The routine `ks2d2s` is the two-sample case of the two-dimensional K–S test. It also calls `quadct`, `pearsn`, and `probks`. Being a two-sample test, it does not need an analytic model.

```

SUBROUTINE ks2d2s(x1,y1,n1,x2,y2,n2,d,prob)
INTEGER n1,n2
REAL d,prob,x1(n1),x2(n2),y1(n1),y2(n2)
C USES pearsn,probks,quadct
Two-dimensional Kolmogorov-Smirnov test on two samples. Given the  $x$  and  $y$  coordinates
of the first sample as  $n1$  values in arrays  $x1(1:n1)$  and  $y1(1:n1)$ , and likewise for the
second sample,  $n2$  values in arrays  $x2$  and  $y2$ , this routine returns the two-dimensional, two-
sample K-S statistic as  $d$ , and its significance level as  $prob$ . Small values of  $prob$  show
that the two samples are significantly different. Note that the test is slightly distribution-
dependent, so  $prob$  is only an estimate.
INTEGER j
REAL d1,d2,dum,dumm,fa,fb,fc,fd,ga,gb,gc,gd,r1,r2,rr,
*      sqen,probks
d1=0.0
do 11 j=1,n1          First, use points in the first sample as origins.
   call quadct(x1(j),y1(j),x1,y1,n1,fa,fb,fc,fd)
   call quadct(x1(j),y1(j),x2,y2,n2,ga,gb,gc,gd)
   d1=max(d1,abs(fa-ga),abs(fb-gb),abs(fc-gc),abs(fd-gd))
enddo 11
d2=0.0
do 12 j=1,n2          Then, use points in the second sample as origins.
   call quadct(x2(j),y2(j),x1,y1,n1,fa,fb,fc,fd)
   call quadct(x2(j),y2(j),x2,y2,n2,ga,gb,gc,gd)
   d2=max(d2,abs(fa-ga),abs(fb-gb),abs(fc-gc),abs(fd-gd))
enddo 12
d=0.5*(d1+d2)          Average the K-S statistics.
sqen=sqrt(float(n1)*float(n2)/float(n1+n2))
call pearsn(x1,y1,n1,r1,dum,dumm)  Get the linear correlation coefficient for each sample.
call pearsn(x2,y2,n2,r2,dum,dumm)
rr=sqrt(1.0-0.5*(r1**2+r2**2))
Estimate the probability using the K-S probability function probks.
prob=probks(d*sqen/(1.0+rr*(0.25-0.75/sqen)))
return
END

```

14.8 Savitzky-Golay Smoothing Filters

In §13.5 we learned something about the construction and application of digital filters, but little guidance was given on *which particular* filter to use. That, of course, depends on what you want to accomplish by filtering. One obvious use for *low-pass* filters is to smooth noisy data.

The premise of data smoothing is that one is measuring a variable that is both slowly varying and also corrupted by random noise. Then it can sometimes be useful to replace each data point by some kind of local average of surrounding data points. Since nearby points measure very nearly the same underlying value, averaging can reduce the level of noise without (much) biasing the value obtained.

We must comment editorially that the smoothing of data lies in a murky area, beyond the fringe of some better posed, and therefore more highly recommended, techniques that are discussed elsewhere in this book. If you are fitting data to a parametric model, for example (see Chapter 15), it is almost always better to use raw data than to use data that has been pre-processed by a smoothing procedure. Another alternative to blind smoothing is so-called “optimal” or Wiener filtering, as discussed in §13.3 and more generally in §13.6. Data smoothing is probably most justified when it is used simply as a graphical technique, to guide the eye through a forest of data points all with large error bars; or as a means of making initial *rough* estimates of simple parameters from a graph.

In this section we discuss a particular type of low-pass filter, well-adapted for data smoothing, and termed variously *Savitzky-Golay* [1], *least-squares* [2], or *DISPO* (Digital Smoothing Polynomial) [3] filters. Rather than having their properties defined in the Fourier domain, and then translated to the time domain, Savitzky-Golay filters derive directly from a particular formulation of the data smoothing problem in the time domain, as we will now see. Savitzky-Golay filters were initially (and are still often) used to render visible the relative widths and heights of spectral lines in noisy spectrometric data.

Recall that a digital filter is applied to a series of equally spaced data values $f_i \equiv f(t_i)$, where $t_i \equiv t_0 + i\Delta$ for some constant sample spacing Δ and $i = \dots -2, -1, 0, 1, 2, \dots$. We have seen (§13.5) that the simplest type of digital filter (the nonrecursive or finite impulse response filter) replaces each data value f_i by a linear combination g_i of itself and some number of nearby neighbors,

$$g_i = \sum_{n=-n_L}^{n_R} c_n f_{i+n} \quad (14.8.1)$$

Here n_L is the number of points used “to the left” of a data point i , i.e., earlier than it, while n_R is the number used to the right, i.e., later. A so-called *causal* filter would have $n_R = 0$.

As a starting point for understanding Savitzky-Golay filters, consider the simplest possible averaging procedure: For some fixed $n_L = n_R$, compute each g_i as the average of the data points from f_{i-n_L} to f_{i+n_R} . This is sometimes called *moving window averaging* and corresponds to equation (14.8.1) with constant $c_n = 1/(n_L + n_R + 1)$. If the underlying function is constant, or is changing linearly with time (increasing or decreasing), then no bias is introduced into the result. Higher points at one end of the averaging interval are on

14.8 Savitzky-Golay Smoothing Filters

In §13.5 we learned something about the construction and application of digital filters, but little guidance was given on *which particular* filter to use. That, of course, depends on what you want to accomplish by filtering. One obvious use for *low-pass* filters is to smooth noisy data.

The premise of data smoothing is that one is measuring a variable that is both slowly varying and also corrupted by random noise. Then it can sometimes be useful to replace each data point by some kind of local average of surrounding data points. Since nearby points measure very nearly the same underlying value, averaging can reduce the level of noise without (much) biasing the value obtained.

We must comment editorially that the smoothing of data lies in a murky area, beyond the fringe of some better posed, and therefore more highly recommended, techniques that are discussed elsewhere in this book. If you are fitting data to a parametric model, for example (see Chapter 15), it is almost always better to use raw data than to use data that has been pre-processed by a smoothing procedure. Another alternative to blind smoothing is so-called “optimal” or Wiener filtering, as discussed in §13.3 and more generally in §13.6. Data smoothing is probably most justified when it is used simply as a graphical technique, to guide the eye through a forest of data points all with large error bars; or as a means of making initial *rough* estimates of simple parameters from a graph.

In this section we discuss a particular type of low-pass filter, well-adapted for data smoothing, and termed variously *Savitzky-Golay* [1], *least-squares* [2], or *DISPO* (Digital Smoothing Polynomial) [3] filters. Rather than having their properties defined in the Fourier domain, and then translated to the time domain, Savitzky-Golay filters derive directly from a particular formulation of the data smoothing problem in the time domain, as we will now see. Savitzky-Golay filters were initially (and are still often) used to render visible the relative widths and heights of spectral lines in noisy spectrometric data.

Recall that a digital filter is applied to a series of equally spaced data values $f_i \equiv f(t_i)$, where $t_i \equiv t_0 + i\Delta$ for some constant sample spacing Δ and $i = \dots -2, -1, 0, 1, 2, \dots$. We have seen (§13.5) that the simplest type of digital filter (the nonrecursive or finite impulse response filter) replaces each data value f_i by a linear combination g_i of itself and some number of nearby neighbors,

$$g_i = \sum_{n=-n_L}^{n_R} c_n f_{i+n} \quad (14.8.1)$$

Here n_L is the number of points used “to the left” of a data point i , i.e., earlier than it, while n_R is the number used to the right, i.e., later. A so-called *causal* filter would have $n_R = 0$.

As a starting point for understanding Savitzky-Golay filters, consider the simplest possible averaging procedure: For some fixed $n_L = n_R$, compute each g_i as the average of the data points from f_{i-n_L} to f_{i+n_R} . This is sometimes called *moving window averaging* and corresponds to equation (14.8.1) with constant $c_n = 1/(n_L + n_R + 1)$. If the underlying function is constant, or is changing linearly with time (increasing or decreasing), then no bias is introduced into the result. Higher points at one end of the averaging interval are on

the average balanced by lower points at the other end. A bias is introduced, however, if the underlying function has a nonzero second derivative. At a local maximum, for example, moving window averaging always reduces the function value. In the spectrometric application, a narrow spectral line has its height reduced and its width increased. Since these parameters are themselves of physical interest, the bias introduced is distinctly undesirable.

Note, however, that moving window averaging does preserve the area under a spectral line, which is its zeroth moment, and also (if the window is symmetric with $n_L = n_R$) its mean position in time, which is its first moment. What is violated is the second moment, equivalent to the line width.

The idea of Savitzky-Golay filtering is to find filter coefficients c_n that preserve higher moments. Equivalently, the idea is to approximate the underlying function within the moving window not by a constant (whose estimate is the average), but by a polynomial of higher order, typically quadratic or quartic: For each point f_i , we least-squares fit a polynomial to all $n_L + n_R + 1$ points in the moving window, and then set g_i to be the value of that polynomial at position i . (If you are not familiar with least-squares fitting, you might want to look ahead to Chapter 15.) We make no use of the value of the polynomial at any other point. When we move on to the next point f_{i+1} , we do a whole new least-squares fit using a shifted window.

All these least-squares fits would be laborious if done as described. Luckily, since the process of least-squares fitting involves only a linear matrix inversion, the coefficients of a fitted polynomial are themselves linear in the values of the data. That means that we can do all the fitting in advance, for fictitious data consisting of all zeros except for a single 1, and then do the fits on the real data just by taking linear combinations. This is the key point, then: There are particular sets of filter coefficients c_n for which equation (14.8.1) “automatically” accomplishes the process of polynomial least-squares fitting inside a moving window.

To derive such coefficients, consider how g_0 might be obtained: We want to fit a polynomial of degree M in i , namely $a_0 + a_1 i + \dots + a_M i^M$ to the values f_{-n_L}, \dots, f_{n_R} . Then g_0 will be the value of that polynomial at $i = 0$, namely a_0 . The design matrix for this problem (§15.4) is

$$A_{ij} = i^j \quad i = -n_L, \dots, n_R, \quad j = 0, \dots, M \quad (14.8.2)$$

and the normal equations for the vector of a_j 's in terms of the vector of f_i 's is in matrix notation

$$(\mathbf{A}^T \cdot \mathbf{A}) \cdot \mathbf{a} = \mathbf{A}^T \cdot \mathbf{f} \quad \text{or} \quad \mathbf{a} = (\mathbf{A}^T \cdot \mathbf{A})^{-1} \cdot (\mathbf{A}^T \cdot \mathbf{f}) \quad (14.8.3)$$

We also have the specific forms

$$\{\mathbf{A}^T \cdot \mathbf{A}\}_{ij} = \sum_{k=-n_L}^{n_R} A_{ki} A_{kj} = \sum_{k=-n_L}^{n_R} k^{i+j} \quad (14.8.4)$$

and

$$\{\mathbf{A}^T \cdot \mathbf{f}\}_j = \sum_{k=-n_L}^{n_R} A_{kj} f_k = \sum_{k=-n_L}^{n_R} k^j f_k \quad (14.8.5)$$

Since the coefficient c_n is the component a_0 when \mathbf{f} is replaced by the unit vector \mathbf{e}_n , $-n_L \leq n < n_R$, we have

$$c_n = \left\{ (\mathbf{A}^T \cdot \mathbf{A})^{-1} \cdot (\mathbf{A}^T \cdot \mathbf{e}_n) \right\}_0 = \sum_{m=0}^M \left\{ (\mathbf{A}^T \cdot \mathbf{A})^{-1} \right\}_{0m} n^m \quad (14.8.6)$$

Note that equation (14.8.6) says that we need only one row of the inverse matrix. (Numerically we can get this by *LU* decomposition with only a single backsubstitution.)

The subroutine `savgol`, below, implements equation (14.8.6). As input, it takes the parameters $nL = n_L$, $nr = n_R$, and $m = M$ (the desired order). Also input is np , the physical length of the output array c , and a parameter $1d$ which for data fitting should be zero. In fact, $1d$ specifies which coefficient among the a_i 's should be returned, and we are here interested in a_0 . For another purpose, namely the computation of numerical derivatives (already mentioned in §5.7) the useful choice is $1d \geq 1$. With $1d = 1$, for example, the filtered first derivative is the convolution (14.8.1) divided by the stepsize Δ . For $1d = k > 1$, the array c must be multiplied by $k!$ to give derivative coefficients. For derivatives, one usually wants $m = 4$ or larger.

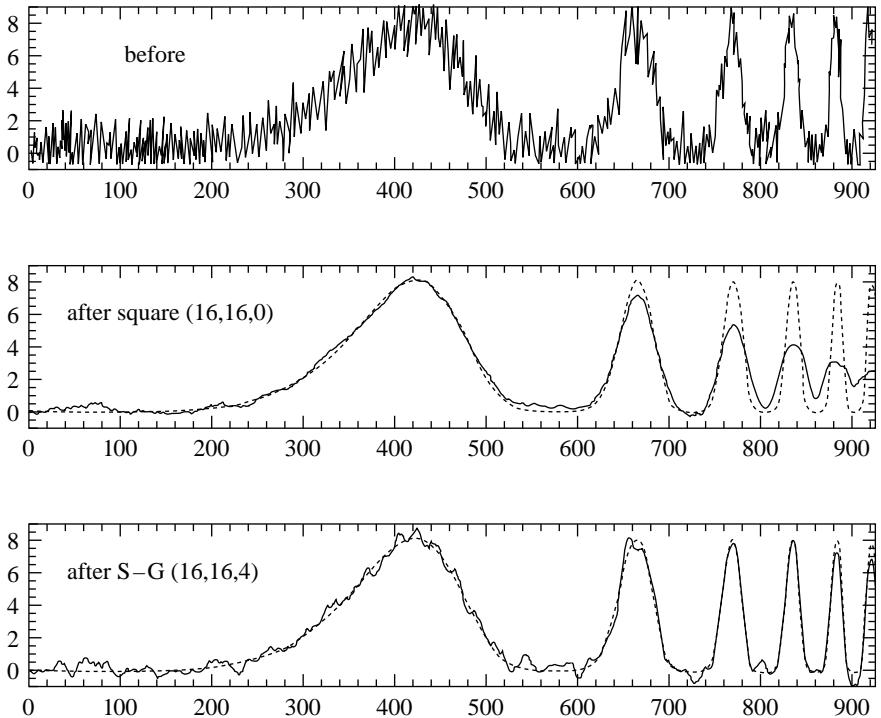

Figure 14.8.1. Top: Synthetic noisy data consisting of a sequence of progressively narrower bumps, and additive Gaussian white noise. Center: Result of smoothing the data by a simple moving window average. The window extends 16 points leftward and rightward, for a total of 33 points. Note that narrow features are broadened and suffer corresponding loss of amplitude. The dotted curve is the underlying function used to generate the synthetic data. Bottom: Result of smoothing the data by a Savitzky-Golay filter (of degree 4) using the same 33 points. While there is less smoothing of the broadest feature, narrower features have their heights and widths preserved.

As output, `savgol` returns the coefficients c_n , for $-n_L \leq n \leq n_R$. These are stored in `c` in “wrap-around order”; that is, c_0 is in `c(1)`, c_{-1} is in `c(2)`, and so on for further negative indices. The value c_1 is stored in `c(np)`, c_2 in `c(np-1)`, and so on for positive indices. This order may seem arcane, but it is the natural one where causal filters have nonzero coefficients in low array elements of `c`. It is also the order required by the subroutine `conv1v` in §13.1, which can be used to apply the digital filter to a data set.

The accompanying table shows some typical output from `savgol`. For orders 2 and 4, the coefficients of Savitzky-Golay filters with several choices of n_L and n_R are shown. The central column is the coefficient applied to the data f_i in obtaining the smoothed g_i . Coefficients to the left are applied to earlier data; to the right, to later. The coefficients always add (within roundoff error) to unity. One sees that, as befits a smoothing operator, the coefficients always have a central positive lobe, but with smaller, outlying corrections of both positive and negative sign. In practice, the Savitzky-Golay filters are most useful for much larger values of n_L and n_R , since these few-point formulas can accomplish only a relatively small amount of smoothing.

Figure 14.8.1 shows a numerical experiment using a 33 point smoothing filter, that is, $n_L = n_R = 16$. The upper panel shows a test function, constructed to have six “bumps” of varying widths, all of height 8 units. To this function Gaussian white noise of unit variance has been added. (The test function without noise is shown as the dotted curves in the center and lower panels.) The widths of the bumps (full width at half of maximum, or FWHM) are 140, 43, 24, 17, 13, and 10, respectively.

The middle panel of Figure 14.8.1 shows the result of smoothing by a moving window

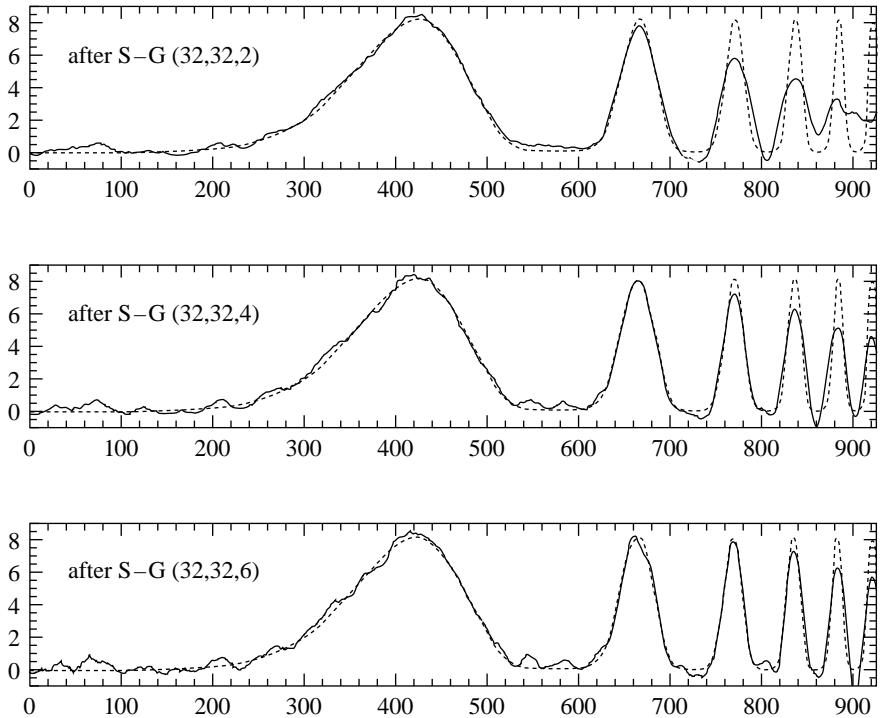

Figure 14.8.2. Result of applying wider 65 point Savitzky-Golay filters to the same data set as in Figure 14.8.1. Top: degree 2. Center: degree 4. Bottom: degree 6. All of these filters are inoptimally broad for the resolution of the narrow features. Higher-order filters do best at preserving feature heights and widths, but do less smoothing on broader features.

average. One sees that the window of width 33 does quite a nice job of smoothing the broadest bump, but that the narrower bumps suffer considerable loss of height and increase of width. The underlying signal (dotted) is very badly represented.

The lower panel shows the result of smoothing with a Savitzky-Golay filter of the identical width, and degree $M = 4$. One sees that the heights and widths of the bumps are quite extraordinarily preserved. A trade-off is that the broadest bump is less smoothed. That is because the central positive lobe of the Savitzky-Golay filter coefficients fills only a fraction of the full 33 point width. As a rough guideline, best results are obtained when the full width of the degree 4 Savitzky-Golay filter is between 1 and 2 times the FWHM of desired features in the data. (References [3] and [4] give additional practical hints.)

