust estimator of the width is the *average deviation* or *mean absolute deviation*, defined by

$$\text{ADev}(x_1 \dots x_N) = \frac{1}{N} \sum_{j=1}^N |x_j - \bar{x}| \quad (14.1.4)$$

One often substitutes the sample median x_{med} for \bar{x} in equation (14.1.4). For any fixed sample, the median in fact minimizes the mean absolute deviation.

Statisticians have historically sniffed at the use of (14.1.4) instead of (14.1.2), since the absolute value brackets in (14.1.4) are “nonanalytic” and make theorem-proving difficult. In recent years, however, the fashion has changed, and the subject of *robust estimation* (meaning, estimation for broad distributions with significant numbers of “outlier” points) has become a popular and important one. Higher moments, or statistics involving higher powers of the input data, are almost always less robust than lower moments or statistics that involve only linear sums or (the lowest moment of all) counting.

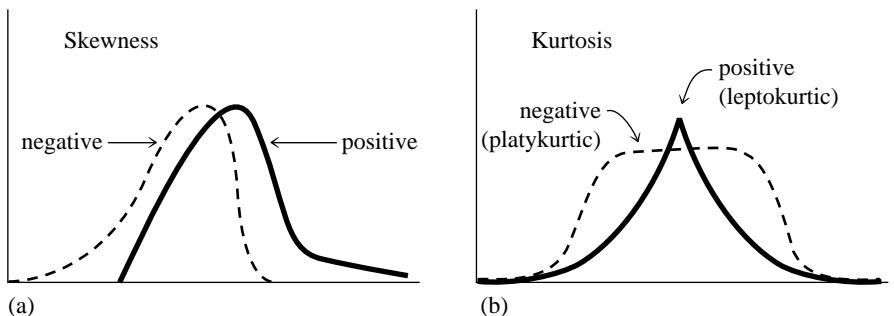

Figure 14.1.1. Distributions whose third and fourth moments are significantly different from a normal (Gaussian) distribution. (a) Skewness or third moment. (b) Kurtosis or fourth moment.

That being the case, the *skewness* or *third moment*, and the *kurtosis* or *fourth moment* should be used with caution or, better yet, not at all.

The skewness characterizes the degree of asymmetry of a distribution around its mean. While the mean, standard deviation, and average deviation are *dimensional* quantities, that is, have the same units as the measured quantities x_j , the skewness is conventionally defined in such a way as to make it *nondimensional*. It is a pure number that characterizes only the shape of the distribution. The usual definition is

$$\text{Skew}(x_1 \dots x_N) = \frac{1}{N} \sum_{j=1}^N \left[\frac{x_j - \bar{x}}{\sigma} \right]^3 \quad (14.1.5)$$

where $\sigma = \sigma(x_1 \dots x_N)$ is the distribution's standard deviation (14.1.3). A positive value of skewness signifies a distribution with an asymmetric tail extending out towards more positive x ; a negative value signifies a distribution whose tail extends out towards more negative x (see Figure 14.1.1).

Of course, any set of N measured values is likely to give a nonzero value for (14.1.5), even if the underlying distribution is in fact symmetrical (has zero skewness). For (14.1.5) to be meaningful, we need to have some idea of *its* standard deviation as an estimator of the skewness of the underlying distribution. Unfortunately, that depends on the shape of the underlying distribution, and rather critically on its tails! For the idealized case of a normal (Gaussian) distribution, the standard deviation of (14.1.5) is approximately $\sqrt{15/N}$ when \bar{x} is the true mean, and $\sqrt{6/N}$ when it is estimated by the sample mean, (14.1.1). In real life it is good practice to believe in skewnesses only when they are several or many times as large as this.

The kurtosis is also a nondimensional quantity. It measures the relative peakedness or flatness of a distribution. Relative to what? A normal distribution, what else! A distribution with positive kurtosis is termed *leptokurtic*; the outline of the Matterhorn is an example. A distribution with negative kurtosis is termed *platykurtic*; the outline of a loaf of bread is an example. (See Figure 14.1.1.) And, as you no doubt expect, an in-between distribution is termed *mesokurtic*.

The conventional definition of the kurtosis is

$$\text{Kurt}(x_1 \dots x_N) = \left\{ \frac{1}{N} \sum_{j=1}^N \left[\frac{x_j - \bar{x}}{\sigma} \right]^4 \right\} - 3 \quad (14.1.6)$$

where the -3 term makes the value zero for a normal distribution.

The standard deviation of (14.1.6) as an estimator of the kurtosis of an underlying normal distribution is $\sqrt{96/N}$ when σ is the true standard deviation, and $\sqrt{24/N}$ when it is the sample estimate (14.1.3). However, the kurtosis depends on such a high moment that there are many real-life distributions for which the standard deviation of (14.1.6) as an estimator is effectively infinite.

Calculation of the quantities defined in this section is perfectly straightforward. Many textbooks use the binomial theorem to expand out the definitions into sums of various powers of the data, e.g., the familiar

$$\text{Var}(x_1 \dots x_N) = \frac{1}{N-1} \left[\left(\sum_{j=1}^N x_j^2 \right) - N\bar{x}^2 \right] \approx \bar{x}^2 - \bar{x}^2 \quad (14.1.7)$$

but this can magnify the roundoff error by a large factor and is generally unjustifiable in terms of computing speed. A clever way to minimize roundoff error, especially for large samples, is to use the *corrected two-pass algorithm* [1]: First calculate \bar{x} , then calculate $\text{Var}(x_1 \dots x_N)$ by

$$\text{Var}(x_1 \dots x_N) = \frac{1}{N-1} \left\{ \sum_{j=1}^N (x_j - \bar{x})^2 - \frac{1}{N} \left[\sum_{j=1}^N (x_j - \bar{x}) \right]^2 \right\} \quad (14.1.8)$$

The second sum would be zero if \bar{x} were exact, but otherwise it does a good job of correcting the roundoff error in the first term.

Semi-Invariants

The mean and variance of independent random variables are additive: If x and y are drawn independently from two, possibly different, probability distributions, then

$$\overline{(x+y)} = \overline{x} + \overline{y} \quad \text{Var}(x+y) = \text{Var}(x) + \text{Var}(y) \quad (14.1.9)$$

Higher moments are not, in general, additive. However, certain combinations of them, called *semi-invariants*, are in fact additive. If the centered moments of a distribution are denoted M_k ,

$$M_k \equiv \left\langle (x_i - \bar{x})^k \right\rangle \quad (14.1.10)$$

so that, e.g., $M_2 = \text{Var}(x)$, then the first few semi-invariants, denoted I_k are given by

$$\begin{aligned} I_2 &= M_2 & I_3 &= M_3 & I_4 &= M_4 - 3M_2^2 \\ I_5 &= M_5 - 10M_2M_3 & I_6 &= M_6 - 15M_2M_4 - 10M_3^2 + 30M_2^3 \end{aligned} \quad (14.1.11)$$

Notice that the skewness and kurtosis, equations (14.1.5) and (14.1.6) are simple powers of the semi-invariants,

$$\text{Skew}(x) = I_3/I_2^{3/2} \quad \text{Kurt}(x) = I_4/I_2^2 \quad (14.1.12)$$

A Gaussian distribution has all its semi-invariants higher than I_2 equal to zero. A Poisson distribution has all of its semi-invariants equal to its mean. For more details, see [2].

Median and Mode

The median of a probability distribution function $p(x)$ is the value x_{med} for which larger and smaller values of x are equally probable:

$$\int_{-\infty}^{x_{\text{med}}} p(x) dx = \frac{1}{2} = \int_{x_{\text{med}}}^{\infty} p(x) dx \quad (14.1.13)$$

The median of a distribution is estimated from a sample of values x_1, \dots, x_N by finding that value x_i which has equal numbers of values above it and below it. Of course, this is not possible when N is even. In that case it is conventional to estimate the median as the mean of the unique *two* central values. If the values x_j $j = 1, \dots, N$ are sorted into ascending (or, for that matter, descending) order, then the formula for the median is

$$x_{\text{med}} = \begin{cases} x_{(N+1)/2}, & N \text{ odd} \\ \frac{1}{2}(x_{N/2} + x_{(N/2)+1}), & N \text{ even} \end{cases} \quad (14.1.14)$$

If a distribution has a strong central tendency, so that most of its area is under a single peak, then the median is an estimator of the central value. It is a more robust estimator than the mean is: The median fails as an estimator only if the area in the tails is large, while the mean fails if the first moment of the tails is large; it is easy to construct examples where the first moment of the tails is large even though their area is negligible.

To find the median of a set of values, one can proceed by sorting the set and then applying (14.1.14). This is a process of order $N \log N$. You might rightly think that this is wasteful, since it yields much more information than just the median (e.g., the upper and lower quartile points, the deciles, etc.). In fact, we saw in §8.5 that the element $x_{(N+1)/2}$ can be located in of order N operations. Consult that section for routines.

The *mode* of a probability distribution function $p(x)$ is the value of x where it takes on a maximum value. The mode is useful primarily when there is a single, sharp maximum, in which case it estimates the central value. Occasionally, a distribution will be *bimodal*, with two relative maxima; then one may wish to know the two modes individually. Note that, in such cases, the mean and median are not very useful, since they will give only a “compromise” value between the two peaks.

14.2 Do Two Distributions Have the Same Means or Variances?

Not uncommonly we want to know whether two distributions have the same mean. For example, a first set of measured values may have been gathered before some event, a second set after it. We want to know whether the event, a “treatment” or a “change in a control parameter,” made a difference.

Our first thought is to ask “how many standard deviations” one sample mean is from the other. That number may in fact be a useful thing to know. It does relate to the strength or “importance” of a difference of means *if that difference is genuine*. However, by itself, it says nothing about whether the difference *is* genuine, that is, statistically significant. A difference of means can be very small compared to the standard deviation, and yet very significant, if the number of data points is large. Conversely, a difference may be moderately large but not significant, if the data

14.2 Do Two Distributions Have the Same Means or Variances?

Not uncommonly we want to know whether two distributions have the same mean. For example, a first set of measured values may have been gathered before some event, a second set after it. We want to know whether the event, a “treatment” or a “change in a control parameter,” made a difference.

Our first thought is to ask “how many standard deviations” one sample mean is from the other. That number may in fact be a useful thing to know. It does relate to the strength or “importance” of a difference of means *if that difference is genuine*. However, by itself, it says nothing about whether the difference *is* genuine, that is, statistically significant. A difference of means can be very small compared to the standard deviation, and yet very significant, if the number of data points is large. Conversely, a difference may be moderately large but not significant, if the data

are sparse. We will be meeting these distinct concepts of *strength* and *significance* several times in the next few sections.

A quantity that measures the significance of a difference of means is not the number of standard deviations that they are apart, but the number of so-called *standard errors* that they are apart. The standard error of a set of values measures the accuracy with which the sample mean estimates the population (or “true”) mean. Typically the standard error is equal to the sample’s standard deviation divided by the square root of the number of points in the sample.

Student’s t-test for Significantly Different Means

Applying the concept of standard error, the conventional statistic for measuring the significance of a difference of means is termed *Student’s t*. When the two distributions are thought to have the same variance, but possibly different means, then Student’s *t* is computed as follows: First, estimate the standard error of the difference of the means, s_D , from the “pooled variance” by the formula

$$s_D = \sqrt{\frac{\sum_{i \in A} (x_i - \bar{x}_A)^2 + \sum_{i \in B} (x_i - \bar{x}_B)^2}{N_A + N_B - 2}} \left(\frac{1}{N_A} + \frac{1}{N_B} \right) \quad (14.2.1)$$

where each sum is over the points in one sample, the first or second, each mean likewise refers to one sample or the other, and N_A and N_B are the numbers of points in the first and second samples, respectively. Second, compute *t* by

$$t = \frac{\bar{x}_A - \bar{x}_B}{s_D} \quad (14.2.2)$$

Third, evaluate the significance of this value of *t* for Student’s distribution with $N_A + N_B - 2$ degrees of freedom, by equations (6.4.7) and (6.4.9), and by the routine *betai* (incomplete beta function) of §6.4.