Figure 14.8.2 shows the result of smoothing the same noisy “data” with broader Savitzky-Golay filters of 3 different orders. Here we have $n_L = n_R = 32$ (65 point filter) and $M = 2, 4, 6$. One sees that, when the bumps are too narrow with respect to the filter size, then even the Savitzky-Golay filter must at some point give out. The higher order filter manages to track narrower features, but at the cost of less smoothing on broad features.

To summarize: Within limits, Savitzky-Golay filtering does manage to provide smoothing without loss of resolution. It does this by assuming that relatively distant data points have some significant redundancy that can be used to reduce the level of noise. The specific nature of the assumed redundancy is that the underlying function should be locally well-fitted by a polynomial. When this is true, as it is for smooth line profiles not too much narrower than the filter width, then the performance of Savitzky-Golay filters can be spectacular. When it is not true, then these filters have no compelling advantage over other classes of smoothing filter coefficients.

A last remark concerns irregularly sampled data, where the values f_i are not uniformly spaced in time. The obvious generalization of Savitzky-Golay filtering would be to do a

least-squares fit within a moving window around each data point, one containing a fixed number of data points to the left (n_L) and right (n_R). Because of the irregular spacing, however, there is no way to obtain universal filter coefficients applicable to more than one data point. One must instead do the actual least-squares fits for each data point. This becomes computationally burdensome for larger n_L , n_R , and M .

As a cheap alternative, one can simply pretend that the data points *are* equally spaced. This amounts to virtually shifting, within each moving window, the data points to equally spaced positions. Such a shift introduces the equivalent of an additional source of noise into the function values. In those cases where smoothing is useful, this noise will often be much smaller than the noise already present. Specifically, if the location of the points is approximately random within the window, then a rough criterion is this: If the change in f across the full width of the $N = n_L + n_R + 1$ point window is less than $\sqrt{N/2}$ times the measurement noise on a single point, then the cheap method can be used.

Chapter 15. Modeling of Data

15.0 Introduction

Given a set of observations, one often wants to condense and summarize the data by fitting it to a “model” that depends on adjustable parameters. Sometimes the model is simply a convenient class of functions, such as polynomials or Gaussians, and the fit supplies the appropriate coefficients. Other times, the model’s parameters come from some underlying theory that the data are supposed to satisfy; examples are coefficients of rate equations in a complex network of chemical reactions, or orbital elements of a binary star. Modeling can also be used as a kind of constrained interpolation, where you want to extend a few data points into a continuous function, but with some underlying idea of what that function should look like.

The basic approach in all cases is usually the same: You choose or design a *figure-of-merit function* (“merit function,” for short) that measures the agreement between the data and the model with a particular choice of parameters. The merit function is conventionally arranged so that small values represent close agreement. The parameters of the model are then adjusted to achieve a minimum in the merit function, yielding *best-fit parameters*. The adjustment process is thus a problem in minimization in many dimensions. This optimization was the subject of Chapter 10; however, there exist special, more efficient, methods that are specific to modeling, and we will discuss these in this chapter.

There are important issues that go beyond the mere finding of best-fit parameters. Data are generally not exact. They are subject to *measurement errors* (called *noise* in the context of signal-processing). Thus, typical data never exactly fit the model that is being used, even when that model is correct. We need the means to assess whether or not the model is appropriate, that is, we need to test the *goodness-of-fit* against some useful statistical standard.

We usually also need to know the accuracy with which parameters are determined by the data set. In other words, we need to know the likely errors of the best-fit parameters.

Finally, it is not uncommon in fitting data to discover that the merit function is not unimodal, with a single minimum. In some cases, we may be interested in global rather than local questions. Not, “how good is this fit?” but rather, “how sure am I that there is not a *very much better* fit in some corner of parameter space?” As we have seen in Chapter 10, especially §10.9, this kind of problem is generally quite difficult to solve.

The important message we want to deliver is that fitting of parameters is not the end-all of parameter estimation. To be genuinely useful, a fitting procedure

should provide (i) parameters, (ii) error estimates on the parameters, and (iii) a statistical measure of goodness-of-fit. When the third item suggests that the model is an unlikely match to the data, then items (i) and (ii) are probably worthless. Unfortunately, many practitioners of parameter estimation never proceed beyond item (i). They deem a fit acceptable if a graph of data and model “looks good.” This approach is known as *chi-by-eye*. Luckily, its practitioners get what they deserve.

15.1 Least Squares as a Maximum Likelihood Estimator

Suppose that we are fitting N data points (x_i, y_i) $i = 1, \dots, N$, to a model that has M adjustable parameters a_j , $j = 1, \dots, M$. The model predicts a functional relationship between the measured independent and dependent variables,

$$y(x) = y(x; a_1 \dots a_M) \quad (15.1.1)$$

where the dependence on the parameters is indicated explicitly on the right-hand side.

What, exactly, do we want to minimize to get fitted values for the a_j 's? The first thing that comes to mind is the familiar least-squares fit,

$$\text{minimize over } a_1 \dots a_M : \quad \sum_{i=1}^N [y_i - y(x_i; a_1 \dots a_M)]^2 \quad (15.1.2)$$

But where does this come from? What general principles is it based on? The answer to these questions takes us into the subject of *maximum likelihood estimators*.

Given a particular data set of x_i 's and y_i 's, we have the intuitive feeling that some parameter sets $a_1 \dots a_M$ are very unlikely — those for which the model function $y(x)$ looks *nothing like* the data — while others may be very likely — those that closely resemble the data. How can we quantify this intuitive feeling? How can we select fitted parameters that are “most likely” to be correct? It is not meaningful to ask the question, “What is the probability that a particular set of fitted parameters $a_1 \dots a_M$ is correct?” The reason is that there is no statistical universe of models from which the parameters are drawn. There is just one model, the correct one, and a statistical universe of data sets that are drawn from it!

15.1 Least Squares as a Maximum Likelihood Estimator

Suppose that we are fitting N data points (x_i, y_i) $i = 1, \dots, N$, to a model that has M adjustable parameters a_j , $j = 1, \dots, M$. The model predicts a functional relationship between the measured independent and dependent variables,

$$y(x) = y(x; a_1 \dots a_M) \quad (15.1.1)$$

where the dependence on the parameters is indicated explicitly on the right-hand side.

What, exactly, do we want to minimize to get fitted values for the a_j 's? The first thing that comes to mind is the familiar least-squares fit,

$$\text{minimize over } a_1 \dots a_M : \quad \sum_{i=1}^N [y_i - y(x_i; a_1 \dots a_M)]^2 \quad (15.1.2)$$

But where does this come from? What general principles is it based on? The answer to these questions takes us into the subject of *maximum likelihood estimators*.

Given a particular data set of x_i 's and y_i 's, we have the intuitive feeling that some parameter sets $a_1 \dots a_M$ are very unlikely — those for which the model function $y(x)$ looks *nothing like* the data — while others may be very likely — those that closely resemble the data. How can we quantify this intuitive feeling? How can we select fitted parameters that are “most likely” to be correct? It is not meaningful to ask the question, “What is the probability that a particular set of fitted parameters $a_1 \dots a_M$ is correct?” The reason is that there is no statistical universe of models from which the parameters are drawn. There is just one model, the correct one, and a statistical universe of data sets that are drawn from it!

That being the case, we can, however, turn the question around, and ask, “*Given a particular set of parameters*, what is the probability that this data set could have occurred?” If the y_i ’s take on continuous values, the probability will always be zero unless we add the phrase, “...plus or minus some fixed Δy on each data point.” So let’s always take this phrase as understood. If the probability of obtaining the data set is infinitesimally small, then we can conclude that the parameters under consideration are “unlikely” to be right. Conversely, our intuition tells us that the data set should not be too improbable for the correct choice of parameters.

In other words, we identify the probability of the data given the parameters (which is a mathematically computable number), as the *likelihood* of the parameters given the data. This identification is entirely based on intuition. It has no formal mathematical basis in and of itself; as we already remarked, statistics is *not* a branch of mathematics!

Once we make this intuitive identification, however, it is only a small further step to decide to fit for the parameters $a_1 \dots a_M$ precisely by finding those values that *maximize* the likelihood defined in the above way. This form of parameter estimation is *maximum likelihood estimation*.

We are now ready to make the connection to (15.1.2). Suppose that each data point y_i has a measurement error that is independently random and distributed as a normal (Gaussian) distribution around the “true” model $y(x)$. And suppose that the standard deviations σ of these normal distributions are the same for all points. Then the probability of the data set is the product of the probabilities of each point,

$$P \propto \prod_{i=1}^N \left\{ \exp \left[-\frac{1}{2} \left(\frac{y_i - y(x_i)}{\sigma} \right)^2 \right] \Delta y \right\} \quad (15.1.3)$$

Notice that there is a factor Δy in each term in the product. Maximizing (15.1.3) is equivalent to maximizing its logarithm, or minimizing the negative of its logarithm, namely,

$$\left[\sum_{i=1}^N \frac{[y_i - y(x_i)]^2}{2\sigma^2} \right] - N \log \Delta y \quad (15.1.4)$$

Since N , σ , and Δy are all constants, minimizing this equation is equivalent to minimizing (15.1.2).

What we see is that least-squares fitting *is* a maximum likelihood estimation of the fitted parameters *if* the measurement errors are independent and normally distributed with constant standard deviation. Notice that we made no assumption about the linearity or nonlinearity of the model $y(x; a_1 \dots)$ in its parameters $a_1 \dots a_M$. Just below, we will relax our assumption of constant standard deviations and obtain the very similar formulas for what is called “chi-square fitting” or “weighted least-squares fitting.” First, however, let us discuss further our very stringent assumption of a normal distribution.

For a hundred years or so, mathematical statisticians have been in love with the fact that the probability distribution of the sum of a very large number of very small random deviations almost always converges to a normal distribution. (For precise statements of this *central limit theorem*, consult [1] or other standard works

on mathematical statistics.) This infatuation tended to focus interest away from the fact that, for real data, the normal distribution is often rather poorly realized, if it is realized at all. We are often taught, rather casually, that, on average, measurements will fall within $\pm\sigma$ of the true value 68 percent of the time, within $\pm 2\sigma$ 95 percent of the time, and within $\pm 3\sigma$ 99.7 percent of the time. Extending this, one would expect a measurement to be off by $\pm 20\sigma$ only one time out of 2×10^{88} . We all know that “glitches” are much more likely than *that!*

In some instances, the deviations from a normal distribution are easy to understand and quantify. For example, in measurements obtained by counting events, the measurement errors are usually distributed as a Poisson distribution, whose cumulative probability function was already discussed in §6.2. When the number of counts going into one data point is large, the Poisson distribution converges towards a Gaussian. However, the convergence is not uniform when measured in fractional accuracy. The more standard deviations out on the tail of the distribution, the larger the number of counts must be before a value close to the Gaussian is realized. The sign of the effect is always the same: The Gaussian predicts that “tail” events are much less likely than they actually (by Poisson) are. This causes such events, when they occur, to skew a least-squares fit much more than they ought.

Other times, the deviations from a normal distribution are not so easy to understand in detail. Experimental points are occasionally just *way off*. Perhaps the power flickered during a point’s measurement, or someone kicked the apparatus, or someone wrote down a wrong number. Points like this are called *outliers*. They can easily turn a least-squares fit on otherwise adequate data into nonsense. Their probability of occurrence in the assumed Gaussian model is so small that the maximum likelihood estimator is willing to distort the whole curve to try to bring them, mistakenly, into line.

The subject of *robust statistics* deals with cases where the normal or Gaussian model is a bad approximation, or cases where outliers are important. We will discuss robust methods briefly in §15.7. All the sections between this one and that one assume, one way or the other, a Gaussian model for the measurement errors in the data. It is quite important that you keep the limitations of that model in mind, even as you use the very useful methods that follow from assuming it.

Finally, note that our discussion of measurement errors has been limited to *statistical* errors, the kind that will average away if we only take enough data. Measurements are also susceptible to *systematic* errors that will not go away with any amount of averaging. For example, the calibration of a metal meter stick might depend on its temperature. If we take all our measurements at the same wrong temperature, then no amount of averaging or numerical processing will correct for this unrecognized systematic error.

Chi-Square Fitting

We considered the chi-square statistic once before, in §14.3. Here it arises in a slightly different context.

If each data point (x_i, y_i) has its own, known standard deviation σ_i , then equation (15.1.3) is modified only by putting a subscript i on the symbol σ . That subscript also propagates docilely into (15.1.4), so that the maximum likelihood

estimate of the model parameters is obtained by minimizing the quantity

$$\chi^2 \equiv \sum_{i=1}^N \left(\frac{y_i - y(x_i; a_1 \dots a_M)}{\sigma_i} \right)^2 \quad (15.1.5)$$

called the “chi-square.”

To whatever extent the measurement errors actually *are* normally distributed, the quantity χ^2 is correspondingly a sum of N squares of normally distributed quantities, each normalized to unit variance. Once we have adjusted the $a_1 \dots a_M$ to minimize the value of χ^2 , the terms in the sum are not all statistically independent. For models that are linear in the a ’s, however, it turns out that the probability distribution for different values of χ^2 at its minimum can nevertheless be derived analytically, and is the *chi-square distribution for $N - M$ degrees of freedom*. We learned how to compute this probability function using the incomplete gamma function `gammq` in §6.2. In particular, equation (6.2.18) gives the probability Q that the chi-square should exceed a particular value χ^2 by chance, where $\nu = N - M$ is the *number of degrees of freedom*. The quantity Q , or its complement $P \equiv 1 - Q$, is frequently tabulated in appendices to statistics books, but we generally find it easier to use `gammq` and compute our own values: $Q = \text{gammq}(0.5\nu, 0.5\chi^2)$. It is quite common, and usually not too wrong, to assume that the chi-square distribution holds even for models that are not strictly linear in the a ’s.

This computed probability gives a quantitative measure for the goodness-of-fit of the model. If Q is a very small probability for some particular data set, then the apparent discrepancies are unlikely to be chance fluctuations. Much more probably either (i) the model is wrong — can be statistically rejected, or (ii) someone has lied to you about the size of the measurement errors σ_i — they are really larger than stated.

It is an important point that the chi-square probability Q does not directly measure the credibility of the assumption that the measurement errors are normally distributed. It assumes they are. In most, but not all, cases, however, the effect of nonnormal errors is to create an abundance of outlier points. These decrease the probability Q , so that we can add another possible, though less definitive, conclusion to the above list: (iii) the measurement errors may not be normally distributed.

Possibility (iii) is fairly common, and also fairly benign. It is for this reason that reasonable experimenters are often rather tolerant of low probabilities Q . It is not uncommon to deem acceptable on equal terms any models with, say, $Q > 0.001$. This is not as sloppy as it sounds: Truly *wrong* models will often be rejected with vastly smaller values of Q , 10^{-18} , say. However, if day-in and day-out you find yourself accepting models with $Q \sim 10^{-3}$, you really should track down the cause.

If you happen to know the actual distribution law of your measurement errors, then you might wish to *Monte Carlo simulate* some data sets drawn from a particular model, cf. §7.2–§7.3. You can then subject these synthetic data sets to your actual fitting procedure, so as to determine both the probability distribution of the χ^2 statistic, and also the accuracy with which your model parameters are reproduced by the fit. We discuss this further in §15.6. The technique is very general, but it can also be very expensive.

At the opposite extreme, it sometimes happens that the probability Q is too large, too near to 1, literally too good to be true! Nonnormal measurement errors cannot in general produce this disease, since the normal distribution is about as “compact”

as a distribution can be. Almost always, the cause of too good a chi-square fit is that the experimenter, in a “fit” of conservatism, has *overestimated* his or her measurement errors. Very rarely, too good a chi-square signals actual fraud, data that has been “fudged” to fit the model.

A rule of thumb is that a “typical” value of χ^2 for a “moderately” good fit is $\chi^2 \approx \nu$. More precise is the statement that the χ^2 statistic has a mean ν and a standard deviation $\sqrt{2\nu}$, and, asymptotically for large ν , becomes normally distributed.

In some cases the uncertainties associated with a set of measurements are not known in advance, and considerations related to χ^2 fitting are used to derive a value for σ . If we assume that all measurements have the same standard deviation, $\sigma_i = \sigma$, and that the model does fit well, then we can proceed by first assigning an arbitrary constant σ to all points, next fitting for the model parameters by minimizing χ^2 , and finally recomputing

$$\sigma^2 = \sum_{i=1}^N [y_i - y(x_i)]^2 / (N - M) \quad (15.1.6)$$

Obviously, this approach prohibits an independent assessment of goodness-of-fit, a fact occasionally missed by its adherents. When, however, the measurement error is not known, this approach at least allows *some* kind of error bar to be assigned to the points.

If we take the derivative of equation (15.1.5) with respect to the parameters a_k , we obtain equations that must hold at the chi-square minimum,

$$0 = \sum_{i=1}^N \left(\frac{y_i - y(x_i)}{\sigma_i^2} \right) \left(\frac{\partial y(x_i; \dots a_k \dots)}{\partial a_k} \right) \quad k = 1, \dots, M \quad (15.1.7)$$

Equation (15.1.7) is, in general, a set of M nonlinear equations for the M unknown a_k . Various of the procedures described subsequently in this chapter derive from (15.1.7) and its specializations.

15.2 Fitting Data to a Straight Line

A concrete example will make the considerations of the previous section more meaningful. We consider the problem of fitting a set of N data points (x_i, y_i) to a straight-line model

$$y(x) = y(x; a, b) = a + bx \quad (15.2.1)$$

as a distribution can be. Almost always, the cause of too good a chi-square fit is that the experimenter, in a “fit” of conservatism, has *overestimated* his or her measurement errors. Very rarely, too good a chi-square signals actual fraud, data that has been “fudged” to fit the model.

A rule of thumb is that a “typical” value of χ^2 for a “moderately” good fit is $\chi^2 \approx \nu$. More precise is the statement that the χ^2 statistic has a mean ν and a standard deviation $\sqrt{2\nu}$, and, asymptotically for large ν , becomes normally distributed.

In some cases the uncertainties associated with a set of measurements are not known in advance, and considerations related to χ^2 fitting are used to derive a value for σ . If we assume that all measurements have the same standard deviation, $\sigma_i = \sigma$, and that the model does fit well, then we can proceed by first assigning an arbitrary constant σ to all points, next fitting for the model parameters by minimizing χ^2 , and finally recomputing

$$\sigma^2 = \sum_{i=1}^N [y_i - y(x_i)]^2 / (N - M) \quad (15.1.6)$$

Obviously, this approach prohibits an independent assessment of goodness-of-fit, a fact occasionally missed by its adherents. When, however, the measurement error is not known, this approach at least allows *some* kind of error bar to be assigned to the points.

If we take the derivative of equation (15.1.5) with respect to the parameters a_k , we obtain equations that must hold at the chi-square minimum,

$$0 = \sum_{i=1}^N \left(\frac{y_i - y(x_i)}{\sigma_i^2} \right) \left(\frac{\partial y(x_i; \dots a_k \dots)}{\partial a_k} \right) \quad k = 1, \dots, M \quad (15.1.7)$$

Equation (15.1.7) is, in general, a set of M nonlinear equations for the M unknown a_k . Various of the procedures described subsequently in this chapter derive from (15.1.7) and its specializations.

15.2 Fitting Data to a Straight Line

A concrete example will make the considerations of the previous section more meaningful. We consider the problem of fitting a set of N data points (x_i, y_i) to a straight-line model

$$y(x) = y(x; a, b) = a + bx \quad (15.2.1)$$

This problem is often called *linear regression*, a terminology that originated, long ago, in the social sciences. We assume that the uncertainty σ_i associated with each measurement y_i is known, and that the x_i 's (values of the dependent variable) are known exactly.

To measure how well the model agrees with the data, we use the chi-square merit function (15.1.5), which in this case is

$$\chi^2(a, b) = \sum_{i=1}^N \left(\frac{y_i - a - bx_i}{\sigma_i} \right)^2 \quad (15.2.2)$$

If the measurement errors are normally distributed, then this merit function will give maximum likelihood parameter estimations of a and b ; if the errors are not normally distributed, then the estimations are not maximum likelihood, but may still be useful in a practical sense. In §15.7, we will treat the case where outlier points are so numerous as to render the χ^2 merit function useless.

Equation (15.2.2) is minimized to determine a and b . At its minimum, derivatives of $\chi^2(a, b)$ with respect to a, b vanish.

$$\begin{aligned} 0 &= \frac{\partial \chi^2}{\partial a} = -2 \sum_{i=1}^N \frac{y_i - a - bx_i}{\sigma_i^2} \\ 0 &= \frac{\partial \chi^2}{\partial b} = -2 \sum_{i=1}^N \frac{x_i(y_i - a - bx_i)}{\sigma_i^2} \end{aligned} \quad (15.2.3)$$

These conditions can be rewritten in a convenient form if we define the following sums:

$$\begin{aligned} S &\equiv \sum_{i=1}^N \frac{1}{\sigma_i^2} & S_x &\equiv \sum_{i=1}^N \frac{x_i}{\sigma_i^2} & S_y &\equiv \sum_{i=1}^N \frac{y_i}{\sigma_i^2} \\ S_{xx} &\equiv \sum_{i=1}^N \frac{x_i^2}{\sigma_i^2} & S_{xy} &\equiv \sum_{i=1}^N \frac{x_i y_i}{\sigma_i^2} \end{aligned} \quad (15.2.4)$$

With these definitions (15.2.3) becomes

$$\begin{aligned} aS + bS_x &= S_y \\ aS_x + bS_{xx} &= S_{xy} \end{aligned} \quad (15.2.5)$$

The solution of these two equations in two unknowns is calculated as

$$\begin{aligned} \Delta &\equiv SS_{xx} - (S_x)^2 \\ a &= \frac{S_{xx}S_y - S_xS_{xy}}{\Delta} \\ b &= \frac{SS_{xy} - S_xS_y}{\Delta} \end{aligned} \quad (15.2.6)$$

Equation (15.2.6) gives the solution for the best-fit model parameters a and b .

We are not done, however. We must estimate the probable uncertainties in the estimates of a and b , since obviously the measurement errors in the data must introduce some uncertainty in the determination of those parameters. If the data are independent, then each contributes its own bit of uncertainty to the parameters. Consideration of propagation of errors shows that the variance σ_f^2 in the value of any function will be

$$\sigma_f^2 = \sum_{i=1}^N \sigma_i^2 \left(\frac{\partial f}{\partial y_i} \right)^2 \quad (15.2.7)$$

For the straight line, the derivatives of a and b with respect to y_i can be directly evaluated from the solution:

$$\begin{aligned} \frac{\partial a}{\partial y_i} &= \frac{S_{xx} - S_x x_i}{\sigma_i^2 \Delta} \\ \frac{\partial b}{\partial y_i} &= \frac{Sx_i - S_x}{\sigma_i^2 \Delta} \end{aligned} \quad (15.2.8)$$

Summing over the points as in (15.2.7), we get

$$\begin{aligned} \sigma_a^2 &= S_{xx}/\Delta \\ \sigma_b^2 &= S/\Delta \end{aligned} \quad (15.2.9)$$

which are the variances in the estimates of a and b , respectively. We will see in §15.6 that an additional number is also needed to characterize properly the probable uncertainty of the parameter estimation. That number is the *covariance* of a and b , and (as we will see below) is given by

$$\text{Cov}(a, b) = -S_x/\Delta \quad (15.2.10)$$

The coefficient of correlation between the uncertainty in a and the uncertainty in b , which is a number between -1 and 1 , follows from (15.2.10) (compare equation 14.5.1),

$$r_{ab} = \frac{-S_x}{\sqrt{SS_{xx}}} \quad (15.2.11)$$

A positive value of r_{ab} indicates that the errors in a and b are likely to have the same sign, while a negative value indicates the errors are anticorrelated, likely to have opposite signs.

We are *still* not done. We must estimate the goodness-of-fit of the data to the model. Absent this estimate, we have not the slightest indication that the parameters a and b in the model have any meaning at all! The probability Q that a value of chi-square as *poor* as the value (15.2.2) should occur by chance is

$$Q = \text{gammq} \left(\frac{N-2}{2}, \frac{\chi^2}{2} \right) \quad (15.2.12)$$

Here `gammq` is our routine for the incomplete gamma function $Q(a, x)$, §6.2. If Q is larger than, say, 0.1, then the goodness-of-fit is believable. If it is larger than, say, 0.001, then the fit *may* be acceptable if the errors are nonnormal or have been moderately underestimated. If Q is less than 0.001 then the model and/or estimation procedure can rightly be called into question. In this latter case, turn to §15.7 to proceed further.

If you do not know the individual measurement errors of the points σ_i , and are proceeding (dangerously) to use equation (15.1.6) for estimating these errors, then here is the procedure for estimating the probable uncertainties of the parameters a and b : Set $\sigma_i \equiv 1$ in all equations through (15.2.6), and multiply σ_a and σ_b , as obtained from equation (15.2.9), by the additional factor $\sqrt{\chi^2/(N-2)}$, where χ^2 is computed by (15.2.2) using the fitted parameters a and b . As discussed above, this procedure is equivalent to *assuming* a good fit, so you get no independent goodness-of-fit probability Q .

In §14.5 we promised a relation between the linear correlation coefficient r (equation 14.5.1) and a goodness-of-fit measure, χ^2 (equation 15.2.2). For unweighted data (all $\sigma_i = 1$), that relation is

$$\chi^2 = (1 - r^2)\text{NVar}(y_1 \dots y_N) \quad (15.2.13)$$

where

$$\text{NVar}(y_1 \dots y_N) \equiv \sum_{i=1}^N (y_i - \bar{y})^2 \quad (15.2.14)$$

For data with varying weights σ_i , the above equations remain valid if the sums in equation (14.5.1) are weighted by $1/\sigma_i^2$.

The following subroutine, `fit`, carries out exactly the operations that we have discussed. When the weights σ are known in advance, the calculations exactly correspond to the formulas above. However, when weights σ are unavailable, the routine *assumes* equal values of σ for each point and *assumes* a good fit, as discussed in §15.1.

The formulas (15.2.6) are susceptible to roundoff error. Accordingly, we rewrite them as follows: Define

$$t_i = \frac{1}{\sigma_i} \left(x_i - \frac{S_x}{S} \right), \quad i = 1, 2, \dots, N \quad (15.2.15)$$

and

$$S_{tt} = \sum_{i=1}^N t_i^2 \quad (15.2.16)$$

Then, as you can verify by direct substitution,

$$b = \frac{1}{S_{tt}} \sum_{i=1}^N \frac{t_i y_i}{\sigma_i} \quad (15.2.17)$$

$$a = \frac{S_y - S_x b}{S} \quad (15.2.18)$$

$$\sigma_a^2 = \frac{1}{S} \left(1 + \frac{S_x^2}{SS_{tt}} \right) \quad (15.2.19)$$

$$\sigma_b^2 = \frac{1}{S_{tt}} \quad (15.2.20)$$

$$\text{Cov}(a, b) = -\frac{S_x}{SS_{tt}} \quad (15.2.21)$$

$$r_{ab} = \frac{\text{Cov}(a, b)}{\sigma_a \sigma_b} \quad (15.2.22)$$

```

q=1.
if(mwt.eq.0) then
  do 15 i=1,ndata
    chi2=chi2+(y(i)-a-b*x(i))**2
  enddo 15
  sigdat=sqrt(chi2/(nndata-2))

15.3 Straight-Line Data with Errors in Both Coordinates

If experimental data are subject to measurement error not only in the y_i 's, but also in the x_i 's, then the task of fitting a straight-line model

$$y(x) = a + bx \quad (15.3.1)$$

is considerably harder. It is straightforward to write down the χ^2 merit function for this case,

$$\chi^2(a, b) = \sum_{i=1}^N \frac{(y_i - a - bx_i)^2}{\sigma_{y,i}^2 + b^2 \sigma_{x,i}^2} \quad (15.3.2)$$

where $\sigma_{x,i}$ and $\sigma_{y,i}$ are, respectively, the x and y standard deviations for the i th point. The weighted sum of variances in the denominator of equation (15.3.2) can be understood both as the variance in the direction of the smallest χ^2 between each data point and the line with slope b , and also as the variance of the linear combination $y_i - a - bx_i$ of two random variables x_i and y_i ,

$$\text{Var}(y_i - a - bx_i) = \text{Var}(y_i) + b^2 \text{Var}(x_i) = \sigma_{y,i}^2 + b^2 \sigma_{x,i}^2 \equiv 1/w_i \quad (15.3.3)$$

The sum of the square of N random variables, each normalized by its variance, is thus χ^2 -distributed.

We want to minimize equation (15.3.2) with respect to a and b . Unfortunately, the occurrence of b in the denominator of equation (15.3.2) makes the resulting equation for the slope $\partial\chi^2/\partial b = 0$ nonlinear. However, the corresponding condition for the intercept, $\partial\chi^2/\partial a = 0$, is still linear and yields

$$a = \left[\sum_i w_i (y_i - bx_i) \right] \Bigg/ \sum_i w_i \quad (15.3.4)$$

where the w_i 's are defined by equation (15.3.3). A reasonable strategy, now, is to use the machinery of Chapter 10 (e.g., the routine brent) for minimizing a general one-dimensional

```

q=1.

15.3 Straight-Line Data with Errors in Both Coordinates

If experimental data are subject to measurement error not only in the y_i 's, but also in the x_i 's, then the task of fitting a straight-line model

$$y(x) = a + bx \quad (15.3.1)$$

is considerably harder. It is straightforward to write down the χ^2 merit function for this case,

$$\chi^2(a, b) = \sum_{i=1}^N \frac{(y_i - a - bx_i)^2}{\sigma_{y,i}^2 + b^2 \sigma_{x,i}^2} \quad (15.3.2)$$

where $\sigma_{x,i}$ and $\sigma_{y,i}$ are, respectively, the x and y standard deviations for the i th point. The weighted sum of variances in the denominator of equation (15.3.2) can be understood both as the variance in the direction of the smallest χ^2 between each data point and the line with slope b , and also as the variance of the linear combination $y_i - a - bx_i$ of two random variables x_i and y_i ,

$$\text{Var}(y_i - a - bx_i) = \text{Var}(y_i) + b^2 \text{Var}(x_i) = \sigma_{y,i}^2 + b^2 \sigma_{x,i}^2 \equiv 1/w_i \quad (15.3.3)$$

The sum of the square of N random variables, each normalized by its variance, is thus χ^2 -distributed.

We want to minimize equation (15.3.2) with respect to a and b . Unfortunately, the occurrence of b in the denominator of equation (15.3.2) makes the resulting equation for the slope $\partial\chi^2/\partial b = 0$ nonlinear. However, the corresponding condition for the intercept, $\partial\chi^2/\partial a = 0$, is still linear and yields

$$a = \left[\sum_i w_i (y_i - bx_i) \right] \Bigg/ \sum_i w_i \quad (15.3.4)$$

where the w_i 's are defined by equation (15.3.3). A reasonable strategy, now, is to use the machinery of Chapter 10 (e.g., the routine brent) for minimizing a general one-dimensional

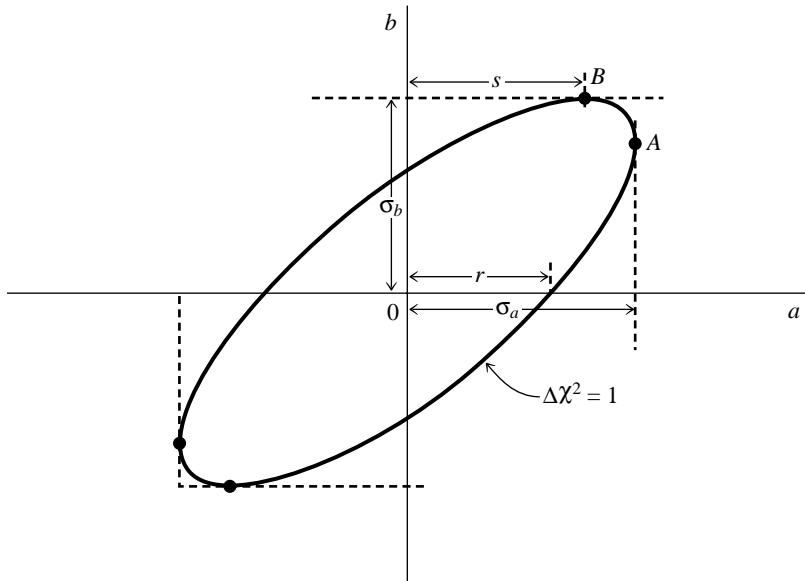

Figure 15.3.1. Standard errors for the parameters a and b . The point B can be found by varying the slope b while simultaneously minimizing the intercept a . This gives the standard error σ_b , and also the value s . The standard error σ_a can then be found by the geometric relation $\sigma_a^2 = s^2 + r^2$.

function to minimize with respect to b , while using equation (15.3.4) at each stage to ensure that the minimum with respect to b is also minimized with respect to a .

Because of the finite error bars on the x_i 's, the minimum χ^2 as a function of b will be finite, though usually large, when b equals infinity (line of infinite slope). The angle $\theta \equiv \arctan b$ is thus more suitable as a parametrization of slope than b itself. The value of χ^2 will then be periodic in θ with period π (not 2π !). If any data points have very small σ_{y_i} 's but moderate or large σ_{x_i} 's, then it is also possible to have a maximum in χ^2 near zero slope, $\theta \approx 0$. In that case, there can sometimes be two χ^2 minima, one at positive slope and the other at negative. Only one of these is the correct global minimum. It is therefore important to have a good starting guess for b (or θ). Our strategy, implemented below, is to scale the y_i 's so as to have variance equal to the x_i 's, then to do a conventional (as in §15.2) linear fit with weights derived from the (scaled) sum $\sigma_{y_i}^2 + \sigma_{x_i}^2$. This yields a good starting guess for b if the data are even *plausibly* related to a straight-line model.

Finding the standard errors σ_a and σ_b on the parameters a and b is more complicated. We will see in §15.6 that, in appropriate circumstances, the standard errors in a and b are the respective projections onto the a and b axes of the “confidence region boundary” where χ^2 takes on a value one greater than its minimum, $\Delta\chi^2 = 1$. In the linear case of §15.2, these projections follow from the Taylor series expansion

$$\Delta\chi^2 \approx \frac{1}{2} \left[\frac{\partial^2\chi^2}{\partial a^2} (\Delta a)^2 + \frac{\partial^2\chi^2}{\partial b^2} (\Delta b)^2 \right] + \frac{\partial^2\chi^2}{\partial a \partial b} \Delta a \Delta b \quad (15.3.5)$$

Because of the present nonlinearity in b , however, analytic formulas for the second derivatives are quite unwieldy; more important, the lowest-order term frequently gives a poor approximation to $\Delta\chi^2$. Our strategy is therefore to find the roots of $\Delta\chi^2 = 1$ numerically, by adjusting the value of the slope b away from the minimum. In the program below the general root finder `zbrent` is used. It may occur that there are no roots at all — for example, if all error bars are so large that all the data points are compatible with each other. It is important, therefore, to make some effort at bracketing a putative root before refining it (cf. §9.1).

Because a is minimized at each stage of varying b , successful numerical root-finding leads to a value of Δa that minimizes χ^2 for the value of Δb that gives $\Delta\chi^2 = 1$. This (see Figure 15.3.1) directly gives the tangent projection of the confidence region onto the b axis,

and thus σ_b . It does not, however, give the tangent projection of the confidence region onto the a axis. In the figure, we have found the point labeled B ; to find σ_a we need to find the point A . Geometry to the rescue: To the extent that the confidence region is approximated by an ellipse, then you can prove (see figure) that $\sigma_a^2 = r^2 + s^2$. The value of s is known from having found the point B . The value of r follows from equations (15.3.2) and (15.3.3) applied at the χ^2 minimum (point O in the figure), giving

$$r^2 = 1 \left/ \sum_i w_i \right. \quad (15.3.6)$$

Actually, since b can go through infinity, this whole procedure makes more sense in (a, θ) space than in (a, b) space. That is in fact how the following program works. Since it is conventional, however, to return standard errors for a and b , not a and θ , we finally use the relation

$$\sigma_b = \sigma_\theta / \cos^2 \theta \quad (15.3.7)$$

We caution that if b and its standard error are both large, so that the confidence region actually includes infinite slope, then the standard error σ_b is not very meaningful. The function `chixy` is normally called only by the routine `fitexy`. However, if you want, you can yourself explore the confidence region by making repeated calls to `chixy` (whose argument is an angle θ , not a slope b), after a single initializing call to `fitexy`.