The significance is a number between zero and one, and is the probability that $|t|$ could be this large or larger just by chance, for distributions with equal means. Therefore, a small numerical value of the significance (0.05 or 0.01) means that the observed difference is “very significant.” The function $A(t|\nu)$ in equation (6.4.7) is one minus the significance.

As a routine, we have

```
SUBROUTINE ttest(data1,n1,data2,n2,t,prob)
INTEGER n1,n2
REAL prob,t,data1(n1),data2(n2)
C USES avevar,betai
Given the arrays data1(1:n1) and data2(1:n2), this routine returns Student's t as t,
and its significance as prob, small values of prob indicating that the arrays have significantly
different means. The data arrays are assumed to be drawn from populations with the same
true variance.
REAL ave1,ave2,df,var,var1,var2,betai
call avevar(data1,n1,ave1,var1)
call avevar(data2,n2,ave2,var2)
df=n1+n2-2                                Degrees of freedom.
var=((n1-1)*var1+(n2-1)*var2)/df          Pooled variance.
t=(ave1-ave2)/sqrt(var*(1./n1+1./n2))      See equation (6.4.9).
prob=betai(0.5*df,0.5,df/(df+t**2))
return
END
```

which makes use of the following routine for computing the mean and variance of a set of numbers,

```
SUBROUTINE avevar(data,n,ave,var)
INTEGER n
REAL ave,var,data(n)
    Given array data(1:n), returns its mean as ave and its variance as var.
INTEGER j
REAL s,ep
ave=0.0
do 11 j=1,n
    ave=ave+data(j)
11   enddo
ave=ave/n
var=0.0
ep=0.0
do 12 j=1,n
    s=data(j)-ave
    ep=ep+s
    var=var+s*s
12   enddo
var=(var-ep**2/n)/(n-1)           Corrected two-pass formula (14.1.8).
return
END
```

The next case to consider is where the two distributions have significantly different variances, but we nevertheless want to know if their means are the same or different. (A treatment for baldness has caused some patients to *lose* all their hair and turned others into werewolves, but we want to know if it helps cure baldness *on the average!*) Be suspicious of the unequal-variance *t*-test: If two distributions have very different variances, then they may also be substantially different in shape; in that case, the difference of the means may not be a particularly useful thing to know.

To find out whether the two data sets have variances that are significantly different, you use the *F-test*, described later on in this section.

The relevant statistic for the unequal variance *t*-test is

$$t = \frac{\overline{x}_A - \overline{x}_B}{[\text{Var}(x_A)/N_A + \text{Var}(x_B)/N_B]^{1/2}} \quad (14.2.3)$$

This statistic is distributed *approximately* as Student's *t* with a number of degrees of freedom equal to

$$\frac{\left[\frac{\text{Var}(x_A)}{N_A} + \frac{\text{Var}(x_B)}{N_B} \right]^2}{\frac{[\text{Var}(x_A)/N_A]^2}{N_A - 1} + \frac{[\text{Var}(x_B)/N_B]^2}{N_B - 1}} \quad (14.2.4)$$

Expression (14.2.4) is in general not an integer, but equation (6.4.7) doesn't care.

The routine is

```
SUBROUTINE tatest(data1,n1,data2,n2,t,prob)
INTEGER n1,n2
REAL prob,t,data1(n1),data2(n2)
C USES avevar,betai
    Given the arrays data1(1:n1) and data2(1:n2), this routine returns Student's t as t,
    and its significance as prob, small values of prob indicating that the arrays have significantly
```

different means. The data arrays are allowed to be drawn from populations with unequal variances.

```
REAL ave1,ave2,df,var1,var2,betai
call avevar(data1,n1,ave1,var1)
call avevar(data2,n2,ave2,var2)
t=(ave1-ave2)/sqrt(var1/n1+var2/n2)
df=(var1/n1+var2/n2)**2/((var1/n1)**2/(n1-1)+(var2/n2)**2/(n2-1))
prob=betai(0.5*df,0.5,df/(df+t**2))
return
END
```

Our final example of a Student's t test is the case of *paired samples*. Here we imagine that much of the variance in *both* samples is due to effects that are point-by-point identical in the two samples. For example, we might have two job candidates who have each been rated by the same ten members of a hiring committee. We want to know if the means of the ten scores differ significantly. We first try `ttest` above, and obtain a value of `prob` that is not especially significant (e.g., > 0.05). But perhaps the significance is being washed out by the tendency of some committee members always to give high scores, others always to give low scores, which increases the apparent variance and thus decreases the significance of any difference in the means. We thus try the paired-sample formulas,

$$\text{Cov}(x_A, x_B) \equiv \frac{1}{N-1} \sum_{i=1}^N (x_{Ai} - \bar{x}_A)(x_{Bi} - \bar{x}_B) \quad (14.2.5)$$

$$s_D = \left[\frac{\text{Var}(x_A) + \text{Var}(x_B) - 2\text{Cov}(x_A, x_B)}{N} \right]^{1/2} \quad (14.2.6)$$

$$t = \frac{\bar{x}_A - \bar{x}_B}{s_D} \quad (14.2.7)$$

where N is the number in each sample (number of pairs). Notice that it is important that a particular value of i label the corresponding points in each sample, that is, the ones that are paired. The significance of the t statistic in (14.2.7) is evaluated for $N - 1$ degrees of freedom.

The routine is

```
SUBROUTINE tptest(data1,data2,n,t,prob)
INTEGER n
REAL prob,t,data1(n),data2(n)
C USES avevar,betai
Given the paired arrays data1(1:n) and data2(1:n), this routine returns Student's t for
paired data as t, and its significance as prob, small values of prob indicating a significant
difference of means.
INTEGER j
REAL ave1,ave2,cov,df,sd,var1,var2,betai
call avevar(data1,n,ave1,var1)
call avevar(data2,n,ave2,var2)
cov=0.
do :: j=1,n
    cov=cov+(data1(j)-ave1)*(data2(j)-ave2)
enddo :: j
df=n-1
cov=cov/df
sd=sqrt((var1+var2-2.*cov)/n)
t=(ave1-ave2)/sd
```

```

prob=betai(0.5*df,0.5,df/(df+t**2))
return
END

```

F-Test for Significantly Different Variances

The *F-test* tests the hypothesis that two samples have different variances by trying to reject the null hypothesis that their variances are actually consistent. The statistic F is the ratio of one variance to the other, so values either $\gg 1$ or $\ll 1$ will indicate very significant differences. The distribution of F in the null case is given in equation (6.4.11), which is evaluated using the routine `betai`. In the most common case, we are willing to disprove the null hypothesis (of equal variances) by either very large or very small values of F , so the correct significance is *two-tailed*, the sum of two incomplete beta functions. It turns out, by equation (6.4.3), that the two tails are always equal; we need compute only one, and double it. Occasionally, when the null hypothesis is strongly viable, the identity of the two tails can become confused, giving an indicated probability greater than one. Changing the probability to two minus itself correctly exchanges the tails. These considerations and equation (6.4.3) give the routine

```

SUBROUTINE ftest(data1,n1,data2,n2,f,prob)
INTEGER n1,n2
REAL f,prob,data1(n1),data2(n2)
C USES avevar,betai
      Given the arrays data1(1:n1) and data2(1:n2), this routine returns the value of f, and
      its significance as prob. Small values of prob indicate that the two arrays have significantly
      different variances.
REAL ave1,ave2,df1,df2,var1,var2,betai
call avevar(data1,n1,ave1,var1)
call avevar(data2,n2,ave2,var2)
if(var1.gt.var2)then      Make F the ratio of the larger variance to the smaller one.
  f=var1/var2
  df1=n1-1
  df2=n2-1
else
  f=var2/var1
  df1=n2-1
  df2=n1-1
endif
prob=2.*betai(0.5*df2,0.5*df1,df2/(df2+df1*f))
if(prob.gt.1.)prob=2.-prob
return
END

```

14.3 Are Two Distributions Different?

Given two sets of data, we can generalize the questions asked in the previous section and ask the single question: Are the two sets drawn from the same distribution function, or from different distribution functions? Equivalently, in proper statistical language, “Can we disprove, to a certain required level of significance, the null hypothesis that two data sets are drawn from the same population distribution function?” Disproving the null hypothesis in effect proves that the data sets are from different distributions. Failing to disprove the null hypothesis, on the other hand, only shows that the data sets can be *consistent* with a single distribution function. One can never *prove* that two data sets come from a single distribution, since (e.g.) no practical amount of data can distinguish between two distributions which differ only by one part in 10^{10} .

Proving that two distributions are different, or showing that they are consistent, is a task that comes up all the time in many areas of research: Are the visible stars distributed uniformly in the sky? (That is, is the distribution of stars as a function of declination — position in the sky — the same as the distribution of sky area as a function of declination?) Are educational patterns the same in Brooklyn as in the Bronx? (That is, are the distributions of people as a function of last-grade-attended the same?) Do two brands of fluorescent lights have the same distribution of burn-out times? Is the incidence of chicken pox the same for first-born, second-born, third-born children, etc.?

These four examples illustrate the four combinations arising from two different dichotomies: (1) The data are either continuous or binned. (2) Either we wish to compare one data set to a known distribution, or we wish to compare two equally unknown data sets. The data sets on fluorescent lights and on stars are continuous, since we can be given lists of individual burnout times or of stellar positions. The data sets on chicken pox and educational level are binned, since we are given tables of numbers of events in discrete categories: first-born, second-born, etc.; or 6th Grade, 7th Grade, etc. Stars and chicken pox, on the other hand, share the property that the null hypothesis is a known distribution (distribution of area in the sky, or incidence of chicken pox in the general population). Fluorescent lights and educational level involve the comparison of two equally unknown data sets (the two brands, or Brooklyn and the Bronx).

One can always turn continuous data into binned data, by grouping the events into specified ranges of the continuous variable(s): declinations between 0 and 10 degrees, 10 and 20, 20 and 30, etc. Binning involves a loss of information, however. Also, there is often considerable arbitrariness as to how the bins should be chosen. Along with many other investigators, we prefer to avoid unnecessary binning of data.

The accepted test for differences between binned distributions is the *chi-square test*. For continuous data as a function of a single variable, the most generally accepted test is the *Kolmogorov-Smirnov test*. We consider each in turn.

Chi-Square Test

Suppose that N_i is the number of events observed in the i th bin, and that n_i is the number expected according to some known distribution. Note that the N_i 's are

14.3 Are Two Distributions Different?

Given two sets of data, we can generalize the questions asked in the previous section and ask the single question: Are the two sets drawn from the same distribution function, or from different distribution functions? Equivalently, in proper statistical language, “Can we disprove, to a certain required level of significance, the null hypothesis that two data sets are drawn from the same population distribution function?” Disproving the null hypothesis in effect proves that the data sets are from different distributions. One can always turn continuous data into binned data, by grouping the events into specified ranges of the continuous variable(s): declinations between 0 and 10 degrees, 10 and 20, 20 and 30, etc. Binning involves a loss of information, however. Also, there is often considerable arbitrariness as to how the bins should be chosen. Along with many other investigators, we prefer to avoid unnecessary binning of data.

The accepted test for differences between binned distributions is the *chi-square test*. For continuous data as a function of a single variable, the most generally accepted test is the *Kolmogorov-Smirnov test*. We consider each in turn.

Chi-Square Test

Suppose that N_i is the number of events observed in the i th bin, and that n_i is the number expected according to some known distribution. Note that the N_i 's are

integers, while the n_i 's may not be. Then the chi-square statistic is

$$\chi^2 = \sum_i \frac{(N_i - n_i)^2}{n_i} \quad (14.3.1)$$

where the sum is over all bins. A large value of χ^2 indicates that the null hypothesis (that the N_i 's are drawn from the population represented by the n_i 's) is rather unlikely.

Any term j in (14.3.1) with $0 = n_j = N_j$ should be omitted from the sum. A term with $n_j = 0$, $N_j \neq 0$ gives an infinite χ^2 , as it should, since in this case the N_i 's cannot possibly be drawn from the n_i 's!