A final caution, repeated from §15.0, is that if the goodness-of-fit is not acceptable (returned probability is too small), the standard errors σ_a and σ_b are surely not believable. In dire circumstances, you might try scaling all your x and y error bars by a constant factor until the probability is acceptable (0.5, say), to get more plausible values for σ_a and σ_b .

```
SUBROUTINE fitexy(x,y,ndat,sigx,sigy,a,b,siga,sigb,chi2,q)
INTEGER ndat,NMAX
REAL x(ndat),y(ndat),sigx(ndat),sigy(ndat),a,b,siga,sigb,chi2,
*      q,POTN,PI,BIG,ACC
PARAMETER (NMAX=1000,POTN=1.571000,BIG=1.e30,PI=3.14159265,
*      ACC=1.e-3)
C USES avevar,brent,chixy,fit,gammq,mnbrak,zbrent
Straight-line fit to input data x(1:ndat) and y(1:ndat) with errors in both x and y, the
respective standard deviations being the input quantities sigx(1:ndat) and sigy(1:ndat).
Output quantities are a and b such that y = a + bx minimizes  $\chi^2$ , whose value is returned
as chi2. The  $\chi^2$  probability is returned as q, a small value indicating a poor fit (sometimes
indicating underestimated errors). Standard errors on a and b are returned as siga and
sigb. These are not meaningful if either (i) the fit is poor, or (ii) b is so large that the
data are consistent with a vertical (infinite b) line. If siga and sigb are returned as BIG,
then the data are consistent with all values of b.

Be aware that the literature on the seemingly straightforward subject of this section is generally confusing and sometimes plain wrong. Deming's [1] early treatment is sound, but its reliance on Taylor expansions gives inaccurate error estimates. References [2-4] are reliable, more recent, general treatments with critiques of earlier work. York [5] and Reed [6] usefully discuss the simple case of a straight line as treated here, but the latter paper has some errors, corrected in [7]. All this commotion has attracted the Bayesians [8-10], who have still different points of view.

15.4 General Linear Least Squares

An immediate generalization of §15.2 is to fit a set of data points (x_i, y_i) to a model that is not just a linear combination of 1 and x (namely $a + bx$), but rather a linear combination of *any* M specified functions of x . For example, the functions could be $1, x, x^2, \dots, x^{M-1}$, in which case their general linear combination,

$$y(x) = a_1 + a_2 x + a_3 x^2 + \cdots + a_M x^{M-1} \quad (15.4.1)$$

is a polynomial of degree $M - 1$. Or, the functions could be sines and cosines, in which case their general linear combination is a harmonic series.

The general form of this kind of model is

$$y(x) = \sum_{k=1}^M a_k X_k(x) \quad (15.4.2)$$

where $X_1(x), \dots, X_M(x)$ are arbitrary fixed functions of x , called the *basis functions*.

Note that the functions $X_k(x)$ can be wildly nonlinear functions of x . In this discussion “linear” refers only to the model’s dependence on its *parameters* a_k .

For these linear models we generalize the discussion of the previous section by defining a merit function

$$\chi^2 = \sum_{i=1}^N \left[\frac{y_i - \sum_{k=1}^M a_k X_k(x_i)}{\sigma_i} \right]^2 \quad (15.4.3)$$

As before, σ_i is the measurement error (standard deviation) of the i th data point, presumed to be known. If the measurement errors are not known, they may all (as discussed at the end of §15.1) be set to the constant value $\sigma = 1$.

Once again, we will pick as best parameters those that minimize χ^2 . There are several different techniques available for finding this minimum. Two are particularly useful, and we will discuss both in this section. To introduce them and elucidate their relationship, we need some notation.

Let \mathbf{A} be a matrix whose $N \times M$ components are constructed from the M basis functions evaluated at the N abscissas x_i , and from the N measurement errors σ_i , by the prescription

$$A_{ij} = \frac{X_j(x_i)}{\sigma_i} \quad (15.4.4)$$

The matrix \mathbf{A} is called the *design matrix* of the fitting problem. Notice that in general \mathbf{A} has more rows than columns, $N \geq M$, since there must be more data points than model parameters to be solved for. (You can fit a straight line to two points, but not a very meaningful quintic!) The design matrix is shown schematically in Figure 15.4.1.

Also define a vector \mathbf{b} of length N by

$$b_i = \frac{y_i}{\sigma_i} \quad (15.4.5)$$

and denote the M vector whose components are the parameters to be fitted, a_1, \dots, a_M , by \mathbf{a} .

15.4 General Linear Least Squares

An immediate generalization of §15.2 is to fit a set of data points (x_i, y_i) to a model that is not just a linear combination of 1 and x (namely $a + bx$), but rather a linear combination of *any* M specified functions of x . For example, the functions could be $1, x, x^2, \dots, x^{M-1}$, in which case their general linear combination,

$$y(x) = a_1 + a_2 x + a_3 x^2 + \cdots + a_M x^{M-1} \quad (15.4.1)$$

is a polynomial of degree $M - 1$. Or, the functions could be sines and cosines, in which case their general linear combination is a harmonic series.

The general form of this kind of model is

$$y(x) = \sum_{k=1}^M a_k X_k(x) \quad (15.4.2)$$

where $X_1(x), \dots, X_M(x)$ are arbitrary fixed functions of x , called the *basis functions*.

Note that the functions $X_k(x)$ can be wildly nonlinear functions of x . In this discussion “linear” refers only to the model’s dependence on its *parameters* a_k .

For these linear models we generalize the discussion of the previous section by defining a merit function

$$\chi^2 = \sum_{i=1}^N \left[\frac{y_i - \sum_{k=1}^M a_k X_k(x_i)}{\sigma_i} \right]^2 \quad (15.4.3)$$

As before, σ_i is the measurement error (standard deviation) of the i th data point, presumed to be known. If the measurement errors are not known, they may all (as discussed at the end of §15.1) be set to the constant value $\sigma = 1$.

Once again, we will pick as best parameters those that minimize χ^2 . There are several different techniques available for finding this minimum. Two are particularly useful, and we will discuss both in this section. To introduce them and elucidate their relationship, we need some notation.

Let \mathbf{A} be a matrix whose $N \times M$ components are constructed from the M basis functions evaluated at the N abscissas x_i , and from the N measurement errors σ_i , by the prescription

$$A_{ij} = \frac{X_j(x_i)}{\sigma_i} \quad (15.4.4)$$

The matrix \mathbf{A} is called the *design matrix* of the fitting problem. Notice that in general \mathbf{A} has more rows than columns, $N \geq M$, since there must be more data points than model parameters to be solved for. (You can fit a straight line to two points, but not a very meaningful quintic!) The design matrix is shown schematically in Figure 15.4.1.

Also define a vector \mathbf{b} of length N by

$$b_i = \frac{y_i}{\sigma_i} \quad (15.4.5)$$

and denote the M vector whose components are the parameters to be fitted, a_1, \dots, a_M , by \mathbf{a} .

$$\begin{array}{c}
 \text{basis functions} \\
 \longleftarrow \qquad \longrightarrow \\
 X_1(\) \quad X_2(\) \quad \cdots \quad X_M(\)
 \end{array}$$

$$\begin{array}{c}
 x_1 \\
 x_2 \\
 \vdots \\
 x_N
 \end{array}
 \left(\begin{array}{cccc}
 \frac{X_1(x_1)}{\sigma_1} & \frac{X_2(x_1)}{\sigma_1} & \cdots & \frac{X_M(x_1)}{\sigma_1} \\
 \frac{X_1(x_2)}{\sigma_2} & \frac{X_2(x_2)}{\sigma_2} & \cdots & \frac{X_M(x_2)}{\sigma_2} \\
 \vdots & \vdots & & \vdots \\
 \vdots & \vdots & & \vdots
 \end{array} \right)$$

Figure 15.4.1. Design matrix for the least-squares fit of a linear combination of M basis functions to N data points. The matrix elements involve the basis functions evaluated at the values of the independent variable at which measurements are made, and the standard deviations of the measured dependent variable. The measured values of the dependent variable do not enter the design matrix.

Solution by Use of the Normal Equations

The minimum of (15.4.3) occurs where the derivative of χ^2 with respect to all M parameters a_k vanishes. Specializing equation (15.1.7) to the case of the model (15.4.2), this condition yields the M equations

$$0 = \sum_{i=1}^N \frac{1}{\sigma_i^2} \left[y_i - \sum_{j=1}^M a_j X_j(x_i) \right] X_k(x_i) \quad k = 1, \dots, M \quad (15.4.6)$$

Interchanging the order of summations, we can write (15.4.6) as the matrix equation

$$\sum_{j=1}^M \alpha_{kj} a_j = \beta_k \quad (15.4.7)$$

where

$$\alpha_{kj} = \sum_{i=1}^N \frac{X_j(x_i) X_k(x_i)}{\sigma_i^2} \quad \text{or equivalently} \quad [\alpha] = \mathbf{A}^T \cdot \mathbf{A} \quad (15.4.8)$$

an $M \times M$ matrix, and

$$\beta_k = \sum_{i=1}^N \frac{y_i X_k(x_i)}{\sigma_i^2} \quad \text{or equivalently} \quad [\beta] = \mathbf{A}^T \cdot \mathbf{b} \quad (15.4.9)$$

a vector of length M .

The equations (15.4.6) or (15.4.7) are called the *normal equations* of the least-squares problem. They can be solved for the vector of parameters \mathbf{a} by the standard methods of Chapter 2, notably LU decomposition and backsubstitution, Cholesky decomposition, or Gauss-Jordan elimination. In matrix form, the normal equations can be written as either

$$[\alpha] \cdot \mathbf{a} = [\beta] \quad \text{or as} \quad (\mathbf{A}^T \cdot \mathbf{A}) \cdot \mathbf{a} = \mathbf{A}^T \cdot \mathbf{b} \quad (15.4.10)$$

The inverse matrix $C_{jk} \equiv [\alpha]_{jk}^{-1}$ is closely related to the probable (or, more precisely, *standard*) uncertainties of the estimated parameters \mathbf{a} . To estimate these uncertainties, consider that

$$a_j = \sum_{k=1}^M [\alpha]_{jk}^{-1} \beta_k = \sum_{k=1}^M C_{jk} \left[\sum_{i=1}^N \frac{y_i X_k(x_i)}{\sigma_i^2} \right] \quad (15.4.11)$$

and that the variance associated with the estimate a_j can be found as in (15.2.7) from

$$\sigma^2(a_j) = \sum_{i=1}^N \sigma_i^2 \left(\frac{\partial a_j}{\partial y_i} \right)^2 \quad (15.4.12)$$

Note that α_{jk} is independent of y_i , so that

$$\frac{\partial a_j}{\partial y_i} = \sum_{k=1}^M C_{jk} X_k(x_i) / \sigma_i^2 \quad (15.4.13)$$

Consequently, we find that

$$\sigma^2(a_j) = \sum_{k=1}^M \sum_{l=1}^M C_{jk} C_{jl} \left[\sum_{i=1}^N \frac{X_k(x_i) X_l(x_i)}{\sigma_i^2} \right] \quad (15.4.14)$$

The final term in brackets is just the matrix $[\alpha]$. Since this is the matrix inverse of $[C]$, (15.4.14) reduces immediately to

$$\sigma^2(a_j) = C_{jj} \quad (15.4.15)$$

In other words, the diagonal elements of $[C]$ are the variances (squared uncertainties) of the fitted parameters \mathbf{a} . It should not surprise you to learn that the off-diagonal elements C_{jk} are the covariances between a_j and a_k (cf. 15.2.10); but we shall defer discussion of these to §15.6.

We will now give a routine that implements the above formulas for the general linear least-squares problem, by the method of normal equations. Since we wish to compute not only the solution vector \mathbf{a} but also the covariance matrix $[C]$, it is most convenient to use Gauss-Jordan elimination (routine `gaussj` of §2.1) to perform the linear algebra. The operation count, in this application, is no larger than that for LU decomposition. If you have no need for the covariance matrix, however, you can save a factor of 3 on the linear algebra by switching to LU decomposition, without

computation of the matrix inverse. In theory, since $\mathbf{A}^T \cdot \mathbf{A}$ is positive definite, Cholesky decomposition is the most efficient way to solve the normal equations. However, in practice most of the computing time is spent in looping over the data to form the equations, and Gauss-Jordan is quite adequate.

We need to warn you that the solution of a least-squares problem directly from the normal equations is rather susceptible to roundoff error. An alternative, and preferred, technique involves *QR* decomposition (§2.10, §11.3, and §11.6) of the design matrix \mathbf{A} . This is essentially what we did at the end of §15.2 for fitting data to a straight line, but without invoking all the machinery of *QR* to derive the necessary formulas. Later in this section, we will discuss other difficulties in the least-squares problem, for which the cure is *singular value decomposition* (SVD), of which we give an implementation. It turns out that SVD also fixes the roundoff problem, so it is our recommended technique for all but “easy” least-squares problems. It is for these easy problems that the following routine, which solves the normal equations, is intended.

The routine below introduces one bookkeeping trick that is quite useful in practical work. Frequently it is a matter of “art” to decide which parameters a_k in a model should be fit from the data set, and which should be held constant at fixed values, for example values predicted by a theory or measured in a previous experiment. One wants, therefore, to have a convenient means for “freezing” and “unfreezing” the parameters a_k . In the following routine the total number of parameters a_k is denoted ma (called M above). As input to the routine, you supply an array $ia(1:ma)$, whose components are either zero or nonzero (e.g., 1). Zeros indicate that you want the corresponding elements of the parameter vector $a(1:ma)$ to be held fixed at their input values. Nonzeros indicate parameters that should be fitted for. On output, any frozen parameters will have their variances, and all their covariances, set to zero in the covariance matrix.

```
SUBROUTINE lfit(x,y,sig,ndat,a,ia,ma,covar,npc,chisq,funcs)
INTEGER ma,ia(ma),npc,ndat,MMAX
REAL chisq,a(ma),covar(npc,npc),sig(ndat),x(ndat),y(ndat)
EXTERNAL funcs
PARAMETER (MMAX=50) Set to the maximum number of coefficients ma.
```

C USES covsrt,gaussj

Given a set of data points $x(1:ndat)$, $y(1:ndat)$ with individual standard deviations $sig(1:ndat)$, use χ^2 minimization to fit for some or all of the coefficients $a(1:ma)$ of a function that depends linearly on a , $y = \sum_i a_i \times afunc_i(x)$. The input array $ia(1:ma)$ indicates by nonzero entries those components of a that should be fitted for, and by zero entries those components that should be held fixed at their input values. The program returns values for $a(1:ma)$, $\chi^2 = chisq$, and the covariance matrix $covar(1:ma,1:ma)$. (Parameters held fixed will return zero covariances.) npc is the physical dimension of $covar(npc,npc)$ in the calling routine. The user supplies a subroutine $funcs(x,afunc,ma)$ that returns the ma basis functions evaluated at $x = x$ in the array $afunc$.

```
INTEGER i,j,k,l,m,mfit
REAL sig2i,sum,wt,ym,afunc(MMAX),beta(MMAX)
mfit=0
do 11 j=1,ma
    if(ia(j).ne.0) mfit=mfit+1
  enddo 11
if(mfit.eq.0) pause 'lfit: no parameters to be fitted'
do 13 j=1,mfit Initialize the (symmetric) matrix.
  do 12 k=1,mfit
    covar(j,k)=0.
  enddo 12
  beta(j)=0.
enddo 13
```

```

do 17 i=1,ndat           Loop over data to accumulate coefficients of the normal
  call funcs(x(i),afunc,ma)   equations.
  ym=y(i)
  if(mfit.lt.ma) then       Subtract off dependences on known pieces of the fitting
    do 14 j=1,ma             function.
      if(ia(j).eq.0) ym=ym-a(j)*afunc(j)
    enddo 14
  endif
  sig2i=1./sig(i)**2
  j=0
  do 16 l=1,ma
    if (ia(l).ne.0) then
      j=j+1
      wt=afunc(l)*sig2i
      k=0
      do 15 m=1,l
        if (ia(m).ne.0) then
          k=k+1
          covar(j,k)=covar(j,k)+wt*afunc(m)
        endif
      enddo 15
      beta(j)=beta(j)+ym*wt
    endif
  enddo 16
enddo 17
do 19 j=2,mfit           Fill in above the diagonal from symmetry.
  do 18 k=1,j-1
    covar(k,j)=covar(j,k)
  enddo 18
enddo 19
call gaussj(covar,mfit,npc,beta,1,1)  Matrix solution.
j=0
do 21 l=1,ma
  if(ia(l).ne.0) then
    j=j+1
    a(l)=beta(j)           Partition solution to appropriate coefficients a.
  endif
enddo 21
chisq=0.                   Evaluate  $\chi^2$  of the fit.
do 23 i=1,ndat
  call funcs(x(i),afunc,ma)
  sum=0.
  do 22 j=1,ma
    sum=sum+a(j)*afunc(j)
  enddo 22
  chisq=chisq+((y(i)-sum)/sig(i))**2
enddo 23
call covsrt(covar,npc,ma,ia,mfit)      Sort covariance matrix to true order of fitting
return                               coefficients.
END

```

That last call to a subroutine `covsrt` is only for the purpose of spreading the covariances back into the full $ma \times ma$ covariance matrix, in the proper rows and columns and with zero variances and covariances set for variables which were held frozen.

The subroutine `covsrt` is as follows.

```

SUBROUTINE covsrt(covar,npc,ma,ia,mfit)
INTEGER ma,mfit,npc,ia(ma)
REAL covar(npc,npc)
Expand in storage the covariance matrix covar, so as to take into account parameters that
are being held fixed. (For the latter, return zero covariances.)
INTEGER i,j,k
REAL swap

```

```

do 12 i=mfit+1,ma
  do 11 j=1,i
    covar(i,j)=0.
    covar(j,i)=0.
  enddo 11
enddo 12
k=mfit
do 15 j=ma,1,-1
  if(ia(j).ne.0)then
    do 13 i=1,ma
      swap=covar(i,k)
      covar(i,k)=covar(i,j)
      covar(i,j)=swap
    enddo 13
    do 14 i=1,ma
      swap=covar(k,i)
      covar(k,i)=covar(j,i)
      covar(j,i)=swap
    enddo 14
    k=k-1
  endif
enddo 15
return
END

```

Solution by Use of Singular Value Decomposition

In some applications, the normal equations are perfectly adequate for linear least-squares problems. However, in many cases the normal equations are very close to singular. A zero pivot element may be encountered during the solution of the linear equations (e.g., in `gaussj`), in which case you get no solution at all. Or a very small pivot may occur, in which case you typically get fitted parameters a_k with very large magnitudes that are delicately (and unstably) balanced to cancel out almost precisely when the fitted function is evaluated.

Why does this commonly occur? The reason is that, more often than experimenters would like to admit, data do not clearly distinguish between two or more of the basis functions provided. If two such functions, or two different combinations of functions, happen to fit the data about equally well — or equally badly — then the matrix $[\alpha]$, unable to distinguish between them, neatly folds up its tent and becomes singular. There is a certain mathematical irony in the fact that least-squares problems are *both* overdetermined (number of data points greater than number of parameters) *and* underdetermined (ambiguous combinations of parameters exist); but that is how it frequently is. The ambiguities can be extremely hard to notice *a priori* in complicated problems.

Enter singular value decomposition (SVD). This would be a good time for you to review the material in §2.6, which we will not repeat here. In the case of an overdetermined system, SVD produces a solution that is the best approximation in the least-squares sense, cf. equation (2.6.10). That is exactly what we want. In the case of an underdetermined system, SVD produces a solution whose values (for us, the a_k 's) are smallest in the least-squares sense, cf. equation (2.6.8). That is also what we want: When some combination of basis functions is irrelevant to the fit, that combination will be driven down to a small, innocuous, value, rather than pushed up to delicately canceling infinities.

In terms of the design matrix \mathbf{A} (equation 15.4.4) and the vector \mathbf{b} (equation 15.4.5), minimization of χ^2 in (15.4.3) can be written as

$$\text{find } \mathbf{a} \quad \text{that minimizes} \quad \chi^2 = |\mathbf{A} \cdot \mathbf{a} - \mathbf{b}|^2 \quad (15.4.16)$$

Comparing to equation (2.6.9), we see that this is precisely the problem that routines svdcmp and svbksb are designed to solve. The solution, which is given by equation (2.6.12), can be rewritten as follows: If \mathbf{U} and \mathbf{V} enter the SVD decomposition of \mathbf{A} according to equation (2.6.1), as computed by svdcmp, then let the vectors $\mathbf{U}_{(i)} i = 1, \dots, M$ denote the *columns* of \mathbf{U} (each one a vector of length N); and let the vectors $\mathbf{V}_{(i)} i = 1, \dots, M$ denote the *columns* of \mathbf{V} (each one a vector of length M). Then the solution (2.6.12) of the least-squares problem (15.4.16) can be written as

$$\mathbf{a} = \sum_{i=1}^M \left(\frac{\mathbf{U}_{(i)} \cdot \mathbf{b}}{w_i} \right) \mathbf{V}_{(i)} \quad (15.4.17)$$

where the w_i are, as in §2.6, the singular values returned by svdcmp.

Equation (15.4.17) says that the fitted parameters \mathbf{a} are linear combinations of the columns of \mathbf{V} , with coefficients obtained by forming dot products of the columns of \mathbf{U} with the weighted data vector (15.4.5). Though it is beyond our scope to prove here, it turns out that the standard (loosely, “probable”) errors in the fitted parameters are also linear combinations of the columns of \mathbf{V} . In fact, equation (15.4.17) can be written in a form displaying these errors as

$$\mathbf{a} = \left[\sum_{i=1}^M \left(\frac{\mathbf{U}_{(i)} \cdot \mathbf{b}}{w_i} \right) \mathbf{V}_{(i)} \right] \pm \frac{1}{w_1} \mathbf{V}_{(1)} \pm \dots \pm \frac{1}{w_M} \mathbf{V}_{(M)} \quad (15.4.18)$$

Here each \pm is followed by a standard deviation. The amazing fact is that, decomposed in this fashion, the standard deviations are all mutually independent (uncorrelated). Therefore they can be added together in root-mean-square fashion. What is going on is that the vectors $\mathbf{V}_{(i)}$ are the principal axes of the error ellipsoid of the fitted parameters \mathbf{a} (see §15.6).

It follows that the variance in the estimate of a parameter a_j is given by

$$\sigma^2(a_j) = \sum_{i=1}^M \frac{1}{w_i^2} [\mathbf{V}_{(i)}]_j^2 = \sum_{i=1}^M \left(\frac{V_{ji}}{w_i} \right)^2 \quad (15.4.19)$$

whose result should be identical with (15.4.14). As before, you should not be surprised at the formula for the covariances, here given without proof,

$$\text{Cov}(a_j, a_k) = \sum_{i=1}^M \left(\frac{V_{ji} V_{ki}}{w_i^2} \right) \quad (15.4.20)$$

We introduced this subsection by noting that the normal equations can fail by encountering a zero pivot. We have not yet, however, mentioned how SVD overcomes this problem. The answer is: If any singular value w_i is zero, its

reciprocal in equation (15.4.18) should be set to zero, not infinity. (Compare the discussion preceding equation 2.6.7.) This corresponds to adding to the fitted parameters \mathbf{a} a *zero* multiple, rather than some random large multiple, of any linear combination of basis functions that are degenerate in the fit. It is a good thing to do!

Moreover, if a singular value w_i is nonzero but very small, you should also define *its* reciprocal to be zero, since its apparent value is probably an artifact of roundoff error, not a meaningful number. A plausible answer to the question “how small is small?” is to edit in this fashion all singular values whose ratio to the largest singular value is less than N times the machine precision ϵ . (You might argue for \sqrt{N} , or a constant, instead of N as the multiple; that starts getting into hardware-dependent questions.)

There is another reason for editing even *additional* singular values, ones large enough that roundoff error is not a question. Singular value decomposition allows you to identify linear combinations of variables that just happen not to contribute much to reducing the χ^2 of your data set. Editing these can sometimes reduce the probable error on your coefficients quite significantly, while increasing the minimum χ^2 only negligibly. We will learn more about identifying and treating such cases in §15.6. In the following routine, the point at which this kind of editing would occur is indicated.

Generally speaking, we recommend that you always use SVD techniques instead of using the normal equations. SVD’s only significant disadvantage is that it requires an extra array of size $N \times M$ to store the whole design matrix. This storage is overwritten by the matrix \mathbf{U} . Storage is also required for the $M \times M$ matrix \mathbf{V} , but this is instead of the same-sized matrix for the coefficients of the normal equations. SVD can be significantly slower than solving the normal equations; however, its great advantage, that it (theoretically) *cannot fail*, more than makes up for the speed disadvantage.

In the routine that follows, the matrices \mathbf{u} , \mathbf{v} and the vector \mathbf{w} are input as working space. np and mp are their various physical dimensions. The logical dimensions of the problem are $ndata$ data points by ma basis functions (and fitted parameters). If you care only about the values \mathbf{a} of the fitted parameters, then \mathbf{u} , \mathbf{v} , \mathbf{w} contain no useful information on output. If you want probable errors for the fitted parameters, read on.

```
SUBROUTINE svdfit(x,y,sig,ndata,a,ma,u,v,w,mp,np,
*      chisq,funcs)
*      INTEGER ma,mp,ndata,np,NMAX,MMAX
REAL chisq,a(ma),sig(ndata),u(mp,np),v(np,np),w(np),
*      x(ndata),y(ndata),TOL
EXTERNAL funcs
PARAMETER (NMAX=1000,MMAX=50,TOL=1.e-5)
      NMAX is the maximum expected value of ndata; MMAX the maximum expected for ma; the
      default TOL value is appropriate for single precision and variables scaled to be of order unity.
C   USES svbksb,svdcmp
      Given a set of data points x(1:ndata),y(1:ndata) with individual standard deviations
      sig(1:ndata), use  $\chi^2$  minimization to determine the ma coefficients a of the fitting function
       $y = \sum_i a_i \times \text{afunc}_i(x)$ . Here we solve the fitting equations using singular value decom-
      position of the ndata by ma matrix, as in §2.6. Arrays u(1:mp,1:np), v(1:np,1:np),
      w(1:np) provide workspace on input; on output they define the singular value decomposi-
      tion, and can be used to obtain the covariance matrix. mp,np are the physical dimensions
      of the matrices u,v,w, as indicated above. It is necessary that mp ≥ ndata, np ≥ ma. The
      program returns values for the ma fit parameters a, and  $\chi^2$ , chisq. The user supplies a
      subroutine funcs(x,afunc,ma) that returns the ma basis functions evaluated at x = x
      in the array afunc.
      INTEGER i,j
```

```

REAL sum,thresh,tmp,wmax,afunc(MMAX),b(NMAX)
do 12 i=1,ndata
    call funcs(x(i),afunc,ma)                                Accumulate coefficients of the fitting ma-
    tmp=1./sig(i)                                              trix.
    do 11 j=1,ma
        u(i,j)=afunc(j)*tmp
    enddo 11
    b(i)=y(i)*tmp
  enddo 12
  call svdcmp(u,ndata,ma,mp,np,w,v)                         Singular value decomposition.
  wmax=0.                                                       Edit the singular values, given TOL from the
  do 13 j=1,ma                                               parameter statement, between here ...
      if(w(j).gt.wmax)wmax=w(j)
  enddo 13
  thresh=TOL*wmax
  do 14 j=1,ma
      if(w(j).lt.thresh)w(j)=0.                               ...and here.
  enddo 14
  call svbksb(u,w,v,ndata,ma,mp,np,b,a)                     Evaluate chi-square.
  chisq=0.
  do 16 i=1,ndata
      call funcs(x(i),afunc,ma)
      sum=0.
      do 15 j=1,ma
          sum=sum+a(j)*afunc(j)
      enddo 15
      chisq=chisq+((y(i)-sum)/sig(i))**2
  enddo 16
  return
END

```

Feeding the matrix v and vector w output by the above program into the following short routine, you easily obtain variances and covariances of the fitted parameters a . The square roots of the variances are the standard deviations of the fitted parameters. The routine straightforwardly implements equation (15.4.20) above, with the convention that singular values equal to zero are recognized as having been edited out of the fit.

```

SUBROUTINE svdvar(v,ma,np,w,cvm,ncvm)
INTEGER ma,ncvm,np,MMAX
REAL cvm(ncvm,ncvm),v(np,np),w(np)
PARAMETER (MMAX=20)                                     Set to the maximum number of fit parameters.
                                                       To evaluate the covariance matrix cvm of the fit for ma parameters obtained by svdfit,
                                                       call this routine with matrices v,w as returned from svdfit. np,ncvm give the physical
                                                       dimensions of v,w,cvm as indicated.
INTEGER i,j,k
REAL sum,wti(MMAX)
do 11 i=1,ma
    wti(i)=0.
    if(w(i).ne.0.) wti(i)=1./(w(i)*w(i))
  enddo 11
  do 14 i=1,ma                                         Sum contributions to covariance matrix (15.4.20).
    do 13 j=1,i
        sum=0.
        do 12 k=1,ma
            sum=sum+v(i,k)*v(j,k)*wti(k)
        enddo 12
        cvm(i,j)=sum
        cvm(j,i)=sum
    enddo 13
  enddo 14
  return
END

```

Examples

Be aware that some apparently nonlinear problems can be expressed so that they are linear. For example, an exponential model with two parameters a and b ,

$$y(x) = a \exp(-bx) \quad (15.4.21)$$

can be rewritten as

$$\log[y(x)] = c - bx \quad (15.4.22)$$

which is linear in its parameters c and b . (Of course you must be aware that such transformations do not exactly take Gaussian errors into Gaussian errors.)

Also watch out for “non-parameters,” as in

$$y(x) = a \exp(-bx + d) \quad (15.4.23)$$

Here the parameters a and d are, in fact, indistinguishable. This is a good example of where the normal equations will be exactly singular, and where SVD will find a zero singular value. SVD will then make a “least-squares” choice for setting a balance between a and d (or, rather, their equivalents in the linear model derived by taking the logarithms). However — and this is true whenever SVD returns a zero singular value — you are better advised to figure out analytically where the degeneracy is among your basis functions, and then make appropriate deletions in the basis set.

Here are two examples for user-supplied routines `funcs`. The first one is trivial and fits a general polynomial to a set of data:

```
SUBROUTINE fpoly(x,p,np)
INTEGER np
REAL x,p(np)
      Fitting routine for a polynomial of degree np-1, with np coefficients.
INTEGER j
p(1)=1.
do 11 j=2,np
      p(j)=p(j-1)*x
11 enddo
return
END
```

The second example is slightly less trivial. It is used to fit Legendre polynomials up to some order `n1-1` through a data set.

```
SUBROUTINE fleg(x,p1,n1)
INTEGER n1
REAL x,p1(n1)
      Fitting routine for an expansion with n1 Legendre polynomials p1, evaluated using the
      recurrence relation as in §5.5.
INTEGER j
REAL d,f1,f2,twox
p1(1)=1.
p1(2)=x
if(n1.gt.2) then
      twox=2.*x
      f2=x
      d=1.
```

```

do ii j=3,nl
  f1=d
  f2=f2+twox
  d=d+1.
  pl(j)=(f2*pl(j-1)-f1*pl(j-2))/d
enddo ii
endif
return
END

```

Multidimensional Fits

If you are measuring a single variable y as a function of more than one variable — say, a *vector* of variables \mathbf{x} , then your basis functions will be functions of a vector, $X_1(\mathbf{x}), \dots, X_M(\mathbf{x})$. The χ^2 merit function is now

$$\chi^2 = \sum_{i=1}^N \left[\frac{y_i - \sum_{k=1}^M a_k X_k(\mathbf{x}_i)}{\sigma_i} \right]^2 \quad (15.4.24)$$

All of the preceding discussion goes through unchanged, with x replaced by \mathbf{x} . In fact, if you are willing to tolerate a bit of programming hack, you can use the above programs without any modification: In both `lfit` and `svdfit`, the only use made of the array elements $\mathbf{x}(i)$ is that each element is in turn passed to the user-supplied routine `funcs`, which duly returns the values of the basis functions at that point. If you set $\mathbf{x}(i)=i$ before calling `lfit` or `svdfit`, and independently provide `funcs` with the true vector values of your data points (e.g., in a `COMMON` block), then `funcs` can translate from the fictitious $\mathbf{x}(i)$'s to the actual data points before doing its work.

15.5 Nonlinear Models

We now consider fitting when the model depends *nonlinearly* on the set of M unknown parameters $a_k, k = 1, 2, \dots, M$. We use the same approach as in previous sections, namely to define a χ^2 merit function and determine best-fit parameters by its minimization. With nonlinear dependences, however, the minimization must proceed iteratively. Given trial values for the parameters, we develop a procedure that improves the trial solution. The procedure is then repeated until χ^2 stops (or effectively stops) decreasing.

```

do ii j=3,nl
  f1=d
  f2=f2+twox
  d=d+1.
  pl(j)=(f2*pl(j-1)-f1*pl(j-2))/d
enddo ii
endif
return
END

```

Multidimensional Fits

If you are measuring a single variable y as a function of more than one variable — say, a *vector* of variables \mathbf{x} , then your basis functions will be functions of a vector, $X_1(\mathbf{x}), \dots, X_M(\mathbf{x})$. The χ^2 merit function is now

$$\chi^2 = \sum_{i=1}^N \left[\frac{y_i - \sum_{k=1}^M a_k X_k(\mathbf{x}_i)}{\sigma_i} \right]^2 \quad (15.4.24)$$

All of the preceding discussion goes through unchanged, with x replaced by \mathbf{x} . In fact, if you are willing to tolerate a bit of programming hack, you can use the above programs without any modification: In both `lfit` and `svdfit`, the only use made of the array elements $\mathbf{x}(i)$ is that each element is in turn passed to the user-supplied routine `funcs`, which duly returns the values of the basis functions at that point. If you set $\mathbf{x}(i)=i$ before calling `lfit` or `svdfit`, and independently provide `funcs` with the true vector values of your data points (e.g., in a `COMMON` block), then `funcs` can translate from the fictitious $\mathbf{x}(i)$'s to the actual data points before doing its work.

15.5 Nonlinear Models

We now consider fitting when the model depends *nonlinearly* on the set of M unknown parameters $a_k, k = 1, 2, \dots, M$. We use the same approach as in previous sections, namely to define a χ^2 merit function and determine best-fit parameters by its minimization. With nonlinear dependences, however, the minimization must proceed iteratively. Given trial values for the parameters, we develop a procedure that improves the trial solution. The procedure is then repeated until χ^2 stops (or effectively stops) decreasing.

How is this problem different from the general nonlinear function minimization problem already dealt with in Chapter 10? Superficially, not at all: Sufficiently close to the minimum, we expect the χ^2 function to be well approximated by a quadratic form, which we can write as

$$\chi^2(\mathbf{a}) \approx \gamma - \mathbf{d} \cdot \mathbf{a} + \frac{1}{2} \mathbf{a} \cdot \mathbf{D} \cdot \mathbf{a} \quad (15.5.1)$$

where \mathbf{d} is an M -vector and \mathbf{D} is an $M \times M$ matrix. (Compare equation 10.6.1.) If the approximation is a good one, we know how to jump from the current trial parameters \mathbf{a}_{cur} to the minimizing ones \mathbf{a}_{min} in a single leap, namely

$$\mathbf{a}_{\text{min}} = \mathbf{a}_{\text{cur}} + \mathbf{D}^{-1} \cdot [-\nabla \chi^2(\mathbf{a}_{\text{cur}})] \quad (15.5.2)$$

(Compare equation 10.7.4.)

On the other hand, (15.5.1) might be a poor local approximation to the shape of the function that we are trying to minimize at \mathbf{a}_{cur} . In that case, about all we can do is take a step down the gradient, as in the steepest descent method (§10.6). In other words,

$$\mathbf{a}_{\text{next}} = \mathbf{a}_{\text{cur}} - \text{constant} \times \nabla \chi^2(\mathbf{a}_{\text{cur}}) \quad (15.5.3)$$

where the constant is small enough not to exhaust the downhill direction.

To use (15.5.2) or (15.5.3), we must be able to compute the gradient of the χ^2 function at any set of parameters \mathbf{a} . To use (15.5.2) we also need the matrix \mathbf{D} , which is the second derivative matrix (Hessian matrix) of the χ^2 merit function, at any \mathbf{a} .

Now, this is the crucial difference from Chapter 10: There, we had no way of directly evaluating the Hessian matrix. We were given only the ability to evaluate the function to be minimized and (in some cases) its gradient. Therefore, we had to resort to iterative methods *not just* because our function was nonlinear, *but also* in order to build up information about the Hessian matrix. Sections 10.7 and 10.6 concerned themselves with two different techniques for building up this information.

Here, life is much simpler. We *know* exactly the form of χ^2 , since it is based on a model function that we ourselves have specified. Therefore the Hessian matrix is known to us. Thus we are free to use (15.5.2) whenever we care to do so. The only reason to use (15.5.3) will be failure of (15.5.2) to improve the fit, signaling failure of (15.5.1) as a good local approximation.

Calculation of the Gradient and Hessian

The model to be fitted is

$$y = y(x; \mathbf{a}) \quad (15.5.4)$$

and the χ^2 merit function is

$$\chi^2(\mathbf{a}) = \sum_{i=1}^N \left[\frac{y_i - y(x_i; \mathbf{a})}{\sigma_i} \right]^2 \quad (15.5.5)$$

The gradient of χ^2 with respect to the parameters \mathbf{a} , which will be zero at the χ^2 minimum, has components

$$\frac{\partial \chi^2}{\partial a_k} = -2 \sum_{i=1}^N \frac{[y_i - y(x_i; \mathbf{a})]}{\sigma_i^2} \frac{\partial y(x_i; \mathbf{a})}{\partial a_k} \quad k = 1, 2, \dots, M \quad (15.5.6)$$

Taking an additional partial derivative gives

$$\frac{\partial^2 \chi^2}{\partial a_k \partial a_l} = 2 \sum_{i=1}^N \frac{1}{\sigma_i^2} \left[\frac{\partial y(x_i; \mathbf{a})}{\partial a_k} \frac{\partial y(x_i; \mathbf{a})}{\partial a_l} - [y_i - y(x_i; \mathbf{a})] \frac{\partial^2 y(x_i; \mathbf{a})}{\partial a_l \partial a_k} \right] \quad (15.5.7)$$

It is conventional to remove the factors of 2 by defining

$$\beta_k \equiv -\frac{1}{2} \frac{\partial \chi^2}{\partial a_k} \quad \alpha_{kl} \equiv \frac{1}{2} \frac{\partial^2 \chi^2}{\partial a_k \partial a_l} \quad (15.5.8)$$

making $[\alpha] = \frac{1}{2}\mathbf{D}$ in equation (15.5.2), in terms of which that equation can be rewritten as the set of linear equations

$$\sum_{l=1}^M \alpha_{kl} \delta a_l = \beta_k \quad (15.5.9)$$

This set is solved for the increments δa_l that, added to the current approximation, give the next approximation. In the context of least-squares, the matrix $[\alpha]$, equal to one-half times the Hessian matrix, is usually called the *curvature matrix*.

Equation (15.5.3), the steepest descent formula, translates to

$$\delta a_l = \text{constant} \times \beta_l \quad (15.5.10)$$

Note that the components α_{kl} of the Hessian matrix (15.5.7) depend both on the first derivatives and on the second derivatives of the basis functions with respect to their parameters. Some treatments proceed to ignore the second derivative without comment. We will ignore it also, but only *after* a few comments.

Second derivatives occur because the gradient (15.5.6) already has a dependence on $\partial y / \partial a_k$, so the next derivative simply must contain terms involving $\partial^2 y / \partial a_l \partial a_k$. The second derivative term can be dismissed when it is zero (as in the linear case of equation 15.4.8), or small enough to be negligible when compared to the term involving the first derivative. It also has an additional possibility of being ignorably small in practice: The term multiplying the second derivative in equation (15.5.7) is $[y_i - y(x_i; \mathbf{a})]$. For a successful model, this term should just be the random measurement error of each point. This error can have either sign, and should in general be uncorrelated with the model. Therefore, the second derivative terms tend to cancel out when summed over i .

Inclusion of the second-derivative term can in fact be destabilizing if the model fits badly or is contaminated by outlier points that are unlikely to be offset by

compensating points of opposite sign. From this point on, we will always use as the definition of α_{kl} the formula

$$\alpha_{kl} = \sum_{i=1}^N \frac{1}{\sigma_i^2} \left[\frac{\partial y(x_i; \mathbf{a})}{\partial a_k} \frac{\partial y(x_i; \mathbf{a})}{\partial a_l} \right] \quad (15.5.11)$$

This expression more closely resembles its linear cousin (15.4.8). You should understand that minor (or even major) fiddling with $[\alpha]$ has no effect at all on what final set of parameters \mathbf{a} is reached, but affects only the iterative route that is taken in getting there. The condition at the χ^2 minimum, that $\beta_k = 0$ for all k , is independent of how $[\alpha]$ is defined.

Levenberg-Marquardt Method

Marquardt [1] has put forth an elegant method, related to an earlier suggestion of Levenberg, for varying smoothly between the extremes of the inverse-Hessian method (15.5.9) and the steepest descent method (15.5.10). The latter method is used far from the minimum, switching continuously to the former as the minimum is approached. This *Levenberg-Marquardt method* (also called *Marquardt method*) works very well in practice and has become the standard of nonlinear least-squares routines.

The method is based on two elementary, but important, insights. Consider the “constant” in equation (15.5.10). What should it be, even in order of magnitude? What sets its scale? There is no information about the answer in the gradient. That tells only the slope, not how far that slope extends. Marquardt’s first insight is that the components of the Hessian matrix, even if they are not usable in any precise fashion, give *some* information about the order-of-magnitude scale of the problem.

The quantity χ^2 is nondimensional, i.e., is a pure number; this is evident from its definition (15.5.5). On the other hand, β_k has the dimensions of $1/a_k$, which may well be dimensional, i.e., have units like cm^{-1} , or kilowatt-hours, or whatever. (In fact, each component of β_k can have different dimensions!) The constant of proportionality between β_k and δa_k must therefore have the dimensions of a_k^2 . Scan the components of $[\alpha]$ and you see that there is only one obvious quantity with these dimensions, and that is $1/\alpha_{kk}$, the reciprocal of the diagonal element. So that must set the scale of the constant. But that scale might itself be too big. So let’s divide the constant by some (nondimensional) fudge factor λ , with the possibility of setting $\lambda \gg 1$ to cut down the step. In other words, replace equation (15.5.10) by

$$\delta a_l = \frac{1}{\lambda \alpha_{ll}} \beta_l \quad \text{or} \quad \lambda \alpha_{ll} \delta a_l = \beta_l \quad (15.5.12)$$

It is necessary that α_{ll} be positive, but this is guaranteed by definition (15.5.11) — another reason for adopting that equation.

Marquardt’s second insight is that equations (15.5.12) and (15.5.9) can be combined if we define a new matrix α' by the following prescription

$$\begin{aligned} \alpha'_{jj} &\equiv \alpha_{jj}(1 + \lambda) \\ \alpha'_{jk} &\equiv \alpha_{jk} \quad (j \neq k) \end{aligned} \quad (15.5.13)$$

and then replace both (15.5.12) and (15.5.9) by

$$\sum_{l=1}^M \alpha'_{kl} \delta a_l = \beta_k \quad (15.5.14)$$

When λ is very large, the matrix α' is forced into being *diagonally dominant*, so equation (15.5.14) goes over to be identical to (15.5.12). On the other hand, as λ approaches zero, equation (15.5.14) goes over to (15.5.9).

Given an initial guess for the set of fitted parameters \mathbf{a} , the recommended Marquardt recipe is as follows:

- Compute $\chi^2(\mathbf{a})$.
- Pick a modest value for λ , say $\lambda = 0.001$.
- (\dagger) Solve the linear equations (15.5.14) for $\delta\mathbf{a}$ and evaluate $\chi^2(\mathbf{a} + \delta\mathbf{a})$.
- If $\chi^2(\mathbf{a} + \delta\mathbf{a}) \geq \chi^2(\mathbf{a})$, increase λ by a factor of 10 (or any other substantial factor) and go back to (\dagger).
- If $\chi^2(\mathbf{a} + \delta\mathbf{a}) < \chi^2(\mathbf{a})$, decrease λ by a factor of 10, update the trial solution $\mathbf{a} \leftarrow \mathbf{a} + \delta\mathbf{a}$, and go back to (\dagger).

Also necessary is a condition for stopping. Iterating to convergence (to machine accuracy or to the roundoff limit) is generally wasteful and unnecessary since the minimum is at best only a statistical estimate of the parameters \mathbf{a} . As we will see in §15.6, a change in the parameters that changes χ^2 by an amount $\ll 1$ is *never* statistically meaningful.

Furthermore, it is not uncommon to find the parameters wandering around near the minimum in a flat valley of complicated topography. The reason is that Marquardt's method generalizes the method of normal equations (§15.4), hence has the same problem as that method with regard to near-degeneracy of the minimum. Outright failure by a zero pivot is possible, but unlikely. More often, a small pivot will generate a large correction which is then rejected, the value of λ being then increased. For sufficiently large λ the matrix $[\alpha']$ is positive definite and can have no small pivots. Thus the method does tend to stay away from zero pivots, but at the cost of a tendency to wander around doing steepest descent in very un-steep degenerate valleys.

These considerations suggest that, in practice, one might as well stop iterating on the first or second occasion that χ^2 decreases by a negligible amount, say either less than 0.01 absolutely or (in case roundoff prevents that being reached) some fractional amount like 10^{-3} . Don't stop after a step where χ^2 increases: That only shows that λ has not yet adjusted itself optimally.

Once the acceptable minimum has been found, one wants to set $\lambda = 0$ and compute the matrix

$$[C] = [\alpha]^{-1} \quad (15.5.15)$$

which, as before, is the estimated covariance matrix of the standard errors in the fitted parameters \mathbf{a} (see next section).

The following pair of subroutines encodes Marquardt's method for nonlinear parameter estimation. Much of the organization matches that used in `lfit` of §15.4. In particular the array `ia(1:ma)` must be input with components one or zero corresponding to whether the respective parameter values `a(1:ma)` are to be fitted for or held fixed at their input values, respectively.

The routine `mqrmin` performs one iteration of Marquardt's method. It is first called (once) with `alamda < 0`, which signals the routine to initialize. `alamda` is returned on the first and all subsequent calls as the suggested value of λ for the next iteration; `a` and `chisq` are always returned as the best parameters found so far and their χ^2 . When convergence is deemed satisfactory, set `alamda` to zero before a final call. The matrices `alpha` and `covar` (which were used as workspace in all previous calls) will then be set to the curvature and covariance matrices for the converged parameter values. The arguments `alpha`, `a`, and `chisq` must not be modified between calls, nor should `alamda` be, except to set it to zero for the final call. When an uphill step is taken, `chisq` and `a` are returned with their input (best) values, but `alamda` is returned with an increased value.

The routine `mrqmin` calls the routine `mrqcdf` for the computation of the matrix $[\alpha]$ (equation 15.5.11) and vector β (equations 15.5.6 and 15.5.8). In turn `mrqcdf` calls the user-supplied routine `funcf(x, a, y, dyda)`, which for input values $x \equiv x_i$ and $a \equiv a$ returns the model function $y \equiv y(x_i; a)$ and the vector of derivatives $dyda \equiv \partial y / \partial a_k$.