The *chi-square probability function* $Q(\chi^2|\nu)$ is an incomplete gamma function, and was already discussed in §6.2 (see equation 6.2.18). Strictly speaking $Q(\chi^2|\nu)$ is the probability that the sum of the squares of ν random *normal* variables of unit variance (and zero mean) will be greater than χ^2 . The terms in the sum (14.3.1) are not individually normal. However, if either the number of bins is large ($\gg 1$), or the number of events in each bin is large ($\gg 1$), then the chi-square probability function is a good approximation to the distribution of (14.3.1) in the case of the null hypothesis. Its use to estimate the significance of the chi-square test is standard.

The appropriate value of ν , the number of degrees of freedom, bears some additional discussion. If the data are collected with the model n_i 's fixed — that is, not later renormalized to fit the total observed number of events $\sum N_i$ — then ν equals the number of bins N_B . (Note that this is *not* the total number of *events*!) Much more commonly, the n_i 's are normalized after the fact so that their sum equals the sum of the N_i 's. In this case the correct value for ν is $N_B - 1$, and the model is said to have one constraint (`knstrn=1` in the program below). If the model that gives the n_i 's has additional free parameters that were adjusted after the fact to agree with the data, then each of these additional “fitted” parameters decreases ν (and increases `knstrn`) by one additional unit.

We have, then, the following program:

```
SUBROUTINE chsone(bins,ebins,nbins,knstrn,df,chsq,prob)
INTEGER knstrn,nbins
REAL chsq,df,prob,bins(nbins),ebins(nbins)
C USES gammq
Given the array bins(1:nbins) containing the observed numbers of events, and an array ebins(1:nbins) containing the expected numbers of events, and given the number of constraints knstrn (normally one), this routine returns (trivially) the number of degrees of freedom df, and (nontrivially) the chi-square chsq and the significance prob. A small value of prob indicates a significant difference between the distributions bins and ebins. Note that bins and ebins are both real arrays, although bins will normally contain integer values.
INTEGER j
REAL gammq
df=nbins-knstrn
chsq=0.
do 11 j=1,nbins
  if(ebins(j).le.0.)pause 'bad expected number in chsone'
  chsq=chsq+(bins(j)-ebins(j))*2/ebins(j)
11  continue
prob=gammq(0.5*df,0.5*chsq)           Chi-square probability function. See §6.2.
return
END
```

Next we consider the case of comparing *two* binned data sets. Let R_i be the number of events in bin i for the first data set, S_i the number of events in the same bin i for the second data set. Then the chi-square statistic is

$$\chi^2 = \sum_i \frac{(R_i - S_i)^2}{R_i + S_i} \quad (14.3.2)$$

Comparing (14.3.2) to (14.3.1), you should note that the denominator of (14.3.2) is *not* just the average of R_i and S_i (which would be an estimator of n_i in 14.3.1). Rather, it is twice the average, the sum. The reason is that each term in a chi-square sum is supposed to approximate the square of a normally distributed quantity with unit variance. The variance of the difference of two normal quantities is the sum of their individual variances, not the average.

If the data were collected in such a way that the sum of the R_i 's is necessarily equal to the sum of S_i 's, then the number of degrees of freedom is equal to one less than the number of bins, $N_B - 1$ (that is, $\text{knstrn} = 1$), the usual case. If this requirement were absent, then the number of degrees of freedom would be N_B . Example: A birdwatcher wants to know whether the distribution of sighted birds as a function of species is the same this year as last. Each bin corresponds to one species. If the birdwatcher takes his data to be the first 1000 birds that he saw in each year, then the number of degrees of freedom is $N_B - 1$. If he takes his data to be all the birds he saw on a random sample of days, the same days in each year, then the number of degrees of freedom is N_B ($\text{knstrn} = 0$). In this latter case, note that he is also testing whether the birds were more numerous overall in one year or the other: That is the extra degree of freedom. Of course, any additional constraints on the data set lower the number of degrees of freedom (i.e., increase knstrn to *more positive* values) in accordance with their number.

The program is

```

SUBROUTINE chstwo(bins1,bins2,nbins,knstrn,df,chsq,prob)
INTEGER knstrn,nbins
REAL chsq,df,prob,bins1(nbins),bins2(nbins)
C USES gammq
      Given the arrays bins1(1:nbins) and bins2(1:nbins), containing two sets of binned
      data, and given the number of constraints knstrn (normally 1 or 0), this routine returns
      the number of degrees of freedom df, the chi-square chsq, and the significance prob.
      A small value of prob indicates a significant difference between the distributions bins1
      and bins2. Note that bins1 and bins2 are both real arrays, although they will normally
      contain integer values.
      INTEGER j
      REAL gammq
      df=nbins-knstrn
      chsq=0.
      do 11 j=1,nbins
         if(bins1(j).eq.0..and.bins2(j).eq.0.)then
            df=df-1.          No data means one less degree of freedom.
         else
            chsq=chsq+(bins1(j)-bins2(j))**2/(bins1(j)+bins2(j))
         endif
      enddo 11
      prob=gammq(0.5*df,0.5*chsq)           Chi-square probability function. See §6.2.
      return
END

```

Equation (14.3.2) and the routine `chstwo` both apply to the case where the total number of data points is the same in the two binned sets. For unequal numbers of data points, the formula analogous to (14.3.2) is

$$\chi^2 = \sum_i \frac{(\sqrt{S/RR_i} - \sqrt{R/SS_i})^2}{R_i + S_i} \quad (14.3.3)$$

where

$$R \equiv \sum_i R_i \quad S \equiv \sum_i S_i \quad (14.3.4)$$

are the respective numbers of data points. It is straightforward to make the corresponding change in `chstwo`.

Kolmogorov-Smirnov Test

The Kolmogorov-Smirnov (or *K-S*) test is applicable to unbinned distributions that are functions of a single independent variable, that is, to data sets where each data point can be associated with a single number (lifetime of each lightbulb when it burns out, or declination of each star). In such cases, the list of data points can be easily converted to an unbiased estimator $S_N(x)$ of the *cumulative* distribution function of the probability distribution from which it was drawn: If the N events are located at values x_i , $i = 1, \dots, N$, then $S_N(x)$ is the function giving the fraction of data points to the left of a given value x . This function is obviously constant between consecutive (i.e., sorted into ascending order) x_i 's, and jumps by the same constant $1/N$ at each x_i . (See Figure 14.3.1.)

Different distribution functions, or sets of data, give different cumulative distribution function estimates by the above procedure. However, all cumulative distribution functions agree at the smallest allowable value of x (where they are zero), and at the largest allowable value of x (where they are unity). (The smallest and largest values might of course be $\pm\infty$.) So it is the behavior between the largest and smallest values that distinguishes distributions.

One can think of any number of statistics to measure the overall difference between two cumulative distribution functions: the absolute value of the area between them, for example. Or their integrated mean square difference. The Kolmogorov-Smirnov D is a particularly simple measure: It is defined as the *maximum value* of the absolute difference between two cumulative distribution functions. Thus, for comparing one data set's $S_N(x)$ to a known cumulative distribution function $P(x)$, the K-S statistic is

$$D = \max_{-\infty < x < \infty} |S_N(x) - P(x)| \quad (14.3.5)$$

while for comparing two different cumulative distribution functions $S_{N_1}(x)$ and $S_{N_2}(x)$, the K-S statistic is

$$D = \max_{-\infty < x < \infty} |S_{N_1}(x) - S_{N_2}(x)| \quad (14.3.6)$$

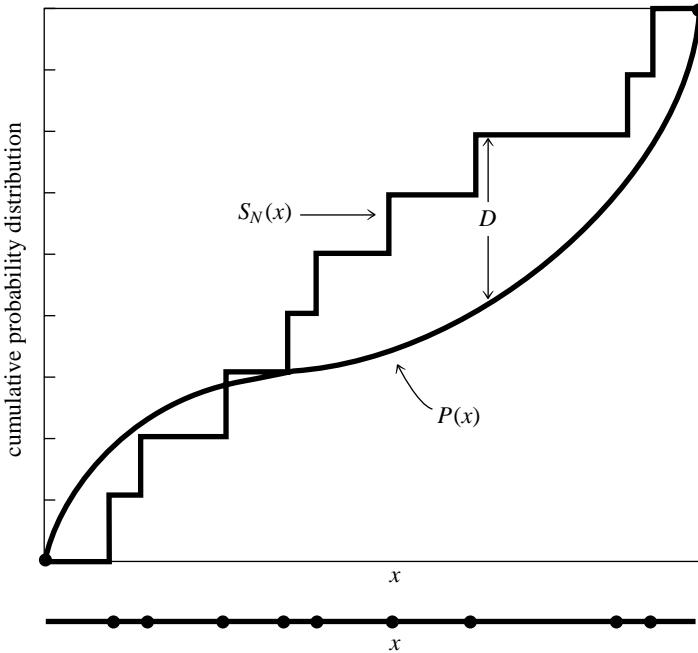

Figure 14.3.1. Kolmogorov-Smirnov statistic D . A measured distribution of values in x (shown as N dots on the lower abscissa) is to be compared with a theoretical distribution whose cumulative probability distribution is plotted as $P(x)$. A step-function cumulative probability distribution $S_N(x)$ is constructed, one that rises an equal amount at each measured point. D is the greatest distance between the two cumulative distributions.

What makes the K-S statistic useful is that *its* distribution in the case of the null hypothesis (data sets drawn from the same distribution) can be calculated, at least to useful approximation, thus giving the significance of any observed nonzero value of D . A central feature of the K-S test is that it is invariant under reparametrization of x ; in other words, you can locally slide or stretch the x axis in Figure 14.3.1, and the maximum distance D remains unchanged. For example, you will get the same significance using x as using $\log x$.

The function that enters into the calculation of the significance can be written as the following sum:

$$Q_{KS}(\lambda) = 2 \sum_{j=1}^{\infty} (-1)^{j-1} e^{-2j^2\lambda^2} \quad (14.3.7)$$

which is a monotonic function with the limiting values

$$Q_{KS}(0) = 1 \quad Q_{KS}(\infty) = 0 \quad (14.3.8)$$

In terms of this function, the significance level of an observed value of D (as a disproof of the null hypothesis that the distributions are the same) is given approximately [1] by the formula

$$\text{Probability } (D > \text{observed}) = Q_{KS}\left(\left[\sqrt{N_e} + 0.12 + 0.11/\sqrt{N_e}\right] D\right) \quad (14.3.9)$$

where N_e is the effective number of data points, $N_e = N$ for the case (14.3.5) of one distribution, and

$$N_e = \frac{N_1 N_2}{N_1 + N_2} \quad (14.3.10)$$

for the case (14.3.6) of two distributions, where N_1 is the number of data points in the first distribution, N_2 the number in the second.

The nature of the approximation involved in (14.3.9) is that it becomes asymptotically accurate as the N_e becomes large, but is already quite good for $N_e \geq 4$, as small a number as one might ever actually use. (See [1].)

So, we have the following routines for the cases of one and two distributions:

```

SUBROUTINE ksone(data,n,func,d,prob)
INTEGER n
REAL d,data(n),func,prob
EXTERNAL func
C USES probks,sort
   Given an array data(1:n), and given a user-supplied function of a single variable func
   which is a cumulative distribution function ranging from 0 (for smallest values of its argument)
   to 1 (for largest values of its argument), this routine returns the K-S statistic d, and
   the significance level prob. Small values of prob show that the cumulative distribution
   function of data is significantly different from func. The array data is modified by being
   sorted into ascending order.
   INTEGER j
REAL dt,en,ff,fn,fo,probks
call sort(n,data)      If the data are already sorted into ascending order, then this call can be omitted.
en=n
d=0.
fo=0.
do 11 j=1,n          Data's c.d.f. before the next step.
   fn=j/en             Loop over the sorted data points.
   ff=func(data(j))    Data's c.d.f. after this step.
   dt=max(abs(fo-ff),abs(fn-ff))  Compare to the user-supplied function.
   if(dt.gt.d)d=dt      Maximum distance.
   fo=fn
11 enddo 11
en=sqrt(en)
prob=probks((en+0.12+0.11/en)*d)  Compute significance.
return
END

```

```

SUBROUTINE kstwo(data1,n1,data2,n2,d,prob)
INTEGER n1,n2
REAL d,prob,data1(n1),data2(n2)
C USES probks,sort
      Given an array data1(1:n1), and an array data2(1:n2), this routine returns the K-
      S statistic d, and the significance level prob for the null hypothesis that the data sets
      are drawn from the same distribution. Small values of prob show that the cumulative
      distribution function of data1 is significantly different from that of data2. The arrays
      data1 and data2 are modified by being sorted into ascending order.
      INTEGER j1,j2
      REAL d1,d2,dt,en1,en2,en,fn1,fn2,probks
      call sort(n1,data1)
      call sort(n2,data2)
      en1=n1
      en2=n2
      j1=1                               Next value of data1 to be processed.
      j2=1                               Ditto, data2.

```

```

fn1=0.
fn2=0.
d=0.
1 if(j1.le.n1.and.j2.le.n2)then           If we are not done...
    d1=data1(j1)
    d2=data2(j2)
    if(d1.le.d2)then                      Next step is in data1.
        fn1=j1/en1
        j1=j1+1
    endif
    if(d2.le.d1)then                      Next step is in data2.
        fn2=j2/en2
        j2=j2+1
    endif
    dt=abs(fn2-fn1)
    if(dt.gt.d)d=dt
goto 1
endif
en=sqrt(en1*en2/(en1+en2))
prob=probks((en+0.12+0.11/en)*d)      Compute significance.
return
END

```

Both of the above routines use the following routine for calculating the function Q_{KS} :

```

FUNCTION probks(alam)
REAL probks,alam,EPS1,EPS2
PARAMETER (EPS1=0.001, EPS2=1.e-8)
    Kolmogorov-Smirnov probability function.
INTEGER j
REAL a2,fac,term,termbf
a2=-2.*alam**2
fac=2.
probks=0.
termbf=0.                         Previous term in sum.
do !! j=1,100
    term=fac*exp(a2*j**2)
    probks=probks+term
    if(abs(term).le.EPS1*termbf.or.abs(term).le.EPS2*probks)return
    fac=-fac                         Alternating signs in sum.
    termbf=abs(term)
endo !!
probks=1.                           Get here only by failing to converge.
return
END

```

Variants on the K-S Test

The sensitivity of the K-S test to deviations from a cumulative distribution function $P(x)$ is not independent of x . In fact, the K-S test tends to be most sensitive around the median value, where $P(x) = 0.5$, and less sensitive at the extreme ends of the distribution, where $P(x)$ is near 0 or 1. The reason is that the difference $|S_N(x) - P(x)|$ does not, in the null hypothesis, have a probability distribution that is independent of x . Rather, its variance is proportional to $P(x)[1 - P(x)]$, which is largest at $P = 0.5$. Since the K-S statistic (14.3.5) is the maximum difference over all x of two cumulative distribution functions, a deviation that might be statistically significant at *its own* value of x gets compared to the expected chance deviation at $P = 0.5$, and is thus discounted. A result is that, while the K-S test is good at

finding *shifts* in a probability distribution, especially changes in the median value, it is not always so good at finding *spreads*, which more affect the tails of the probability distribution, and which may leave the median unchanged.

One way of increasing the power of the K-S statistic out on the tails is to replace D (equation 14.3.5) by a so-called *stabilized* or *weighted* statistic [2-4], for example the *Anderson-Darling statistic*,

$$D^* = \max_{-\infty < x < \infty} \frac{|S_N(x) - P(x)|}{\sqrt{P(x)[1 - P(x)]}} \quad (14.3.11)$$

Unfortunately, there is no simple formula analogous to equations (14.3.7) and (14.3.9) for this statistic, although Noé [5] gives a computational method using a recursion relation and provides a graph of numerical results. There are many other possible similar statistics, for example

$$D^{**} = \int_{P=0}^1 \frac{|S_N(x) - P(x)|^2}{P(x)[1 - P(x)]} dP(x) \quad (14.3.12)$$

which is also discussed by Anderson and Darling (see [3]).

Another approach, which we prefer as simpler and more direct, is due to Kuiper [6,7]. We already mentioned that the standard K-S test is invariant under reparametrizations of the variable x . An even more general symmetry, which guarantees equal sensitivities at all values of x , is to wrap the x axis around into a circle (identifying the points at $\pm\infty$), and to look for a statistic that is now invariant under all shifts and parametrizations on the circle. This allows, for example, a probability distribution to be “cut” at some central value of x , and the left and right halves to be interchanged, without altering the statistic or its significance.

Kuiper’s statistic, defined as

$$V = D_+ + D_- = \max_{-\infty < x < \infty} [S_N(x) - P(x)] + \max_{-\infty < x < \infty} [P(x) - S_N(x)] \quad (14.3.13)$$

is the sum of the maximum distance of $S_N(x)$ above and below $P(x)$. You should be able to convince yourself that this statistic has the desired invariance on the circle: Sketch the indefinite integral of two probability distributions defined on the circle as a function of angle around the circle, as the angle goes through several times 360° . If you change the starting point of the integration, D_+ and D_- change individually, but their sum is constant.

Furthermore, there is a simple formula for the asymptotic distribution of the statistic V , directly analogous to equations (14.3.7)–(14.3.10). Let

$$Q_{KP}(\lambda) = 2 \sum_{j=1}^{\infty} (4j^2\lambda^2 - 1)e^{-2j^2\lambda^2} \quad (14.3.14)$$

which is monotonic and satisfies

$$Q_{KP}(0) = 1 \quad Q_{KP}(\infty) = 0 \quad (14.3.15)$$

In terms of this function the significance level is [1]

$$\text{Probability } (V > \text{observed}) = Q_{KP} \left(\left[\sqrt{N_e} + 0.155 + 0.24/\sqrt{N_e} \right] V \right) \quad (14.3.16)$$

Here N_e is N in the one-sample case, or is given by equation (14.3.10) in the case of two samples.

Of course, Kuiper’s test is ideal for any problem originally defined on a circle, for example, to test whether the distribution in longitude of something agrees with some theory, or whether two somethings have different distributions in longitude. (See also [8].)

We will leave to you the coding of routines analogous to `ksone`, `kstwo`, and `probks`, above. (For $\lambda < 0.4$, don’t try to do the sum 14.3.14. Its value is 1, to 7 figures, but the series can require many terms to converge, and loses accuracy to roundoff.)

Two final cautionary notes: First, we should mention that all varieties of K-S test lack the ability to discriminate some kinds of distributions. A simple example is a probability distribution with a narrow “notch” within which the probability falls to zero. Such a distribution is of course ruled out by the existence of even one data point within the notch,

but, because of its cumulative nature, a K–S test would require many data points in the notch before signaling a discrepancy.

Second, we should note that, if you estimate any parameters from a data set (e.g., a mean and variance), then the distribution of the K–S statistic D for a cumulative distribution function $P(x)$ that *uses the estimated parameters* is no longer given by equation (14.3.9). In general, you will have to determine the new distribution yourself, e.g., by Monte Carlo methods.

14.4 Contingency Table Analysis of Two Distributions

In this section, and the next two sections, we deal with *measures of association* for two distributions. The situation is this: Each data point has two or more different quantities associated with it, and we want to know whether knowledge of one quantity gives us any demonstrable advantage in predicting the value of another quantity. In many cases, one variable will be an “independent” or “control” variable, and another will be a “dependent” or “measured” variable. Then, we want to know if the latter variable *is* in fact dependent on or *associated* with the former variable. If it is, we want to have some quantitative measure of the strength of the association. One often hears this loosely stated as the question of whether two variables are *correlated* or *uncorrelated*, but we will reserve those terms for a particular kind of association (linear, or at least monotonic), as discussed in §14.5 and §14.6.

Notice that, as in previous sections, the different concepts of significance and strength appear: The association between two distributions may be very significant even if that association is weak — if the quantity of data is large enough.

It is useful to distinguish among some different kinds of variables, with different categories forming a loose hierarchy.

- A variable is called *nominal* if its values are the members of some unordered set. For example, “state of residence” is a nominal variable that (in the U.S.) takes on one of 50 values; in astrophysics, “type of galaxy” is a nominal variable with the three values “spiral,” “elliptical,” and “irregular.”

but, because of its cumulative nature, a K–S test would require many data points in the notch before signaling a discrepancy.

Second, we should note that, if you estimate any parameters from a data set (e.g., a mean and variance), then the distribution of the K–S statistic D for a cumulative distribution function $P(x)$ that *uses the estimated parameters* is no longer given by equation (14.3.9). In general, you will have to determine the new distribution yourself, e.g., by Monte Carlo methods.

14.4 Contingency Table Analysis of Two Distributions

In this section, and the next two sections, we deal with *measures of association* for two distributions. The situation is this: Each data point has two or more different quantities associated with it, and we want to know whether knowledge of one quantity gives us any demonstrable advantage in predicting the value of another quantity. In many cases, one variable will be an “independent” or “control” variable, and another will be a “dependent” or “measured” variable. Then, we want to know if the latter variable *is* in fact dependent on or *associated* with the former variable. If it is, we want to have some quantitative measure of the strength of the association. One often hears this loosely stated as the question of whether two variables are *correlated* or *uncorrelated*, but we will reserve those terms for a particular kind of association (linear, or at least monotonic), as discussed in §14.5 and §14.6.

Notice that, as in previous sections, the different concepts of significance and strength appear: The association between two distributions may be very significant even if that association is weak — if the quantity of data is large enough.

It is useful to distinguish among some different kinds of variables, with different categories forming a loose hierarchy.

- A variable is called *nominal* if its values are the members of some unordered set. For example, “state of residence” is a nominal variable that (in the U.S.) takes on one of 50 values; in astrophysics, “type of galaxy” is a nominal variable with the three values “spiral,” “elliptical,” and “irregular.”

- A variable is termed *ordinal* if its values are the members of a discrete, but ordered, set. Examples are: grade in school, planetary order from the Sun (Mercury = 1, Venus = 2, . . .), number of offspring. There need not be any concept of “equal metric distance” between the values of an ordinal variable, only that they be intrinsically ordered.
- We will call a variable *continuous* if its values are real numbers, as are times, distances, temperatures, etc. (Social scientists sometimes distinguish between *interval* and *ratio* continuous variables, but we do not find that distinction very compelling.)

A continuous variable can always be made into an ordinal one by binning it into ranges. If we choose to ignore the ordering of the bins, then we can turn it into a nominal variable. Nominal variables constitute the lowest type of the hierarchy, and therefore the most general. For example, a set of *several* continuous or ordinal variables can be turned, if crudely, into a single nominal variable, by coarsely binning each variable and then taking each distinct combination of bin assignments as a single nominal value. When multidimensional data are sparse, this is often the only sensible way to proceed.

The remainder of this section will deal with measures of association between *nominal* variables. For any pair of nominal variables, the data can be displayed as a *contingency table*, a table whose rows are labeled by the values of one nominal variable, whose columns are labeled by the values of the other nominal variable, and whose entries are nonnegative integers giving the number of observed events for each combination of row and column (see Figure 14.4.1). The analysis of association between nominal variables is thus called *contingency table analysis* or *crosstabulation analysis*.

We will introduce two different approaches. The first approach, based on the chi-square statistic, does a good job of characterizing the significance of association, but is only so-so as a measure of the strength (principally because its numerical values have no very direct interpretations). The second approach, based on the information-theoretic concept of *entropy*, says nothing at all about the significance of association (use chi-square for that!), but is capable of very elegantly characterizing the strength of an association already known to be significant.