```

SUBROUTINE mrqmin(x,y,sig,ndata,a,ia,ma,covar,alpha,nca,
   chisq,funcs,alamda)
INTEGER ma,nca,ndata,ia(ma),MMAX
REAL alamda,chisq,funcs,a(ma),alpha(nca,nca),covar(nca,nca),
   sig(ndata),x(ndata),y(ndata)
PARAMETER (MMAX=20)                                     Set to largest number of fit parameters.
C USES covsrt,gaussj,mrqcof
Levenberg-Marquardt method, attempting to reduce the value  $\chi^2$  of a fit between a set of data points  $x(1:ndata)$ ,  $y(1:ndata)$  with individual standard deviations  $sig(1:ndata)$ , and a nonlinear function dependent on  $ma$  coefficients  $a(1:ma)$ . The input array  $ia(1:ma)$  indicates by nonzero entries those components of  $a$  that should be fitted for, and by zero entries those components that should be held fixed at their input values. The program returns current best-fit values for the parameters  $a(1:ma)$ , and  $\chi^2 = chisq$ . The arrays  $covar(1:nca,1:nca)$ ,  $alpha(1:nca,1:nca)$  with physical dimension  $nca$  ( $\geq$  the number of fitted parameters) are used as working space during most iterations. Supply a subroutine  $funcs(x,a,yfit,dyda,ma)$  that evaluates the fitting function  $yfit$ , and its derivatives  $dyda$  with respect to the fitting parameters  $a$  at  $x$ . On the first call provide an initial guess for the parameters  $a$ , and set  $alamda < 0$  for initialization (which then sets  $alamda=.001$ ). If a step succeeds  $chisq$  becomes smaller and  $alamda$  decreases by a factor of 10. If a step fails  $alamda$  grows by a factor of 10. You must call this routine repeatedly until convergence is achieved. Then, make one final call with  $alamda=0$ , so that  $covar(1:ma,1:ma)$  returns the covariance matrix, and  $alpha$  the curvature matrix. (Parameters held fixed will return zero covariances.)

```

Example

The following subroutine `fgauss` is an example of a user-supplied subroutine `funcs`. Used with the above routine `mrqmin` (in turn using `mrqcof`, `covsrt`, and `gaussj`), it fits for the model

$$y(x) = \sum_{k=1}^K B_k \exp \left[- \left(\frac{x - E_k}{G_k} \right)^2 \right] \quad (15.5.16)$$

which is a sum of K Gaussians, each having a variable position, amplitude, and width. We store the parameters in the order $B_1, E_1, G_1, B_2, E_2, G_2, \dots, B_K, E_K, G_K$.