Measures of Association Based on Chi-Square

Some notation first: Let N_{ij} denote the number of events that occur with the first variable x taking on its i th value, and the second variable y taking on its j th value. Let N denote the total number of events, the sum of all the N_{ij} 's. Let $N_{i\cdot}$ denote the number of events for which the first variable x takes on its i th value regardless of the value of y ; $N_{\cdot j}$ is the number of events with the j th value of y regardless of x . So we have

$$\begin{aligned} N_{i\cdot} &= \sum_j N_{ij} & N_{\cdot j} &= \sum_i N_{ij} \\ N &= \sum_i N_{i\cdot} = \sum_j N_{\cdot j} \end{aligned} \tag{14.4.1}$$

	1. red	2. green	...	
1. male	# of red males N_{11}	# of green males N_{12}	...	# of males N_1
2. female	# of red females N_{21}	# of green females N_{22}	...	# of females N_2
:	:	:	...	:
	# of red $N_{\cdot 1}$	# of green $N_{\cdot 2}$...	total # N

Figure 14.4.1. Example of a contingency table for two nominal variables, here sex and color. The row and column marginals (totals) are shown. The variables are “nominal,” i.e., the order in which their values are listed is arbitrary and does not affect the result of the contingency table analysis. If the ordering of values has some intrinsic meaning, then the variables are “ordinal” or “continuous,” and correlation techniques (§14.5–§14.6) can be utilized.

$N_{\cdot j}$ and $N_{i \cdot}$ are sometimes called the *row and column totals* or *marginals*, but we will use these terms cautiously since we can never keep straight which are the rows and which are the columns!

The null hypothesis is that the two variables x and y have no association. In this case, the probability of a particular value of x given a particular value of y should be the same as the probability of that value of x regardless of y . Therefore, in the null hypothesis, the expected number for any N_{ij} , which we will denote n_{ij} , can be calculated from only the row and column totals,

$$\frac{n_{ij}}{N_{\cdot j}} = \frac{N_{i \cdot}}{N} \quad \text{which implies} \quad n_{ij} = \frac{N_{i \cdot} N_{\cdot j}}{N} \quad (14.4.2)$$

Notice that if a column or row total is zero, then the expected number for all the entries in that column or row is also zero; in that case, the never-occurring bin of x or y should simply be removed from the analysis.

The chi-square statistic is now given by equation (14.3.1), which, in the present case, is summed over all entries in the table,

$$\chi^2 = \sum_{i,j} \frac{(N_{ij} - n_{ij})^2}{n_{ij}} \quad (14.4.3)$$

The number of degrees of freedom is equal to the number of entries in the table (product of its row size and column size) minus the number of constraints that have arisen from our use of the data themselves to determine the n_{ij} . Each row total and column total is a constraint, except that this overcounts by one, since the total of the

column totals and the total of the row totals both equal N , the total number of data points. Therefore, if the table is of size I by J , the number of degrees of freedom is $IJ - I - J + 1$. Equation (14.4.3), along with the chi-square probability function (§6.2), now give the significance of an association between the variables x and y .

Suppose there is a significant association. How do we quantify its strength, so that (e.g.) we can compare the strength of one association with another? The idea here is to find some reparametrization of χ^2 which maps it into some convenient interval, like 0 to 1, where the result is not dependent on the quantity of data that we happen to sample, but rather depends only on the underlying population from which the data were drawn. There are several different ways of doing this. Two of the more common are called *Cramer's V* and the *contingency coefficient C*.

The formula for Cramer's V is

$$V = \sqrt{\frac{\chi^2}{N \min(I-1, J-1)}} \quad (14.4.4)$$

where I and J are again the numbers of rows and columns, and N is the total number of events. Cramer's V has the pleasant property that it lies between zero and one inclusive, equals zero when there is no association, and equals one only when the association is perfect: All the events in any row lie in one unique column, and vice versa. (In chess parlance, no two rooks, placed on a nonzero table entry, can capture each other.)

In the case of $I = J = 2$, Cramer's V is also referred to as the *phi* statistic.

The contingency coefficient C is defined as

$$C = \sqrt{\frac{\chi^2}{\chi^2 + N}} \quad (14.4.5)$$

It also lies between zero and one, but (as is apparent from the formula) it can never achieve the upper limit. While it can be used to compare the strength of association of two tables with the same I and J , its upper limit depends on I and J . Therefore it can never be used to compare tables of different sizes.

The trouble with both Cramer's V and the contingency coefficient C is that, when they take on values in between their extremes, there is no very direct interpretation of what that value means. For example, you are in Las Vegas, and a friend tells you that there is a small, but significant, association between the color of a croupier's eyes and the occurrence of red and black on his roulette wheel. Cramer's V is about 0.028, your friend tells you. You know what the usual odds against you are (because of the green zero and double zero on the wheel). Is this association sufficient for you to make money? Don't ask us!

```
SUBROUTINE cntab1(nn,ni,nj,chisq,df,prob,cramrv,ccc)
INTEGER ni,nj,nn(ni,nj),MAXI,MAXJ
REAL ccc,chisq,cramrv,df,prob,TINY
PARAMETER (MAXI=100,MAXJ=100,TINY=1.e-30)      Maximum table size, and a small number.
C USES gammq
Given a two-dimensional contingency table in the form of an integer array nn(1:ni,1:nj),
this routine returns the chi-square chisq, the number of degrees of freedom df, the significance level prob (small values indicating a significant association), and two measures of association, Cramer's V (cramrv) and the contingency coefficient C (ccc).

Will be total number of events.
Number of rows
and columns.
Get the row totals.

Eliminate any zero rows by reducing the
number.
Get the column totals.

Eliminate any zero columns.

Corrected number of degrees of freedom.

Do the chi-square sum.

Chi-square probability function.

Measures of Association Based on Entropy

Consider the game of “twenty questions,” where by repeated yes/no questions you try to eliminate all except one correct possibility for an unknown object. Better yet, consider a generalization of the game, where you are allowed to ask multiple choice questions as well as binary (yes/no) ones. The categories in your multiple choice questions are supposed to be mutually exclusive and exhaustive (as are “yes” and “no”).

The value to you of an answer increases with the number of possibilities that it eliminates. More specifically, an answer that eliminates all except a fraction p of the remaining possibilities can be assigned a value $-\ln p$ (a positive number, since $p < 1$). The purpose of the logarithm is to make the value additive, since (e.g.) one question that eliminates all but 1/6 of the possibilities is considered as good as two questions that, in sequence, reduce the number by factors 1/2 and 1/3.

So that is the value of an answer; but what is the value of a question? If there are I possible answers to the question ($i = 1, \dots, I$) and the fraction of possibilities consistent with the i th answer is p_i (with the sum of the p_i 's equal to one), then the value of the question is the expectation value of the value of the answer, denoted H ,

$$H = - \sum_{i=1}^I p_i \ln p_i \quad (14.4.6)$$

In evaluating (14.4.6), note that

$$\lim_{p \rightarrow 0} p \ln p = 0 \quad (14.4.7)$$

The value H lies between 0 and $\ln I$. It is zero only when one of the p_i 's is one, all the others zero: In this case, the question is valueless, since its answer is preordained. H takes on its maximum value when all the p_i 's are equal, in which case the question is sure to eliminate all but a fraction $1/I$ of the remaining possibilities.

The value H is conventionally termed the *entropy* of the distribution given by the p_i 's, a terminology borrowed from statistical physics.

So far we have said nothing about the association of two variables; but suppose we are deciding what question to ask next in the game and have to choose between two candidates, or possibly want to ask both in one order or another. Suppose that one question, x , has I possible answers, labeled by i , and that the other question, y , has J possible answers, labeled by j . Then the possible outcomes of asking both questions form a contingency table whose entries N_{ij} , when normalized by dividing by the total number of remaining possibilities N , give all the information about the p 's. In particular, we can make contact with the notation (14.4.1) by identifying

$$\begin{aligned} p_{ij} &= \frac{N_{ij}}{N} \\ p_{i\cdot} &= \frac{N_{i\cdot}}{N} \quad (\text{outcomes of question } x \text{ alone}) \\ p_{\cdot j} &= \frac{N_{\cdot j}}{N} \quad (\text{outcomes of question } y \text{ alone}) \end{aligned} \quad (14.4.8)$$

The entropies of the questions x and y are, respectively,

$$H(x) = - \sum_i p_{i\cdot} \ln p_{i\cdot} \quad H(y) = - \sum_j p_{\cdot j} \ln p_{\cdot j} \quad (14.4.9)$$

The entropy of the two questions together is

$$H(x, y) = - \sum_{i,j} p_{ij} \ln p_{ij} \quad (14.4.10)$$

Now what is the entropy of the question y *given* x (that is, if x is asked first)? It is the expectation value over the answers to x of the entropy of the restricted y distribution that lies in a single column of the contingency table (corresponding to the x answer):

$$H(y|x) = - \sum_i p_{i\cdot} \sum_j \frac{p_{ij}}{p_{i\cdot}} \ln \frac{p_{ij}}{p_{i\cdot}} = - \sum_{i,j} p_{ij} \ln \frac{p_{ij}}{p_{i\cdot}} \quad (14.4.11)$$

Correspondingly, the entropy of x given y is

$$H(x|y) = - \sum_j p_{\cdot j} \sum_i \frac{p_{ij}}{p_{\cdot j}} \ln \frac{p_{ij}}{p_{\cdot j}} = - \sum_{i,j} p_{ij} \ln \frac{p_{ij}}{p_{\cdot j}} \quad (14.4.12)$$

We can readily prove that the entropy of y given x is never more than the entropy of y alone, i.e., that asking x first can only reduce the usefulness of asking y (in which case the two variables are *associated!*):

$$\begin{aligned}
 H(y|x) - H(y) &= - \sum_{i,j} p_{ij} \ln \frac{p_{ij}/p_i}{p_j} \\
 &= \sum_{i,j} p_{ij} \ln \frac{p_j p_i}{p_{ij}} \\
 &\leq \sum_{i,j} p_{ij} \left(\frac{p_j p_i}{p_{ij}} - 1 \right) \\
 &= \sum_{i,j} p_i p_j - \sum_{i,j} p_{ij} \\
 &= 1 - 1 = 0
 \end{aligned} \tag{14.4.13}$$

where the inequality follows from the fact

$$\ln w \leq w - 1 \tag{14.4.14}$$

We now have everything we need to define a measure of the “dependency” of y on x , that is to say a measure of association. This measure is sometimes called the *uncertainty coefficient* of y . We will denote it as $U(y|x)$,

$$U(y|x) \equiv \frac{H(y) - H(y|x)}{H(y)} \tag{14.4.15}$$

This measure lies between zero and one, with the value 0 indicating that x and y have no association, the value 1 indicating that knowledge of x completely predicts y . For in-between values, $U(y|x)$ gives the fraction of y ’s entropy $H(y)$ that is lost if x is already known (i.e., that is redundant with the information in x). In our game of “twenty questions,” $U(y|x)$ is the fractional loss in the utility of question y if question x is to be asked first.

If we wish to view x as the dependent variable, y as the independent one, then interchanging x and y we can of course define the dependency of x on y ,

$$U(x|y) \equiv \frac{H(x) - H(x|y)}{H(x)} \tag{14.4.16}$$

If we want to treat x and y symmetrically, then the useful combination turns out to be

$$U(x,y) \equiv 2 \left[\frac{H(y) + H(x) - H(x,y)}{H(x) + H(y)} \right] \tag{14.4.17}$$

If the two variables are completely independent, then $H(x,y) = H(x) + H(y)$, so (14.4.17) vanishes. If the two variables are completely dependent, then $H(x) = H(y) = H(x,y)$, so (14.4.16) equals unity. In fact, you can use the identities (easily proved from equations 14.4.9–14.4.12)

$$H(x,y) = H(x) + H(y|x) = H(y) + H(x|y) \tag{14.4.18}$$

to show that

$$U(x, y) = \frac{H(x)U(x|y) + H(y)U(y|x)}{H(x) + H(y)} \quad (14.4.19)$$

i.e., that the symmetrical measure is just a weighted average of the two asymmetrical measures (14.4.15) and (14.4.16), weighted by the entropy of each variable separately.

Here is a program for computing all the quantities discussed, $H(x)$, $H(y)$, $H(x|y)$, $H(y|x)$, $H(x, y)$, $U(x|y)$, $U(y|x)$, and $U(x, y)$:

```
SUBROUTINE cntab2(nn,ni,nj,h,hx,hy,hygx,hxgy,uygx,uxgy,uxy)
INTEGER ni,nj,nn(ni,nj),MAXI,MAXJ
REAL h,hx,hxgy,hy,hygx,uxgy,uxy,uygx,TINY
PARAMETER (MAXI=100,MAXJ=100,TINY=1.e-30)
Given a two-dimensional contingency table in the form of an integer array nn(i,j), where
i labels the x variable and ranges from 1 to ni, j labels the y variable and ranges from 1 to
nj, this routine returns the entropy h of the whole table, the entropy hx of the x distribution,
the entropy hy of the y distribution, the entropy hygx of y given x, the entropy hxgy of
x given y, the dependency uygx of y on x (eq. 14.4.15), the dependency uxgy of x on y
(eq. 14.4.16), and the symmetrical dependency uxy (eq. 14.4.17).
Parameters: MAXI and MAXJ define the maximum size of table; TINY is a small number.
INTEGER i,j
REAL p,sum,sumi(MAXI),sumj(MAXJ)
sum=0

14.5 Linear Correlation

We next turn to measures of association between variables that are ordinal or continuous, rather than nominal. Most widely used is the *linear correlation coefficient*. For pairs of quantities (x_i, y_i) , $i = 1, \dots, N$, the linear correlation coefficient r (also called the product-moment correlation coefficient, or *Pearson's r*) is given by the formula

$$r = \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2} \sqrt{\sum_i (y_i - \bar{y})^2}} \quad (14.5.1)$$

where, as usual, \bar{x} is the mean of the x_i 's, \bar{y} is the mean of the y_i 's.

The value of r lies between -1 and 1 , inclusive. It takes on a value of 1 , termed “complete positive correlation,” when the data points lie on a perfect straight line with positive slope, with x and y increasing together. The value 1 holds independent of the magnitude of the slope. If the data points lie on a perfect straight line with negative slope, y decreasing as x increases, then r has the value -1 ; this is called “complete negative correlation.” A value of r near zero indicates that the variables x and y are *uncorrelated*.

When a correlation is known to be significant, r is one conventional way of summarizing its strength. In fact, the value of r can be translated into a statement about what residuals (root mean square deviations) are to be expected if the data are fitted to a straight line by the least-squares method (see §15.2, especially equations 15.2.13 – 15.2.14). Unfortunately, r is a rather poor statistic for deciding whether an observed correlation is statistically significant, and/or whether one observed correlation is significantly stronger than another. The reason is that r is ignorant of the individual distributions of x and y , so there is no universal way to compute its distribution in the case of the null hypothesis.

About the only general statement that can be made is this: If the null hypothesis is that x and y are uncorrelated, and if the distributions for x and y each have enough convergent moments (“tails” die off sufficiently rapidly), and if N is large

14.5 Linear Correlation

We next turn to measures of association between variables that are ordinal or continuous, rather than nominal. Most widely used is the *linear correlation coefficient*. For pairs of quantities (x_i, y_i) , $i = 1, \dots, N$, the linear correlation coefficient r (also called the product-moment correlation coefficient, or *Pearson's r*) is given by the formula

$$r = \frac{\sum_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_i (x_i - \bar{x})^2} \sqrt{\sum_i (y_i - \bar{y})^2}} \quad (14.5.1)$$

where, as usual, \bar{x} is the mean of the x_i 's, \bar{y} is the mean of the y_i 's.

The value of r lies between -1 and 1 , inclusive. It takes on a value of 1 , termed “complete positive correlation,” when the data points lie on a perfect straight line with positive slope, with x and y increasing together. The value 1 holds independent of the magnitude of the slope. If the data points lie on a perfect straight line with negative slope, y decreasing as x increases, then r has the value -1 ; this is called “complete negative correlation.” A value of r near zero indicates that the variables x and y are *uncorrelated*.

When a correlation is known to be significant, r is one conventional way of summarizing its strength. In fact, the value of r can be translated into a statement about what residuals (root mean square deviations) are to be expected if the data are fitted to a straight line by the least-squares method (see §15.2, especially equations 15.2.13 – 15.2.14). Unfortunately, r is a rather poor statistic for deciding whether an observed correlation is statistically significant, and/or whether one observed correlation is significantly stronger than another. The reason is that r is ignorant of the individual distributions of x and y , so there is no universal way to compute its distribution in the case of the null hypothesis.

About the only general statement that can be made is this: If the null hypothesis is that x and y are uncorrelated, and if the distributions for x and y each have enough convergent moments (“tails” die off sufficiently rapidly), and if N is large

(typically > 500), then r is distributed approximately normally, with a mean of zero and a standard deviation of $1/\sqrt{N}$. In that case, the (double-sided) significance of the correlation, that is, the probability that $|r|$ should be larger than its observed value in the null hypothesis, is

$$\operatorname{erfc}\left(\frac{|r|\sqrt{N}}{\sqrt{2}}\right) \quad (14.5.2)$$

where $\operatorname{erfc}(x)$ is the complementary error function, equation (6.2.8), computed by the routines `erfc` or `erfcc` of §6.2. A small value of (14.5.2) indicates that the two distributions are significantly correlated. (See expression 14.5.9 below for a more accurate test.)

Most statistics books try to go beyond (14.5.2) and give additional statistical tests that can be made using r . In almost all cases, however, these tests are valid only for a very special class of hypotheses, namely that the distributions of x and y jointly form a *binormal* or *two-dimensional Gaussian* distribution around their mean values, with joint probability density

$$p(x, y) dx dy = \text{const.} \times \exp\left[-\frac{1}{2}(a_{11}x^2 - 2a_{12}xy + a_{22}y^2)\right] dx dy \quad (14.5.3)$$

where a_{11} , a_{12} , and a_{22} are arbitrary constants. For this distribution r has the value

$$r = -\frac{a_{12}}{\sqrt{a_{11}a_{22}}} \quad (14.5.4)$$

There are occasions when (14.5.3) may be known to be a good model of the data. There may be other occasions when we are willing to take (14.5.3) as at least a rough and ready guess, since many two-dimensional distributions do resemble a binormal distribution, at least not too far out on their tails. In either situation, we can use (14.5.3) to go beyond (14.5.2) in any of several directions:

First, we can allow for the possibility that the number N of data points is not large. Here, it turns out that the statistic

$$t = r \sqrt{\frac{N-2}{1-r^2}} \quad (14.5.5)$$

is distributed in the null case (of no correlation) like Student's t -distribution with $\nu = N - 2$ degrees of freedom, whose two-sided significance level is given by $1 - A(t|\nu)$ (equation 6.4.7). As N becomes large, this significance and (14.5.2) become asymptotically the same, so that one never does worse by using (14.5.5), even if the binormal assumption is not well substantiated.

Second, when N is only moderately large (≥ 10), we can compare whether the difference of two significantly nonzero r 's, e.g., from different experiments, is itself significant. In other words, we can quantify whether a change in some control variable significantly alters an existing correlation between two other variables. This is done by using *Fisher's z-transformation* to associate each measured r with a corresponding z ,

$$z = \frac{1}{2} \ln\left(\frac{1+r}{1-r}\right) \quad (14.5.6)$$

Then, each z is approximately normally distributed with a mean value

$$\bar{z} = \frac{1}{2} \left[\ln \left(\frac{1 + r_{\text{true}}}{1 - r_{\text{true}}} \right) + \frac{r_{\text{true}}}{N - 1} \right] \quad (14.5.7)$$

where r_{true} is the actual or population value of the correlation coefficient, and with a standard deviation

$$\sigma(z) \approx \frac{1}{\sqrt{N-3}} \quad (14.5.8)$$

Equations (14.5.7) and (14.5.8), when they are valid, give several useful statistical tests. For example, the significance level at which a measured value of r differs from some hypothesized value r_{true} is given by

$$\operatorname{erfc}\left(\frac{|z - \bar{z}| \sqrt{N-3}}{\sqrt{2}}\right) \quad (14.5.9)$$

where z and \bar{z} are given by (14.5.6) and (14.5.7), with small values of (14.5.9) indicating a significant difference. (Setting $\bar{z} = 0$ makes expression 14.5.9 a more accurate replacement for expression 14.5.2 above.) Similarly, the significance of a difference between two measured correlation coefficients r_1 and r_2 is

$$\operatorname{erfc} \left(\frac{|z_1 - z_2|}{\sqrt{2} \sqrt{\frac{1}{N_1-3} + \frac{1}{N_2-3}}} \right) \quad (14.5.10)$$

where z_1 and z_2 are obtained from r_1 and r_2 using (14.5.6), and where N_1 and N_2 are, respectively, the number of data points in the measurement of r_1 and r_2 .

All of the significances above are two-sided. If you wish to disprove the null hypothesis in favor of a one-sided hypothesis, such as that $r_1 > r_2$ (where the sense of the inequality was decided *a priori*), then (i) if your measured r_1 and r_2 have the wrong sense, you have failed to demonstrate your one-sided hypothesis, but (ii) if they have the right ordering, you can multiply the significances given above by 0.5, which makes them more significant.

But keep in mind: These interpretations of the r statistic can be completely meaningless if the joint probability distribution of your variables x and y is too different from a binormal distribution.

14.6 Nonparametric or Rank Correlation

It is precisely the uncertainty in interpreting the significance of the linear correlation coefficient r that leads us to the important concepts of *nonparametric* or *rank correlation*. As before, we are given N pairs of measurements (x_i, y_i) . Before, difficulties arose because we did not necessarily know the probability distribution function from which the x_i 's or y_i 's were drawn.

The key concept of nonparametric correlation is this: If we replace the value of each x_i by the value of its *rank* among all the other x_i 's in the sample, that is, $1, 2, 3, \dots, N$, then the resulting list of numbers will be drawn from a perfectly known distribution function, namely uniformly from the integers between 1 and N , inclusive. Better than uniformly, in fact, since if the x_i 's are all distinct, then each integer will occur precisely once. If some of the x_i 's have identical values, it is conventional to assign to all these "ties" the mean of the ranks that they would have had if their values had been slightly different. This *midrank* will sometimes be an

14.6 Nonparametric or Rank Correlation

It is precisely the uncertainty in interpreting the significance of the linear correlation coefficient r that leads us to the important concepts of *nonparametric* or *rank correlation*. As before, we are given N pairs of measurements (x_i, y_i) . Before, difficulties arose because we did not necessarily know the probability distribution function from which the x_i 's or y_i 's were drawn.

The key concept of nonparametric correlation is this: If we replace the value of each x_i by the value of its *rank* among all the other x_i 's in the sample, that is, $1, 2, 3, \dots, N$, then the resulting list of numbers will be drawn from a perfectly known distribution function, namely uniformly from the integers between 1 and N , inclusive. Better than uniformly, in fact, since if the x_i 's are all distinct, then each integer will occur precisely once. If some of the x_i 's have identical values, it is conventional to assign to all these "ties" the mean of the ranks that they would have had if their values had been slightly different. This *midrank* will sometimes be an

integer, sometimes a half-integer. In all cases the sum of all assigned ranks will be the same as the sum of the integers from 1 to N , namely $\frac{1}{2}N(N + 1)$.

Of course we do exactly the same procedure for the y_i 's, replacing each value by its rank among the other y_i 's in the sample.

Now we are free to invent statistics for detecting correlation between uniform sets of integers between 1 and N , keeping in mind the possibility of ties in the ranks. There is, of course, some loss of information in replacing the original numbers by ranks. We could construct some rather artificial examples where a correlation could be detected parametrically (e.g., in the linear correlation coefficient r), but could not be detected nonparametrically. Such examples are very rare in real life, however, and the slight loss of information in ranking is a small price to pay for a very major advantage: When a correlation is demonstrated to be present nonparametrically, then it is really there! (That is, to a certainty level that depends on the significance chosen.) Nonparametric correlation is more robust than linear correlation, more resistant to unplanned defects in the data, in the same sort of sense that the median is more robust than the mean. For more on the concept of robustness, see §15.7.