```

SUBROUTINE fgauss(x,a,y,dyda,na)
INTEGER na
REAL x,y,a(na),dyda(na)
y(x;a) is the sum of na/3 Gaussians (15.5.16). The amplitude, center, and width of the
Gaussians are stored in consecutive locations of a: a(i) =  $B_k$ , a(i+1) =  $E_k$ , a(i+2) =
 $G_k$ ,  $k = 1, \dots, na/3$ .
INTEGER i
REAL arg,ex,fac
y=0.
do ii i=1,na-1,3
    arg=(x-a(i+1))/a(i+2)
    ex=exp(-arg**2)
    fac=a(i)*ex*2.*arg
    y=y+a(i)*ex
    dyda(i)=ex
    dyda(i+1)=fac/a(i+2)
    dyda(i+2)=fac*arg/a(i+2)
enddo ii
return
END

```

More Advanced Methods for Nonlinear Least Squares

The Levenberg-Marquardt algorithm can be implemented as a model-trust region method for minimization (see §9.7 and ref. [2]) applied to the special case of a least squares function. A code of this kind due to Moré [3] can be found in MINPACK [4]. Another algorithm for nonlinear least-squares keeps the second-derivative term we dropped in the Levenberg-Marquardt method whenever it would be better to do so. These methods are called “full Newton-type” methods and are reputed to be more robust than Levenberg-Marquardt, but more complex. One implementation is the code NL2SOL [5].

15.6 Confidence Limits on Estimated Model Parameters

Several times already in this chapter we have made statements about the standard errors, or uncertainties, in a set of M estimated parameters \mathbf{a} . We have given some formulas for computing standard deviations or variances of individual parameters (equations 15.2.9, 15.4.15, 15.4.19), as well as some formulas for covariances between pairs of parameters (equation 15.2.10; remark following equation 15.4.15; equation 15.4.20; equation 15.5.15).

In this section, we want to be more explicit regarding the precise meaning of these quantitative uncertainties, and to give further information about how quantitative confidence limits on fitted parameters can be estimated. The subject can get somewhat technical, and even somewhat confusing, so we will try to make precise statements, even when they must be offered without proof.

Figure 15.6.1 shows the conceptual scheme of an experiment that “measures” a set of parameters. There is some underlying true set of parameters \mathbf{a}_{true} that are known to Mother Nature but hidden from the experimenter. These true parameters are statistically realized, along with random measurement errors, as a measured data set, which we will symbolize as $\mathcal{D}_{(0)}$. The data set $\mathcal{D}_{(0)}$ is known to the experimenter. He or she fits the data to a model by χ^2 minimization or some other technique, and obtains measured, i.e., fitted, values for the parameters, which we here denote $\mathbf{a}_{(0)}$.

Because measurement errors have a random component, $\mathcal{D}_{(0)}$ is not a unique realization of the true parameters \mathbf{a}_{true} . Rather, there are infinitely many other realizations of the true parameters as “hypothetical data sets” each of which *could* have been the one measured, but happened not to be. Let us symbolize these by $\mathcal{D}_{(1)}, \mathcal{D}_{(2)}, \dots$. Each one, had it been realized, would have given a slightly different set of fitted parameters, $\mathbf{a}_{(1)}, \mathbf{a}_{(2)}, \dots$, respectively. These parameter sets $\mathbf{a}_{(i)}$ therefore occur with some probability distribution in the M -dimensional space of all possible parameter sets \mathbf{a} . The actual measured set $\mathbf{a}_{(0)}$ is one member drawn from this distribution.

Even more interesting than the probability distribution of $\mathbf{a}_{(i)}$ would be the distribution of the difference $\mathbf{a}_{(i)} - \mathbf{a}_{\text{true}}$. This distribution differs from the former one by a translation that puts Mother Nature’s true value at the origin. If we knew *this* distribution, we would know everything that there is to know about the quantitative uncertainties in our experimental measurement $\mathbf{a}_{(0)}$.

So the name of the game is to find some way of estimating or approximating the probability distribution of $\mathbf{a}_{(i)} - \mathbf{a}_{\text{true}}$ without knowing \mathbf{a}_{true} and without having available to us an infinite universe of hypothetical data sets.

Monte Carlo Simulation of Synthetic Data Sets

Although the measured parameter set $\mathbf{a}_{(0)}$ is not the true one, let us consider a fictitious world in which it *was* the true one. Since we hope that our measured parameters are not *too* wrong, we hope that that fictitious world is not too different from the actual world with parameters \mathbf{a}_{true} . In particular, let us hope — no, let us *assume* — that the shape of the probability distribution $\mathbf{a}_{(i)} - \mathbf{a}_{(0)}$ in the fictitious world is the same, or very nearly the same, as the shape of the probability distribution

15.6 Confidence Limits on Estimated Model Parameters

Several times already in this chapter we have made statements about the standard errors, or uncertainties, in a set of M estimated parameters \mathbf{a} . We have given some formulas for computing standard deviations or variances of individual parameters (equations 15.2.9, 15.4.15, 15.4.19), as well as some formulas for covariances between pairs of parameters (equation 15.2.10; remark following equation 15.4.15; equation 15.4.20; equation 15.5.15).

In this section, we want to be more explicit regarding the precise meaning of these quantitative uncertainties, and to give further information about how quantitative confidence limits on fitted parameters can be estimated. The subject can get somewhat technical, and even somewhat confusing, so we will try to make precise statements, even when they must be offered without proof.

Figure 15.6.1 shows the conceptual scheme of an experiment that “measures” a set of parameters. There is some underlying true set of parameters \mathbf{a}_{true} that are known to Mother Nature but hidden from the experimenter. These true parameters are statistically realized, along with random measurement errors, as a measured data set, which we will symbolize as $\mathcal{D}_{(0)}$. The data set $\mathcal{D}_{(0)}$ is known to the experimenter. He or she fits the data to a model by χ^2 minimization or some other technique, and obtains measured, i.e., fitted, values for the parameters, which we here denote $\mathbf{a}_{(0)}$.

Because measurement errors have a random component, $\mathcal{D}_{(0)}$ is not a unique realization of the true parameters \mathbf{a}_{true} . Rather, there are infinitely many other realizations of the true parameters as “hypothetical data sets” each of which *could* have been the one measured, but happened not to be. Let us symbolize these by $\mathcal{D}_{(1)}, \mathcal{D}_{(2)}, \dots$. Each one, had it been realized, would have given a slightly different set of fitted parameters, $\mathbf{a}_{(1)}, \mathbf{a}_{(2)}, \dots$, respectively. These parameter sets $\mathbf{a}_{(i)}$ therefore occur with some probability distribution in the M -dimensional space of all possible parameter sets \mathbf{a} . The actual measured set $\mathbf{a}_{(0)}$ is one member drawn from this distribution.

Even more interesting than the probability distribution of $\mathbf{a}_{(i)}$ would be the distribution of the difference $\mathbf{a}_{(i)} - \mathbf{a}_{\text{true}}$. This distribution differs from the former one by a translation that puts Mother Nature’s true value at the origin. If we knew *this* distribution, we would know everything that there is to know about the quantitative uncertainties in our experimental measurement $\mathbf{a}_{(0)}$.

So the name of the game is to find some way of estimating or approximating the probability distribution of $\mathbf{a}_{(i)} - \mathbf{a}_{\text{true}}$ without knowing \mathbf{a}_{true} and without having available to us an infinite universe of hypothetical data sets.

Monte Carlo Simulation of Synthetic Data Sets

Although the measured parameter set $\mathbf{a}_{(0)}$ is not the true one, let us consider a fictitious world in which it *was* the true one. Since we hope that our measured parameters are not *too* wrong, we hope that that fictitious world is not too different from the actual world with parameters \mathbf{a}_{true} . In particular, let us hope — no, let us *assume* — that the shape of the probability distribution $\mathbf{a}_{(i)} - \mathbf{a}_{(0)}$ in the fictitious world is the same, or very nearly the same, as the shape of the probability distribution

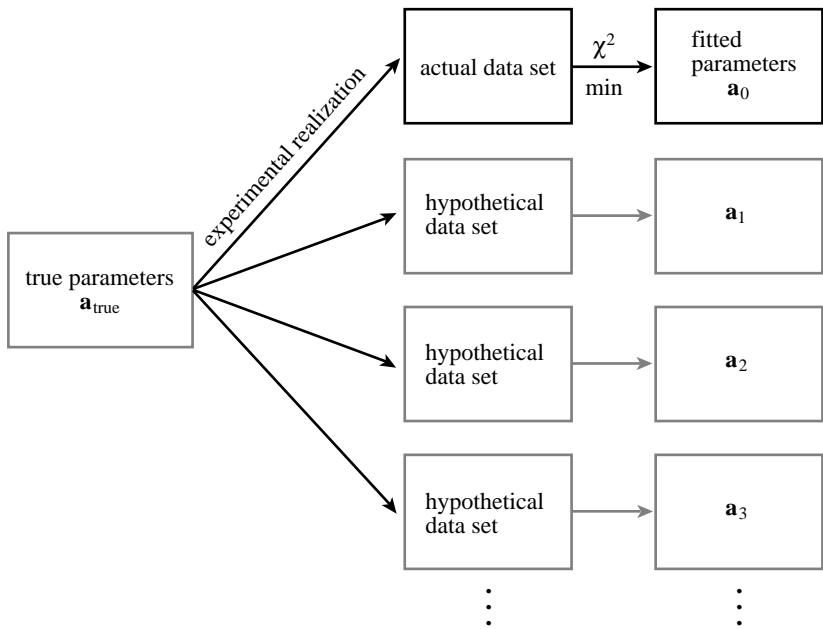

Figure 15.6.1. A statistical universe of data sets from an underlying model. True parameters \mathbf{a}_{true} are realized in a data set, from which fitted (observed) parameters \mathbf{a}_0 are obtained. If the experiment were repeated many times, new data sets and new values of the fitted parameters would be obtained.

$\mathbf{a}_{(i)} - \mathbf{a}_{\text{true}}$ in the real world. Notice that we are not assuming that $\mathbf{a}_{(0)}$ and \mathbf{a}_{true} are equal; they are certainly not. We are only assuming that the way in which random errors enter the experiment and data analysis does not vary rapidly as a function of \mathbf{a}_{true} , so that $\mathbf{a}_{(0)}$ can serve as a reasonable surrogate.

Now, often, the distribution of $\mathbf{a}_{(i)} - \mathbf{a}_{(0)}$ in the fictitious world *is* within our power to calculate (see Figure 15.6.2). If we know something about the process that generated our data, given an assumed set of parameters $\mathbf{a}_{(0)}$, then we can usually figure out how to *simulate* our own sets of “synthetic” realizations of these parameters as “synthetic data sets.” The procedure is to draw random numbers from appropriate distributions (cf. §7.2–§7.3) so as to mimic our best understanding of the underlying process and measurement errors in our apparatus. With such random draws, we construct data sets with exactly the same numbers of measured points, and precisely the same values of all control (independent) variables, as our actual data set $\mathcal{D}_{(0)}$. Let us call these simulated data sets $\mathcal{D}_{(1)}^S, \mathcal{D}_{(2)}^S, \dots$. By construction these are supposed to have exactly the same statistical relationship to $\mathbf{a}_{(0)}$ as the $\mathcal{D}_{(i)}$ ’s have to \mathbf{a}_{true} . (For the case where you don’t know enough about what you are measuring to do a credible job of simulating it, see below.)

Next, for each $\mathcal{D}_{(j)}^S$, perform exactly the same procedure for estimation of parameters, e.g., χ^2 minimization, as was performed on the actual data to get the parameters $\mathbf{a}_{(0)}$, giving simulated measured parameters $\mathbf{a}_{(1)}^S, \mathbf{a}_{(2)}^S, \dots$. Each simulated measured parameter set yields a point $\mathbf{a}_{(i)}^S - \mathbf{a}_{(0)}$. Simulate enough data sets and enough derived simulated measured parameters, and you map out the desired probability distribution in M dimensions.

In fact, the ability to do *Monte Carlo simulations* in this fashion has revo-

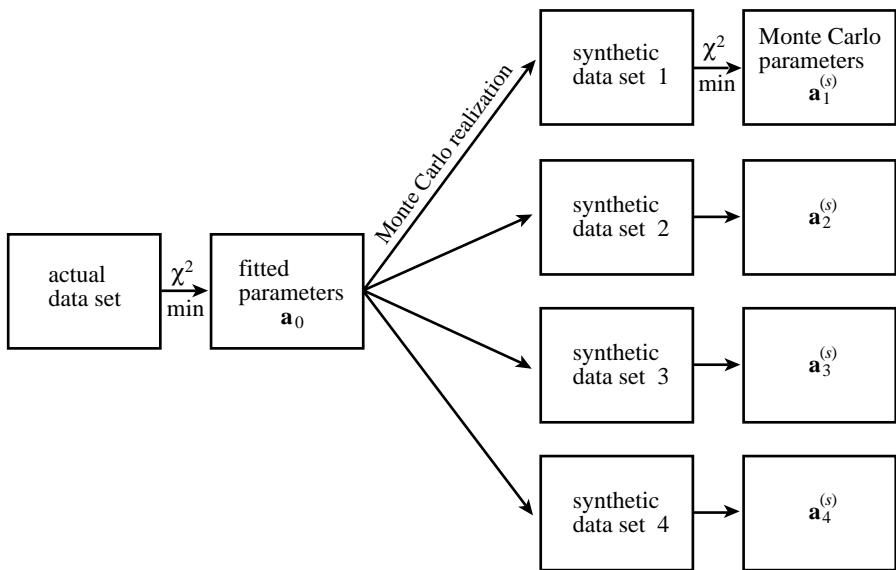

Figure 15.6.2. Monte Carlo simulation of an experiment. The fitted parameters from an actual experiment are used as surrogates for the true parameters. Computer-generated random numbers are used to simulate many synthetic data sets. Each of these is analyzed to obtain its fitted parameters. The distribution of these fitted parameters around the (known) surrogate true parameters is thus studied.

lutionized many fields of modern experimental science. Not only is one able to characterize the errors of parameter estimation in a very precise way; one can also try out on the computer different methods of parameter estimation, or different data reduction techniques, and seek to minimize the uncertainty of the result according to any desired criteria. Offered the choice between mastery of a five-foot shelf of analytical statistics books and middling ability at performing statistical Monte Carlo simulations, we would surely choose to have the latter skill.

Quick-and-Dirty Monte Carlo: The Bootstrap Method

Here is a powerful technique that can often be used when you don't know enough about the underlying process, or the nature of your measurement errors, to do a credible Monte Carlo simulation. Suppose that your data set consists of N independent and identically distributed (or iid) "data points." Each data point probably consists of several numbers, e.g., one or more control variables (uniformly distributed, say, in the range that you have decided to measure) and one or more associated measured values (each distributed however Mother Nature chooses). "Iid" means that the sequential order of the data points is not of consequence to the process that you are using to get the fitted parameters \mathbf{a} . For example, a χ^2 sum like (15.5.5) does not care in what order the points are added. Even simpler examples are the mean value of a measured quantity, or the mean of some function of the measured quantities.

The *bootstrap method* [1] uses the actual data set $\mathcal{D}_{(0)}^S$, with its N data points, to generate any number of synthetic data sets $\mathcal{D}_{(1)}^S, \mathcal{D}_{(2)}^S, \dots$, also with N data points. The procedure is simply to draw N data points at a time with replacement from the

set $\mathcal{D}_{(0)}^S$. Because of the replacement, you do not simply get back your original data set each time. You get sets in which a random fraction of the original points, typically $\sim 1/e \approx 37\%$, are replaced by *duplicated* original points. Now, exactly as in the previous discussion, you subject these data sets to the same estimation procedure as was performed on the actual data, giving a set of simulated measured parameters $\mathbf{a}_{(1)}^S, \mathbf{a}_{(2)}^S, \dots$. These will be distributed around $\mathbf{a}_{(0)}$ in close to the same way that $\mathbf{a}_{(0)}$ is distributed around \mathbf{a}_{true} .

Sounds like getting something for nothing, doesn't it? In fact, it has taken more than a decade for the bootstrap method to become accepted by statisticians. By now, however, enough theorems have been proved to render the bootstrap reputable (see [2] for references). The basic idea behind the bootstrap is that the actual data set, viewed as a probability distribution consisting of delta functions at the measured values, is in most cases the best — or only — available estimator of the underlying probability distribution. It takes courage, but one can often simply use *that* distribution as the basis for Monte Carlo simulations.

Watch out for cases where the bootstrap's “iid” assumption is violated. For example, if you have made measurements at evenly spaced intervals of some control variable, then you can *usually* get away with pretending that these are “iid,” uniformly distributed over the measured range. However, some estimators of \mathbf{a} (e.g., ones involving Fourier methods) might be particularly sensitive to all the points on a grid being present. In that case, the bootstrap is going to give a wrong distribution. Also watch out for estimators that look at anything like small-scale clumpiness within the N data points, or estimators that sort the data and look at sequential differences. Obviously the bootstrap will fail on these, too. (The theorems justifying the method are still true, but some of their technical assumptions are violated by these examples.)

For a large class of problems, however, the bootstrap does yield easy, *very quick*, Monte Carlo estimates of the errors in an estimated parameter set.

Confidence Limits

Rather than present all details of the probability distribution of errors in parameter estimation, it is common practice to summarize the distribution in the form of *confidence limits*. The full probability distribution is a function defined on the M -dimensional space of parameters \mathbf{a} . A *confidence region* (or *confidence interval*) is just a region of that M -dimensional space (hopefully a small region) that contains a certain (hopefully large) percentage of the total probability distribution. You point to a confidence region and say, e.g., “there is a 99 percent chance that the true parameter values fall within this region around the measured value.”

It is worth emphasizing that you, the experimenter, get to pick both the *confidence level* (99 percent in the above example), and the shape of the confidence region. The only requirement is that your region does include the stated percentage of probability. Certain percentages are, however, customary in scientific usage: 68.3 percent (the lowest confidence worthy of quoting), 90 percent, 95.4 percent, 99 percent, and 99.73 percent. Higher confidence levels are conventionally “ninety-nine point nine . . . nine.” As for shape, obviously you want a region that is compact and reasonably centered on your measurement $\mathbf{a}_{(0)}$, since the whole purpose of a confidence limit is to inspire confidence in that measured value. In one dimension,

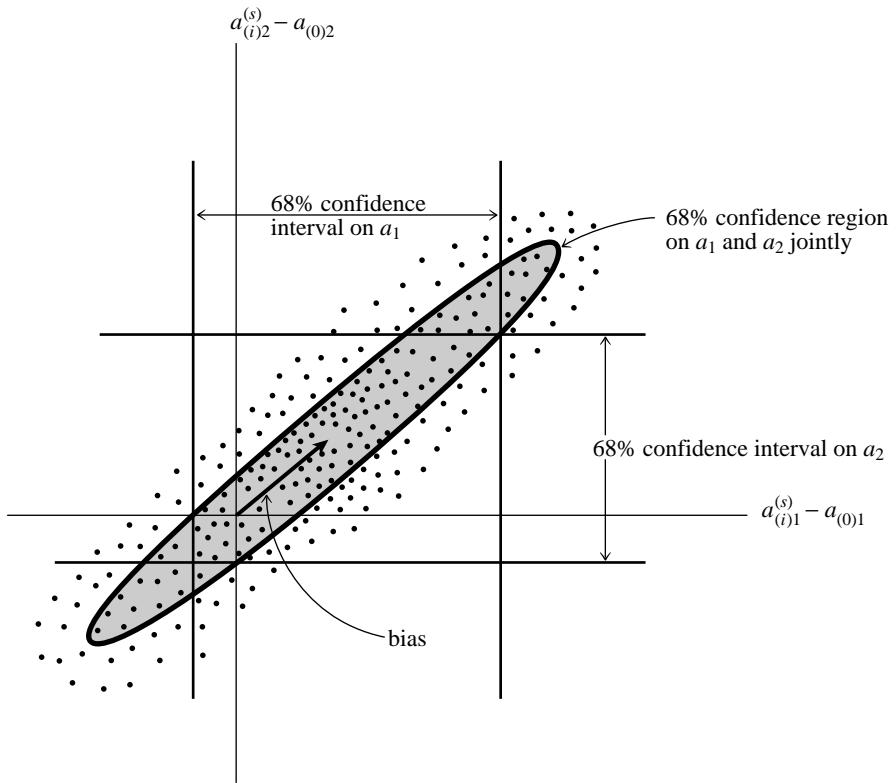

Figure 15.6.3. Confidence intervals in 1 and 2 dimensions. The same fraction of measured points (here 68%) lies (i) between the two vertical lines, (ii) between the two horizontal lines, (iii) within the ellipse.

the convention is to use a line segment centered on the measured value; in higher dimensions, ellipses or ellipsoids are most frequently used.

You might suspect, correctly, that the numbers 68.3 percent, 95.4 percent, and 99.73 percent, and the use of ellipsoids, have some connection with a normal distribution. That is true historically, but not always relevant nowadays. In general, the probability distribution of the parameters will not be normal, and the above numbers, used as levels of confidence, are purely matters of convention.

Figure 15.6.3 sketches a possible probability distribution for the case $M = 2$. Shown are three different confidence regions which might usefully be given, all at the same confidence level. The two vertical lines enclose a band (horizontal interval) which represents the 68 percent confidence interval for the variable a_1 without regard to the value of a_2 . Similarly the horizontal lines enclose a 68 percent confidence interval for a_2 . The ellipse shows a 68 percent confidence interval for a_1 and a_2 jointly. Notice that to enclose the same probability as the two bands, the ellipse must necessarily extend outside of both of them (a point we will return to below).

Constant Chi-Square Boundaries as Confidence Limits

When the method used to estimate the parameters $\mathbf{a}_{(0)}$ is chi-square minimization, as in the previous sections of this chapter, then there is a natural choice for the

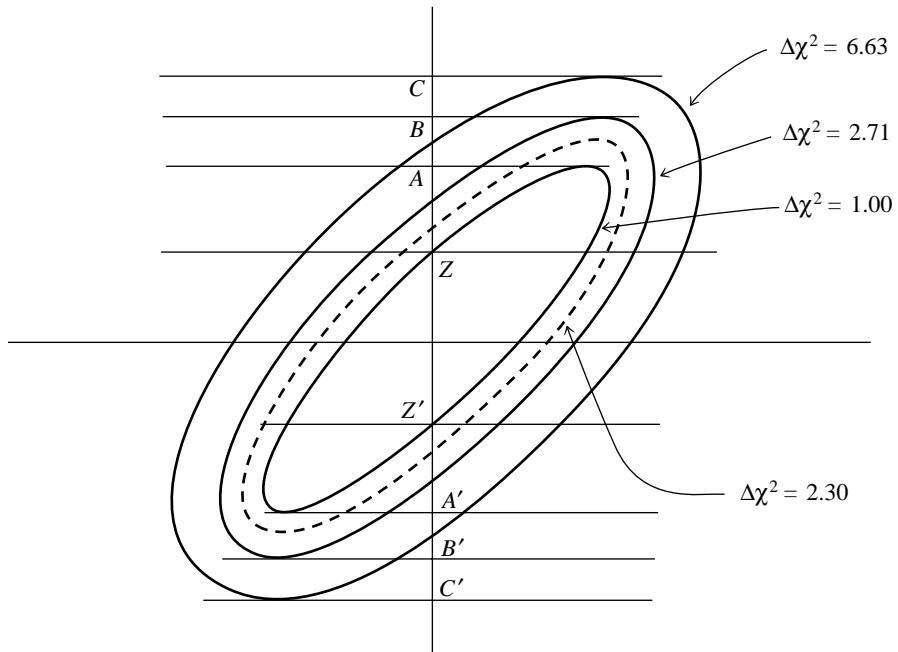

Figure 15.6.4. Confidence region ellipses corresponding to values of chi-square larger than the fitted minimum. The solid curves, with $\Delta\chi^2 = 1.00, 2.71, 6.63$ project onto one-dimensional intervals AA' , BB' , CC' . These intervals — not the ellipses themselves — contain 68.3%, 90%, and 99% of normally distributed data. The ellipse that contains 68.3% of normally distributed data is shown dashed, and has $\Delta\chi^2 = 2.30$. For additional numerical values, see accompanying table.

shape of confidence intervals, whose use is almost universal. For the observed data set $\mathcal{D}_{(0)}$, the value of χ^2 is a minimum at $\mathbf{a}_{(0)}$. Call this minimum value χ_{\min}^2 . If the vector \mathbf{a} of parameter values is perturbed away from $\mathbf{a}_{(0)}$, then χ^2 increases. The region within which χ^2 increases by no more than a set amount $\Delta\chi^2$ defines some M -dimensional confidence region around $\mathbf{a}_{(0)}$. If $\Delta\chi^2$ is set to be a large number, this will be a big region; if it is small, it will be small. Somewhere in between there will be choices of $\Delta\chi^2$ that cause the region to contain, variously, 68 percent, 90 percent, etc. of probability distribution for \mathbf{a} 's, as defined above. These regions are taken as the confidence regions for the parameters $\mathbf{a}_{(0)}$.

Very frequently one is interested not in the full M -dimensional confidence region, but in individual confidence regions for some smaller number ν of parameters. For example, one might be interested in the confidence interval of each parameter taken separately (the bands in Figure 15.6.3), in which case $\nu = 1$. In that case, the natural confidence regions in the ν -dimensional subspace of the M -dimensional parameter space are the *projections* of the M -dimensional regions defined by fixed $\Delta\chi^2$ into the ν -dimensional spaces of interest. In Figure 15.6.4, for the case $M = 2$, we show regions corresponding to several values of $\Delta\chi^2$. The one-dimensional confidence interval in a_2 corresponding to the region bounded by $\Delta\chi^2 = 1$ lies between the lines A and A' .

Notice that the projection of the higher-dimensional region on the lower-dimensional space is used, not the intersection. The intersection would be the band between Z and Z' . It is *never* used. It is shown in the figure only for the purpose of

making this cautionary point, that it should not be confused with the projection.

Probability Distribution of Parameters in the Normal Case

You may be wondering why we have, in this section up to now, made no connection at all with the error estimates that come out of the χ^2 fitting procedure, most notably the covariance matrix C_{ij} . The reason is this: χ^2 minimization is a useful means for estimating parameters even if the measurement errors are not normally distributed. While normally distributed errors are required if the χ^2 parameter estimate is to be a maximum likelihood estimator (§15.1), one is often willing to give up that property in return for the relative convenience of the χ^2 procedure. Only in extreme cases, measurement error distributions with very large “tails,” is χ^2 minimization abandoned in favor of more robust techniques, as will be discussed in §15.7.