As always in statistics, some particular choices of a statistic have already been invented for us and consecrated, if not beatified, by popular use. We will discuss two, the *Spearman rank-order correlation coefficient* (r_s), and *Kendall's tau* (τ).

Spearman Rank-Order Correlation Coefficient

Let R_i be the rank of x_i among the other x 's, S_i be the rank of y_i among the other y 's, ties being assigned the appropriate midrank as described above. Then the rank-order correlation coefficient is defined to be the linear correlation coefficient of the ranks, namely,

$$r_s = \frac{\sum_i (R_i - \bar{R})(S_i - \bar{S})}{\sqrt{\sum_i (R_i - \bar{R})^2} \sqrt{\sum_i (S_i - \bar{S})^2}} \quad (14.6.1)$$

The significance of a nonzero value of r_s is tested by computing

$$t = r_s \sqrt{\frac{N - 2}{1 - r_s^2}} \quad (14.6.2)$$

which is distributed approximately as Student's distribution with $N - 2$ degrees of freedom. A key point is that this approximation does not depend on the original distribution of the x 's and y 's; it is always the same approximation, and always pretty good.

It turns out that r_s is closely related to another conventional measure of nonparametric correlation, the so-called *sum squared difference of ranks*, defined as

$$D = \sum_{i=1}^N (R_i - S_i)^2 \quad (14.6.3)$$

(This D is sometimes denoted D^{**} , where the asterisks are used to indicate that ties are treated by midranking.)

When there are no ties in the data, then the exact relation between D and r_s is

$$r_s = 1 - \frac{6D}{N^3 - N} \quad (14.6.4)$$

When there are ties, then the exact relation is slightly more complicated: Let f_k be the number of ties in the k th group of ties among the R_i 's, and let g_m be the number of ties in the m th group of ties among the S_i 's. Then it turns out that

$$r_s = \frac{1 - \frac{6}{N^3 - N} [D + \frac{1}{12} \sum_k (f_k^3 - f_k) + \frac{1}{12} \sum_m (g_m^3 - g_m)]}{\left[1 - \frac{\sum_k (f_k^3 - f_k)}{N^3 - N} \right]^{1/2} \left[1 - \frac{\sum_m (g_m^3 - g_m)}{N^3 - N} \right]^{1/2}} \quad (14.6.5)$$

holds exactly. Notice that if all the f_k 's and all the g_m 's are equal to one, meaning that there are no ties, then equation (14.6.5) reduces to equation (14.6.4).

In (14.6.2) we gave a t -statistic that tests the significance of a nonzero r_s . It is also possible to test the significance of D directly. The expectation value of D in the null hypothesis of uncorrelated data sets is

$$\bar{D} = \frac{1}{6}(N^3 - N) - \frac{1}{12} \sum_k (f_k^3 - f_k) - \frac{1}{12} \sum_m (g_m^3 - g_m) \quad (14.6.6)$$

its variance is

$$\begin{aligned} \text{Var}(D) &= \frac{(N-1)N^2(N+1)^2}{36} \\ &\times \left[1 - \frac{\sum_k (f_k^3 - f_k)}{N^3 - N} \right] \left[1 - \frac{\sum_m (g_m^3 - g_m)}{N^3 - N} \right] \end{aligned} \quad (14.6.7)$$

and it is approximately normally distributed, so that the significance level is a complementary error function (cf. equation 14.5.2). Of course, (14.6.2) and (14.6.7) are not independent tests, but simply variants of the same test. In the program that follows, we return both the significance level obtained by using (14.6.2) and the significance level obtained by using (14.6.7); their discrepancy will give you an idea of how good the approximations are. You will also notice that we break off the task of assigning ranks (including tied midranks) into a separate routine, `crank`.

```

SUBROUTINE spear(data1,data2,n,wksp1,wksp2,d,zd,probds,probrs)
INTEGER n
REAL d,probds,probrs,rs,zd,data1(n),data2(n),wksp1(n),wksp2(n)
C USES betai,crank,erfcc,sort2
      Given two data arrays, data1(1:n) and data2(1:n), each of length n, and given two
      workspaces of the same length, this routine returns their sum-squared difference of ranks as
      D, the number of standard deviations by which D deviates from its null-hypothesis expected
      value as zd, the two-sided significance level of this deviation as probds, Spearman's rank
      correlation rs as rs, and the two-sided significance level of its deviation from zero as
      probrs. The workspaces can be identical to the data arrays, but in that case the data
      arrays are destroyed. The external routines crank (below) and sort2 (§8.2) are used. A

```

Kendall's Tau

Kendall's τ is even more nonparametric than Spearman's r_s or D . Instead of using the numerical difference of ranks, it uses only the relative ordering of ranks: higher in rank, lower in rank, or the same in rank. But in that case we don't even have to rank the data! Ranks will be higher, lower, or the same if and only if the values are larger, smaller, or equal, respectively. On balance, we prefer r_s as being the more straightforward nonparametric test, but both statistics are in general use. In fact, τ and r_s are very strongly correlated and, in most applications, are effectively the same test.

To define τ , we start with the N data points (x_i, y_i) . Now consider all $\frac{1}{2}N(N - 1)$ pairs of data points, where a data point cannot be paired with itself, and where the points in either order count as one pair. We call a pair *concordant* if the relative ordering of the ranks of the two x 's (or for that matter the two y 's themselves) is the same as the relative ordering of the ranks of the two y 's (or for that matter the two x 's themselves). We call a pair *discordant* if the relative ordering of the ranks of the two x 's is opposite from the relative ordering of the ranks of the two y 's. If there is a tie in either the ranks of the two x 's or the ranks of the two y 's, then we don't call the pair either concordant or discordant. If the tie is in the x 's, we will call the pair an "extra y pair." If the tie is in the y 's, we will call the pair an "extra x pair." If the tie is in both the x 's and the y 's, we don't call the pair anything at all. Are you still with us?

Kendall's τ is now the following simple combination of these various counts:

$$\tau = \frac{\text{concordant} - \text{discordant}}{\sqrt{\text{concordant} + \text{discordant} + \text{extra-}y} \sqrt{\text{concordant} + \text{discordant} + \text{extra-}x}} \quad (14.6.8)$$

You can easily convince yourself that this must lie between 1 and -1 , and that it takes on the extreme values only for complete rank agreement or complete rank reversal, respectively.

More important, Kendall has worked out, from the combinatorics, the approximate distribution of τ in the null hypothesis of no association between x and y . In this case τ is approximately normally distributed, with zero expectation value and a variance of

$$\text{Var}(\tau) = \frac{4N + 10}{9N(N - 1)} \quad (14.6.9)$$

The following program proceeds according to the above description, and therefore loops over all pairs of data points. Beware: This is an $O(N^2)$ algorithm, unlike the algorithm for r_s , whose dominant sort operations are of order $N \log N$. If you are routinely computing Kendall's τ for data sets of more than a few thousand points, you may be in for some serious computing. If, however, you are willing to bin your data into a moderate number of bins, then read on.

```

SUBROUTINE kend11(data1,data2,n,tau,z,prob)
INTEGER n
REAL prob,tau,z,data1(n),data2(n)

      return
END

```

Sometimes it happens that there are only a few possible values each for x and y . In that case, the data can be recorded as a contingency table (see §14.4) that gives the number of data points for each contingency of x and y .

Spearman's rank-order correlation coefficient is not a very natural statistic under these circumstances, since it assigns to each x and y bin a not-very-meaningful midrank value and then totals up vast numbers of identical rank differences. Kendall's tau, on the other hand, with its simple counting, remains quite natural. Furthermore, its $O(N^2)$ algorithm is no longer a problem, since we can arrange for it to loop over pairs of contingency table entries (each containing many data points) instead of over pairs of data points. This is implemented in the program that follows.

Note that Kendall's tau can be applied only to contingency tables where both variables are *ordinal*, i.e., well-ordered, and that it looks specifically for monotonic correlations, not for arbitrary associations. These two properties make it less general than the methods of §14.4, which applied to *nominal*, i.e., unordered, variables and arbitrary associations.

Comparing kend11 above with kend12 below, you will see that we have "floated" a number of variables. This is because the number of events in a contingency table might be sufficiently large as to cause overflows in some of the

integer arithmetic, while the number of individual data points in a list could not possibly be that large [for an $O(N^2)$ routine!].

```

SUBROUTINE kendl2(tab,i,j,ip,jp,tau,z,prob)
INTEGER i,ip,j,jp
REAL prob,tau,z,tab(ip,jp)
C USES erfcc
      Given a two-dimensional table tab of physical dimension (ip,jp) and logical dimension
      (i,j), such that tab(k,l) contains the number of events falling in bin k of one variable
      and bin l of another, this program returns Kendall's  $\tau$  as tau, its number of standard
      deviations from zero as z, and its two-sided significance level as prob. Small values of prob
      indicate a significant correlation (tau positive) or anticorrelation (tau negative) between
      the two variables. Although tab is a real array, it will normally contain integral values.

14.7 Do Two-Dimensional Distributions Differ?

We here discuss a useful generalization of the K–S test (§14.3) to *two-dimensional* distributions. This generalization is due to Fasano and Franceschini [1], a variant on an earlier idea due to Peacock [2].

In a two-dimensional distribution, each data point is characterized by an (x, y) pair of values. An example near to our hearts is that each of the 19 neutrinos that were detected from Supernova 1987A is characterized by a time t_i and by an energy E_i (see [3]). We might wish to know whether these measured pairs (t_i, E_i) , $i = 1 \dots 19$ are consistent with a theoretical model that predicts neutrino flux as a function of both time and energy — that is, a two-dimensional probability distribution in the (x, y) [here, (t, E)] plane. That would be a one-sample test. Or, given two sets of neutrino detections, from two comparable detectors, we might want to know whether they are compatible with each other, a two-sample test.

In the spirit of the tried-and-true, one-dimensional K–S test, we want to range over the (x, y) plane in search of some kind of maximum *cumulative* difference between two two-dimensional distributions. Unfortunately, cumulative probability distribution is not well-defined in more than one dimension! Peacock's insight was that a good surrogate is the *integrated probability in each of four natural quadrants* around a given point (x_i, y_i) , namely the total probabilities (or fraction of data) in $(x > x_i, y > y_i)$, $(x < x_i, y > y_i)$, $(x < x_i, y < y_i)$, $(x > x_i, y < y_i)$. The two-dimensional K–S statistic D is now taken to be the maximum difference (ranging both over data points and over quadrants) of the corresponding integrated probabilities. When comparing two data sets, the value of D may depend on which data set is ranged over. In that case, define an effective D as the average of the two values obtained. If you are confused at this point about the exact definition of D , don't fret; the accompanying computer routines amount to a precise algorithmic definition.

Figure 14.7.1 gives a feeling for what is going on. The 65 triangles and 35 squares seem to have somewhat different distributions in the plane. The dotted lines are centered on the triangle that maximizes the D statistic; the maximum occurs in the upper-left quadrant. That quadrant contains only 0.12 of all the triangles, but it contains 0.56 of all the squares. The value of D is thus 0.44. Is this statistically significant?

Even for fixed sample sizes, it is unfortunately not rigorously true that the distribution of D in the null hypothesis is independent of the shape of the two-dimensional distribution. In this respect the two-dimensional K–S test is not as natural as its one-dimensional parent. However, extensive Monte Carlo integrations have shown that the distribution of the two-dimensional D is *very nearly* identical for even quite different distributions, as long as they have the same coefficient of correlation r , defined in the usual way by equation (14.5.1). In their paper, Fasano and Franceschini tabulate Monte Carlo results for (what amounts to) the distribution of D as a function of (of course) D , sample size N , and coefficient of correlation r . Analyzing their results, one finds that the significance levels for the two-dimensional K–S test can be summarized by the simple, though approximate, formulas,

$$\text{Probability } (D > \text{observed}) = Q_{KS} \left(\frac{\sqrt{N} D}{1 + \sqrt{1 - r^2}(0.25 - 0.75/\sqrt{N})} \right) \quad (14.7.1)$$

for the one-sample case, and the same for the two-sample case, but with

$$N = \frac{N_1 N_2}{N_1 + N_2}. \quad (14.7.2)$$

The above formulas are accurate enough when $N \gtrsim 20$, and when the indicated probability (significance level) is less than (more significant than) 0.20 or so. When the indicated probability is > 0.20 , its value may not be accurate, but the implication that the data and model (or two data sets) are not significantly different is certainly correct. Notice that in the limit of $r \rightarrow 1$ (perfect correlation), equations (14.7.1) and (14.7.2) reduce to equations (14.3.9) and (14.3.10): The two-dimensional data lie on a perfect straight line, and the two-dimensional K–S test becomes a one-dimensional K–S test.

14.7 Do Two-Dimensional Distributions Differ?

We here discuss a useful generalization of the K–S test (§14.3) to *two-dimensional* distributions. This generalization is due to Fasano and Franceschini [1], a variant on an earlier idea due to Peacock [2].

In a two-dimensional distribution, each data point is characterized by an (x, y) pair of values. An example near to our hearts is that each of the 19 neutrinos that were detected from Supernova 1987A is characterized by a time t_i and by an energy E_i (see [3]). We might wish to know whether these measured pairs (t_i, E_i) , $i = 1 \dots 19$ are consistent with a theoretical model that predicts neutrino flux as a function of both time and energy — that is, a two-dimensional probability distribution in the (x, y) [here, (t, E)] plane. That would be a one-sample test. Or, given two sets of neutrino detections, from two comparable detectors, we might want to know whether they are compatible with each other, a two-sample test.

In the spirit of the tried-and-true, one-dimensional K–S test, we want to range over the (x, y) plane in search of some kind of maximum *cumulative* difference between two two-dimensional distributions. Unfortunately, cumulative probability distribution is not well-defined in more than one dimension! Peacock's insight was that a good surrogate is the *integrated probability in each of four natural quadrants* around a given point (x_i, y_i) , namely the total probabilities (or fraction of data) in $(x > x_i, y > y_i)$, $(x < x_i, y > y_i)$, $(x < x_i, y < y_i)$, $(x > x_i, y < y_i)$. The two-dimensional K–S statistic D is now taken to be the maximum difference (ranging both over data points and over quadrants) of the corresponding integrated probabilities. When comparing two data sets, the value of D may depend on which data set is ranged over. In that case, define an effective D as the average of the two values obtained. If you are confused at this point about the exact definition of D , don't fret; the accompanying computer routines amount to a precise algorithmic definition.

Figure 14.7.1 gives a feeling for what is going on. The 65 triangles and 35 squares seem to have somewhat different distributions in the plane. The dotted lines are centered on the triangle that maximizes the D statistic; the maximum occurs in the upper-left quadrant. That quadrant contains only 0.12 of all the triangles, but it contains 0.56 of all the squares. The value of D is thus 0.44. Is this statistically significant?

Even for fixed sample sizes, it is unfortunately not rigorously true that the distribution of D in the null hypothesis is independent of the shape of the two-dimensional distribution. In this respect the two-dimensional K–S test is not as natural as its one-dimensional parent. However, extensive Monte Carlo integrations have shown that the distribution of the two-dimensional D is *very nearly* identical for even quite different distributions, as long as they have the same coefficient of correlation r , defined in the usual way by equation (14.5.1). In their paper, Fasano and Franceschini tabulate Monte Carlo results for (what amounts to) the distribution of D as a function of (of course) D , sample size N , and coefficient of correlation r . Analyzing their results, one finds that the significance levels for the two-dimensional K–S test can be summarized by the simple, though approximate, formulas,

$$\text{Probability } (D > \text{observed}) = Q_{KS} \left(\frac{\sqrt{N} D}{1 + \sqrt{1 - r^2}(0.25 - 0.75/\sqrt{N})} \right) \quad (14.7.1)$$

for the one-sample case, and the same for the two-sample case, but with

$$N = \frac{N_1 N_2}{N_1 + N_2}. \quad (14.7.2)$$

The above formulas are accurate enough when $N \gtrsim 20$, and when the indicated probability (significance level) is less than (more significant than) 0.20 or so. When the indicated probability is > 0.20 , its value may not be accurate, but the implication that the data and model (or two data sets) are not significantly different is certainly correct. Notice that in the limit of $r \rightarrow 1$ (perfect correlation), equations (14.7.1) and (14.7.2) reduce to equations (14.3.9) and (14.3.10): The two-dimensional data lie on a perfect straight line, and the two-dimensional K–S test becomes a one-dimensional K–S test.

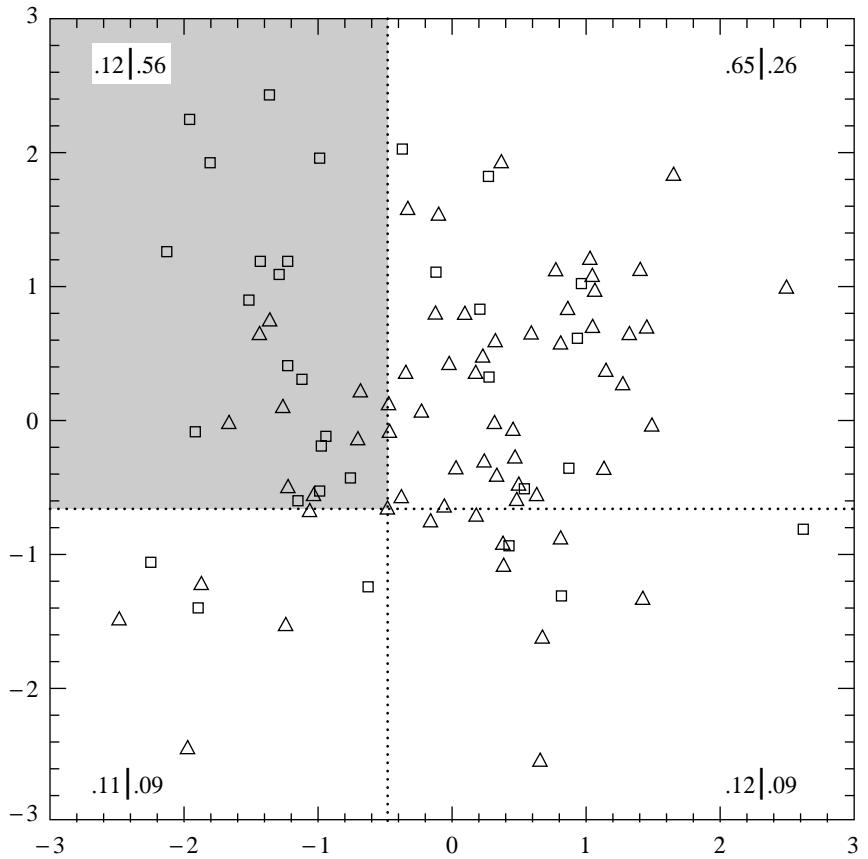

Figure 14.7.1. Two-dimensional distributions of 65 triangles and 35 squares. The two-dimensional K–S test finds that point one of whose quadrants (shown by dotted lines) maximizes the difference between fraction of triangles and fraction of squares. Then, equation (14.7.1) indicates whether the difference is statistically significant, i.e., whether the triangles and squares must have different underlying distributions.

The significance level for the data in Figure 14.7.1, by the way, is about 0.001. This establishes to a near-certainty that the triangles and squares were drawn from different distributions. (As in fact they were.)

Of course, if you do not want to rely on the Monte Carlo experiments embodied in equation (14.7.1), you can do your own: Generate a lot of synthetic data sets from your model, each one with the same number of points as the real data set. Compute D for each synthetic data set, using the accompanying computer routines (but ignoring their calculated probabilities), and count what fraction of the time these synthetic D 's exceed the D from the real data. That fraction is your significance.

One disadvantage of the two-dimensional tests, by comparison with their one-dimensional progenitors, is that the two-dimensional tests require of order N^2 operations: Two nested loops of order N take the place of an $N \log N$ sort. For small computers, this restricts the usefulness of the tests to N less than several thousand.

We now give computer implementations. The one-sample case is embodied in the routine `ks2d1s` (that is, 2-dimensions, 1-sample). This routine calls a straightforward utility routine `quadct` to count points in the four quadrants, and it calls a user-supplied routine `quadvl` that must be capable of returning the integrated probability of an analytic model in each of four quadrants around an arbitrary (x, y) point. A trivial sample `quadvl` is shown; realistic `quadvls` can be quite complicated, often incorporating numerical quadratures over

analytic two-dimensional distributions.

```
SUBROUTINE ks2d1s(x1,y1,n1,quadvl,d1,prob)
INTEGER n1
REAL d1,prob,x1(n1),y1(n1)
EXTERNAL quadvl
C USES pearsn,probks,quadct,quadvl
      Two-dimensional Kolmogorov-Smirnov test of one sample against a model. Given the  $x$  and  $y$  coordinates of  $n1$  data points in arrays  $x1(1:n1)$  and  $y1(1:n1)$ , and given a user-supplied function  $quadvl$  that exemplifies the model, this routine returns the two-dimensional K-S statistic as  $d1$ , and its significance level as  $prob$ . Small values of  $prob$  show that the sample is significantly different from the model. Note that the test is slightly distribution-dependent, so  $prob$  is only an estimate.
INTEGER j
REAL dum,dumm,fa,fb,fc,fd,ga,gb,gc,gd,r1,rr,sqen,probks
d1=0.0
do :: j=1,n1                                Loop over the data points.
      call quadct(x1(j),y1(j),x1,y1,n1,fa,fb,fc,fd)
      call quadvl(x1(j),y1(j),ga,gb,gc,gd)
      d1=max(d1,abs(fa-ga),abs(fb-gb),abs(fc-gc),abs(fd-gd))
      For both the sample and the model, the distribution is integrated in each of four quadrants, and the maximum difference is saved.
enddo :: 
call pearsn(x1,y1,n1,r1,dum,dumm)  Get the linear correlation coefficient r1.
sqen=sqrt(float(n1))
rr=sqrt(1.0-r1**2)
      Estimate the probability using the K-S probability function probks.
prob=probks(d1*sqen/(1.0+rr*(0.25-0.75/sqen)))
return
END

SUBROUTINE quadct(x,y,xx,yy,nn,fa,fb,fc,fd)
INTEGER nn
REAL fa,fb,fc,fd,x,y,xx(nn),yy(nn)
      Given an origin  $(x, y)$ , and an array of  $nn$  points with coordinates  $xx$  and  $yy$ , count how many of them are in each quadrant around the origin, and return the normalized fractions. Quadrants are labeled alphabetically, counterclockwise from the upper right. Used by  $ks2d1s$  and  $ks2d2s$ .
INTEGER k,na,nb,nc,nd
REAL ff
na=0
nb=0
nc=0
nd=0
do :: k=1,nn
      if(yy(k).gt.y)then
          if(xx(k).gt.x)then
              na=na+1
          else
              nb=nb+1
          endif
      else
          if(xx(k).gt.x)then
              nd=nd+1
          else
              nc=nc+1
          endif
      endif
enddo :: 
ff=1.0/nn
fa=ff*na
fb=ff*nb
```

```

fc=ff*nc
fd=ff*nd
return
END

SUBROUTINE quadvl(x,y,fa,fb,fc,fd)
REAL fa,fb,fc,fd,x,y
This is a sample of a user-supplied routine to be used with ks2d1s. In this case, the model
distribution is uniform inside the square  $-1 < x < 1$ ,  $-1 < y < 1$ . In general this routine
should return, for any point  $(x, y)$ , the fraction of the total distribution in each of the
four quadrants around that point. The fractions,  $fa$ ,  $fb$ ,  $fc$ , and  $fd$ , must add up to 1.
Quadrants are alphabetical, counterclockwise from the upper right.
REAL qa,qb,qc,qd
qa=min(2.,max(0.,1.-x))
qb=min(2.,max(0.,1.-y))
qc=min(2.,max(0.,x+1.))
qd=min(2.,max(0.,y+1.))
fa=0.25*qa*qb
fb=0.25*qb*qc
fc=0.25*qc*qd
fd=0.25*qd*qa
return
END

```