However, the formal covariance matrix that comes out of a χ^2 minimization has a clear quantitative interpretation only if (or to the extent that) the measurement errors actually are normally distributed. In the case of *nonnormal* errors, you are “allowed”

- to fit for parameters by minimizing χ^2
- to use a contour of constant $\Delta\chi^2$ as the boundary of your confidence region
- to use Monte Carlo simulation or detailed analytic calculation in determining which contour $\Delta\chi^2$ is the correct one for your desired confidence level
- to give the covariance matrix C_{ij} as the “formal covariance matrix of the fit.”

You are *not* allowed

- to use formulas that we now give for the case of normal errors, which establish quantitative relationships among $\Delta\chi^2$, C_{ij} , and the confidence level.

Here are the key theorems that hold when (i) the measurement errors are normally distributed, and either (ii) the model is linear in its parameters or (iii) the sample size is large enough that the uncertainties in the fitted parameters \mathbf{a} do not extend outside a region in which the model could be replaced by a suitable linearized model. [Note that condition (iii) does not preclude your use of a nonlinear routine like `mqrfit` to find the fitted parameters.]

Theorem A. χ^2_{\min} is distributed as a chi-square distribution with $N - M$ degrees of freedom, where N is the number of data points and M is the number of fitted parameters. This is the basic theorem that lets you evaluate the goodness-of-fit of the model, as discussed above in §15.1. We list it first to remind you that unless the goodness-of-fit is credible, the whole estimation of parameters is suspect.

Theorem B. If $\mathbf{a}_{(j)}^S$ is drawn from the universe of simulated data sets with actual parameters $\mathbf{a}_{(0)}$, then the probability distribution of $\delta\mathbf{a} \equiv \mathbf{a}_{(j)}^S - \mathbf{a}_{(0)}$ is the multivariate normal distribution

$$P(\delta\mathbf{a}) da_1 \dots da_M = \text{const.} \times \exp\left(-\frac{1}{2}\delta\mathbf{a} \cdot [\alpha] \cdot \delta\mathbf{a}\right) da_1 \dots da_M$$

where $[\alpha]$ is the curvature matrix defined in equation (15.5.8).

Theorem C. If $\mathbf{a}_{(j)}^S$ is drawn from the universe of simulated data sets with actual parameters $\mathbf{a}_{(0)}$, then the quantity $\Delta\chi^2 \equiv \chi^2(\mathbf{a}_{(j)}) - \chi^2(\mathbf{a}_{(0)})$ is distributed as

a chi-square distribution with M degrees of freedom. Here the χ^2 's are all evaluated using the fixed (actual) data set $\mathcal{D}_{(0)}$. This theorem makes the connection between particular values of $\Delta\chi^2$ and the fraction of the probability distribution that they enclose as an M -dimensional region, i.e., the confidence level of the M -dimensional confidence region.

Theorem D. Suppose that $\mathbf{a}_{(j)}^S$ is drawn from the universe of simulated data sets (as above), that its first ν components a_1, \dots, a_ν are held fixed, and that its remaining $M - \nu$ components are varied so as to minimize χ^2 . Call this minimum value χ_ν^2 . Then $\Delta\chi_\nu^2 \equiv \chi_\nu^2 - \chi_{\min}^2$ is distributed as a chi-square distribution with ν degrees of freedom. If you consult Figure 15.6.4, you will see that this theorem connects the *projected* $\Delta\chi^2$ region with a confidence level. In the figure, a point that is held fixed in a_2 and allowed to vary in a_1 minimizing χ^2 will seek out the ellipse whose top or bottom edge is tangent to the line of constant a_2 , and is therefore the line that projects it onto the smaller-dimensional space.

As a first example, let us consider the case $\nu = 1$, where we want to find the confidence interval of a single parameter, say a_1 . Notice that the chi-square distribution with $\nu = 1$ degree of freedom is the same distribution as that of the square of a single normally distributed quantity. Thus $\Delta\chi_\nu^2 < 1$ occurs 68.3 percent of the time (1- σ for the normal distribution), $\Delta\chi_\nu^2 < 4$ occurs 95.4 percent of the time (2- σ for the normal distribution), $\Delta\chi_\nu^2 < 9$ occurs 99.73 percent of the time (3- σ for the normal distribution), etc. In this manner you find the $\Delta\chi_\nu^2$ that corresponds to your desired confidence level. (Additional values are given in the accompanying table.)

Let $\delta\mathbf{a}$ be a change in the parameters whose first component is arbitrary, δa_1 , but the rest of whose components are chosen to minimize the $\Delta\chi^2$. Then Theorem D applies. The value of $\Delta\chi^2$ is given in general by

$$\Delta\chi^2 = \delta\mathbf{a} \cdot [\alpha] \cdot \delta\mathbf{a} \quad (15.6.1)$$

which follows from equation (15.5.8) applied at χ_{\min}^2 where $\beta_k = 0$. Since $\delta\mathbf{a}$ by hypothesis minimizes χ^2 in all but its first component, the second through M th components of the normal equations (15.5.9) continue to hold. Therefore, the solution of (15.5.9) is

$$\delta\mathbf{a} = [\alpha]^{-1} \cdot \begin{pmatrix} c \\ 0 \\ \vdots \\ 0 \end{pmatrix} = [C] \cdot \begin{pmatrix} c \\ 0 \\ \vdots \\ 0 \end{pmatrix} \quad (15.6.2)$$

where c is one arbitrary constant that we get to adjust to make (15.6.1) give the desired left-hand value. Plugging (15.6.2) into (15.6.1) and using the fact that $[C]$ and $[\alpha]$ are inverse matrices of one another, we get

$$c = \delta a_1 / C_{11} \quad \text{and} \quad \Delta\chi_\nu^2 = (\delta a_1)^2 / C_{11} \quad (15.6.3)$$

or

$$\delta a_1 = \pm \sqrt{\Delta\chi_\nu^2} \sqrt{C_{11}} \quad (15.6.4)$$

At last! A relation between the confidence interval $\pm\delta a_1$ and the formal standard error $\sigma_1 \equiv \sqrt{C_{11}}$. Not unreasonably, we find that the 68 percent confidence interval is $\pm\sigma_1$, the 95 percent confidence interval is $\pm 2\sigma_1$, etc.

$\Delta\chi^2$ as a Function of Confidence Level and Degrees of Freedom						
p	ν					
	1	2	3	4	5	6
68.3%	1.00	2.30	3.53	4.72	5.89	7.04
90%	2.71	4.61	6.25	7.78	9.24	10.6
95.4%	4.00	6.17	8.02	9.70	11.3	12.8
99%	6.63	9.21	11.3	13.3	15.1	16.8
99.73%	9.00	11.8	14.2	16.3	18.2	20.1
99.99%	15.1	18.4	21.1	23.5	25.7	27.8

These considerations hold not just for the individual parameters a_i , but also for any linear combination of them: If

$$b \equiv \sum_{k=1}^M c_k a_k = \mathbf{c} \cdot \mathbf{a} \quad (15.6.5)$$

then the 68 percent confidence interval on b is

$$\delta b = \pm \sqrt{\mathbf{c} \cdot [C] \cdot \mathbf{c}} \quad (15.6.6)$$

However, these simple, normal-sounding numerical relationships do *not* hold in the case $\nu > 1$ [3]. In particular, $\Delta\chi^2 = 1$ is not the boundary, nor does it project onto the boundary, of a 68.3 percent confidence region when $\nu > 1$. If you want to calculate not confidence intervals in one parameter, but confidence ellipses in two parameters jointly, or ellipsoids in three, or higher, then you must follow the following prescription for implementing Theorems C and D above:

- Let ν be the number of fitted parameters whose joint confidence region you wish to display, $\nu \leq M$. Call these parameters the “parameters of interest.”
- Let p be the confidence limit desired, e.g., $p = 0.68$ or $p = 0.95$.
- Find Δ (i.e., $\Delta\chi^2$) such that the probability of a chi-square variable with ν degrees of freedom being less than Δ is p . For some useful values of p and ν , Δ is given in the table. For other values, you can use the routine `gammq` and a simple root-finding routine (e.g., bisection) to find Δ such that `gammq`($\nu/2, \Delta/2$) = $1 - p$.
- Take the $M \times M$ covariance matrix $[C] = [\alpha]^{-1}$ of the chi-square fit. Copy the intersection of the ν rows and columns corresponding to the parameters of interest into a $\nu \times \nu$ matrix denoted $[C_{\text{proj}}]$.
- Invert the matrix $[C_{\text{proj}}]$. (In the one-dimensional case this was just taking the reciprocal of the element C_{11} .)
- The equation for the elliptical boundary of your desired confidence region in the ν -dimensional subspace of interest is

$$\Delta = \delta \mathbf{a}' \cdot [C_{\text{proj}}]^{-1} \cdot \delta \mathbf{a}' \quad (15.6.7)$$

where $\delta \mathbf{a}'$ is the ν -dimensional vector of parameters of interest.

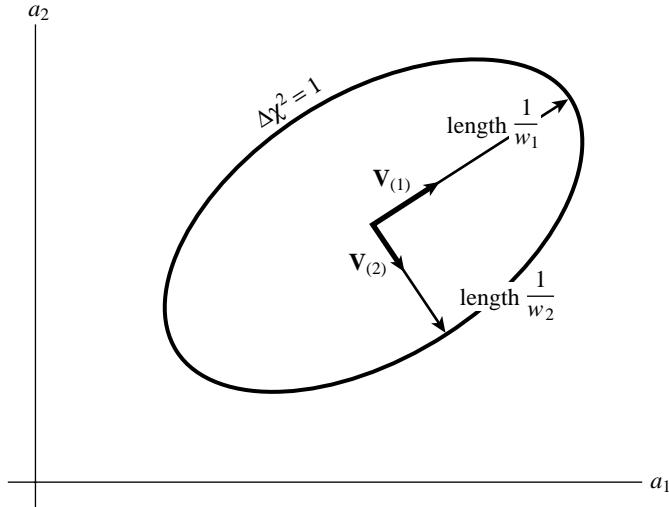

Figure 15.6.5. Relation of the confidence region ellipse $\Delta\chi^2 = 1$ to quantities computed by singular value decomposition. The vectors $\mathbf{V}_{(i)}$ are unit vectors along the principal axes of the confidence region. The semi-axes have lengths equal to the reciprocal of the singular values w_i . If the axes are all scaled by some constant factor α , $\Delta\chi^2$ is scaled by the factor α^2 .

If you are confused at this point, you may find it helpful to compare Figure 15.6.4 and the accompanying table, considering the case $M = 2$ with $\nu = 1$ and $\nu = 2$. You should be able to verify the following statements: (i) The horizontal band between C and C' contains 99 percent of the probability distribution, so it is a confidence limit on a_2 alone at this level of confidence. (ii) Ditto the band between B and B' at the 90 percent confidence level. (iii) The dashed ellipse, labeled by $\Delta\chi^2 = 2.30$, contains 68.3 percent of the probability distribution, so it is a confidence region for a_1 and a_2 jointly, at this level of confidence.

Confidence Limits from Singular Value Decomposition

When you have obtained your χ^2 fit by singular value decomposition (§15.4), the information about the fit's formal errors comes packaged in a somewhat different, but generally more convenient, form. The columns of the matrix \mathbf{V} are an orthonormal set of M vectors that are the principal axes of the $\Delta\chi^2 = \text{constant}$ ellipsoids. We denote the columns as $\mathbf{V}_{(1)} \dots \mathbf{V}_{(M)}$. The lengths of those axes are inversely proportional to the corresponding singular values $w_1 \dots w_M$; see Figure 15.6.5. The boundaries of the ellipsoids are thus given by

$$\Delta\chi^2 = w_1^2(\mathbf{V}_{(1)} \cdot \delta\mathbf{a})^2 + \dots + w_M^2(\mathbf{V}_{(M)} \cdot \delta\mathbf{a})^2 \quad (15.6.8)$$

which is the justification for writing equation (15.4.18) above. Keep in mind that it is *much* easier to plot an ellipsoid given a list of its vector principal axes, than given its matrix quadratic form!

The formula for the covariance matrix $[C]$ in terms of the columns $\mathbf{V}_{(i)}$ is

$$[C] = \sum_{i=1}^M \frac{1}{w_i^2} \mathbf{V}_{(i)} \otimes \mathbf{V}_{(i)} \quad (15.6.9)$$

or, in components,

$$C_{jk} = \sum_{i=1}^M \frac{1}{w_i^2} V_{ji} V_{ki} \quad (15.6.10)$$

15.7 Robust Estimation

The concept of *robustness* has been mentioned in passing several times already. In §14.1 we noted that the median was a more robust estimator of central value than the mean; in §14.6 it was mentioned that rank correlation is more robust than linear correlation. The concept of outlier points as exceptions to a Gaussian model for experimental error was discussed in §15.1.

The term “robust” was coined in statistics by G.E.P. Box in 1953. Various definitions of greater or lesser mathematical rigor are possible for the term, but in general, referring to a statistical estimator, it means “insensitive to small departures from the idealized assumptions for which the estimator is optimized.” [1,2] The word “small” can have two different interpretations, both important: either fractionally small departures for all data points, or else fractionally large departures for a small number of data points. It is the latter interpretation, leading to the notion of outlier points, that is generally the most stressful for statistical procedures.

Statisticians have developed various sorts of robust statistical estimators. Many, if not most, can be grouped in one of three categories.

M-estimates follow from maximum-likelihood arguments very much as equations (15.1.5) and (15.1.7) followed from equation (15.1.3). M-estimates are usually the most relevant class for model-fitting, that is, estimation of parameters. We therefore consider these estimates in some detail below.

L-estimates are “linear combinations of order statistics.” These are most applicable to estimations of central value and central tendency, though they can occasionally be applied to some problems in estimation of parameters. Two “typical” L-estimates will give you the general idea. They are (i) the median, and (ii) *Tukey’s trimean*, defined as the weighted average of the first, second, and third quartile points in a distribution, with weights 1/4, 1/2, and 1/4, respectively.

R-estimates are estimates based on rank tests. For example, the equality or inequality of two distributions can be estimated by the *Wilcoxon test* of computing the mean rank of one distribution in a combined sample of both distributions. The Kolmogorov-Smirnov statistic (equation 14.3.6) and the Spearman rank-order

$$C_{jk} = \sum_{i=1}^M \frac{1}{w_i^2} V_{ji} V_{ki} \quad (15.6.10)$$

15.7 Robust Estimation

The concept of *robustness* has been mentioned in passing several times already. In §14.1 we noted that the median was a more robust estimator of central value than the mean; in §14.6 it was mentioned that rank correlation is more robust than linear correlation. The concept of outlier points as exceptions to a Gaussian model for experimental error was discussed in §15.1.

The term “robust” was coined in statistics by G.E.P. Box in 1953. Various definitions of greater or lesser mathematical rigor are possible for the term, but in general, referring to a statistical estimator, it means “insensitive to small departures from the idealized assumptions for which the estimator is optimized.” [1,2] The word “small” can have two different interpretations, both important: either fractionally small departures for all data points, or else fractionally large departures for a small number of data points. It is the latter interpretation, leading to the notion of outlier points, that is generally the most stressful for statistical procedures.

Statisticians have developed various sorts of robust statistical estimators. Many, if not most, can be grouped in one of three categories.

M-estimates follow from maximum-likelihood arguments very much as equations (15.1.5) and (15.1.7) followed from equation (15.1.3). M-estimates are usually the most relevant class for model-fitting, that is, estimation of parameters. We therefore consider these estimates in some detail below.

L-estimates are “linear combinations of order statistics.” These are most applicable to estimations of central value and central tendency, though they can occasionally be applied to some problems in estimation of parameters. Two “typical” L-estimates will give you the general idea. They are (i) the median, and (ii) *Tukey’s trimean*, defined as the weighted average of the first, second, and third quartile points in a distribution, with weights 1/4, 1/2, and 1/4, respectively.

R-estimates are estimates based on rank tests. For example, the equality or inequality of two distributions can be estimated by the *Wilcoxon test* of computing the mean rank of one distribution in a combined sample of both distributions. The Kolmogorov-Smirnov statistic (equation 14.3.6) and the Spearman rank-order

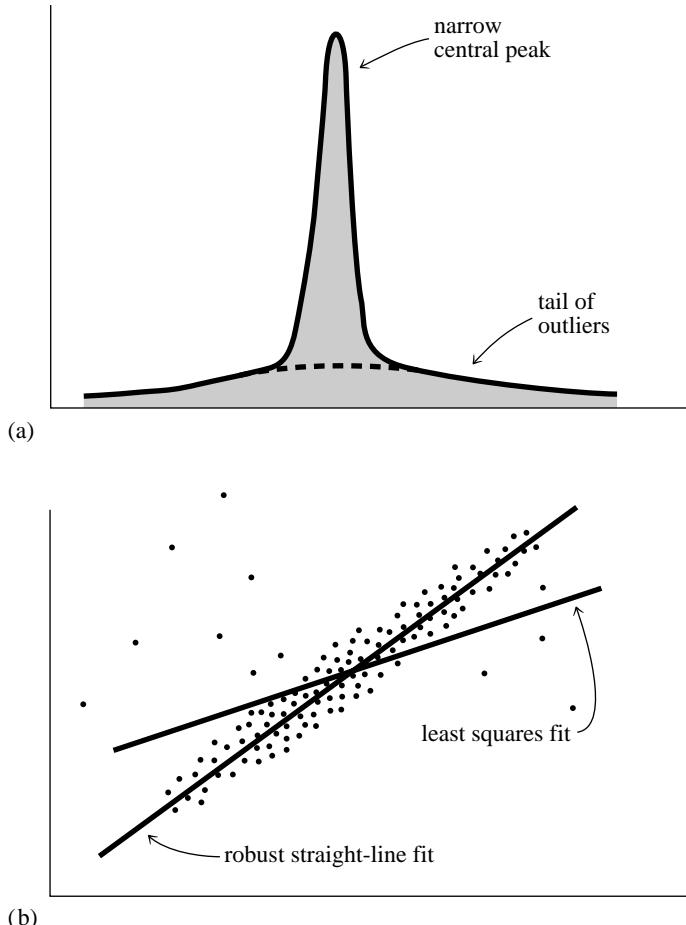

Figure 15.7.1. Examples where robust statistical methods are desirable: (a) A one-dimensional distribution with a tail of outliers; statistical fluctuations in these outliers can prevent accurate determination of the position of the central peak. (b) A distribution in two dimensions fitted to a straight line; non-robust techniques such as least-squares fitting can have undesired sensitivity to outlying points.

correlation coefficient (14.6.1) are R-estimates in essence, if not always by formal definition.

Some other kinds of robust techniques, coming from the fields of optimal control and filtering rather than from the field of mathematical statistics, are mentioned at the end of this section. Some examples where robust statistical methods are desirable are shown in Figure 15.7.1.

Estimation of Parameters by Local M-Estimates

Suppose we know that our measurement errors are not normally distributed. Then, in deriving a maximum-likelihood formula for the estimated parameters \mathbf{a} in a model $y(x; \mathbf{a})$, we would write instead of equation (15.1.3)

$$P = \prod_{i=1}^N \{\exp [-\rho(y_i, y\{x_i; \mathbf{a}\})] \Delta y\} \quad (15.7.1)$$

where the function ρ is the negative logarithm of the probability density. Taking the logarithm of (15.7.1) analogously with (15.1.4), we find that we want to minimize the expression

$$\sum_{i=1}^N \rho(y_i, y(x_i; \mathbf{a})) \quad (15.7.2)$$

Very often, it is the case that the function ρ depends not independently on its two arguments, measured y_i and predicted $y(x_i)$, but only on their difference, at least if scaled by some weight factors σ_i which we are able to assign to each point. In this case the M-estimate is said to be *local*, and we can replace (15.7.2) by the prescription

$$\text{minimize over } \mathbf{a} \quad \sum_{i=1}^N \rho\left(\frac{y_i - y(x_i; \mathbf{a})}{\sigma_i}\right) \quad (15.7.3)$$

where the function $\rho(z)$ is a function of a single variable $z \equiv [y_i - y(x_i)]/\sigma_i$.

If we now define the derivative of $\rho(z)$ to be a function $\psi(z)$,

$$\psi(z) \equiv \frac{d\rho(z)}{dz} \quad (15.7.4)$$

then the generalization of (15.1.7) to the case of a general M-estimate is

$$0 = \sum_{i=1}^N \frac{1}{\sigma_i} \psi\left(\frac{y_i - y(x_i)}{\sigma_i}\right) \left(\frac{\partial y(x_i; \mathbf{a})}{\partial a_k}\right) \quad k = 1, \dots, M \quad (15.7.5)$$

If you compare (15.7.3) to (15.1.3), and (15.7.5) to (15.1.7), you see at once that the specialization for normally distributed errors is

$$\rho(z) = \frac{1}{2}z^2 \quad \psi(z) = z \quad (\text{normal}) \quad (15.7.6)$$

If the errors are distributed as a *double* or *two-sided exponential*, namely

$$\text{Prob } \{y_i - y(x_i)\} \sim \exp\left(-\left|\frac{y_i - y(x_i)}{\sigma_i}\right|\right) \quad (15.7.7)$$

then, by contrast,

$$\rho(x) = |x| \quad \psi(x) = \text{sgn}(x) \quad (\text{double exponential}) \quad (15.7.8)$$

Comparing to equation (15.7.3), we see that in this case the maximum likelihood estimator is obtained by minimizing the *mean absolute deviation*, rather than the mean square deviation. Here the tails of the distribution, although exponentially decreasing, are asymptotically much larger than any corresponding Gaussian.

A distribution with even more extensive — therefore sometimes even more realistic — tails is the *Cauchy* or *Lorentzian* distribution,

$$\text{Prob } \{y_i - y(x_i)\} \sim \frac{1}{1 + \frac{1}{2} \left(\frac{y_i - y(x_i)}{\sigma_i}\right)^2} \quad (15.7.9)$$

This implies

$$\rho(z) = \log\left(1 + \frac{1}{2}z^2\right) \quad \psi(z) = \frac{z}{1 + \frac{1}{2}z^2} \quad (\text{Lorentzian}) \quad (15.7.10)$$

Notice that the ψ function occurs as a weighting function in the generalized normal equations (15.7.5). For normally distributed errors, equation (15.7.6) says that the more deviant the points, the greater the weight. By contrast, when tails are somewhat more prominent, as in (15.7.7), then (15.7.8) says that all deviant points get the same relative weight, with only the sign information used. Finally, when the tails are even larger, (15.7.10) says the ψ increases with deviation, then starts *decreasing*, so that very deviant points — the true outliers — are not counted at all in the estimation of the parameters.

This general idea, that the weight given individual points should first increase with deviation, then decrease, motivates some additional prescriptions for ψ which do not especially correspond to standard, textbook probability distributions. Two examples are

Andrew's sine

$$\psi(z) = \begin{cases} \sin(z/c) & |z| < c\pi \\ 0 & |z| > c\pi \end{cases} \quad (15.7.11)$$

If the measurement errors happen to be normal after all, with standard deviations σ_i , then it can be shown that the optimal value for the constant c is $c = 2.1$.

Tukey's biweight

$$\psi(z) = \begin{cases} z(1 - z^2/c^2)^2 & |z| < c \\ 0 & |z| > c \end{cases} \quad (15.7.12)$$

where the optimal value of c for normal errors is $c = 6.0$.

Numerical Calculation of M-Estimates

To fit a model by means of an M-estimate, you first decide which M-estimate you want, that is, which matching pair ρ, ψ you want to use. We rather like (15.7.8) or (15.7.10).

You then have to make an unpleasant choice between two fairly difficult problems. Either find the solution of the nonlinear set of M equations (15.7.5), or else minimize the single function in M variables (15.7.3).

Notice that the function (15.7.8) has a discontinuous ψ , and a discontinuous derivative for ρ . Such discontinuities frequently wreak havoc on both general nonlinear equation solvers and general function minimizing routines. You might now think of rejecting (15.7.8) in favor of (15.7.10), which is smoother. However, you will find that the latter choice is also bad news for many general equation solving or minimization routines: small changes in the fitted parameters can drive $\psi(z)$ off its peak into one or the other of its asymptotically small regimes. Therefore, different terms in the equation spring into or out of action (almost as bad as analytic discontinuities).

Don't despair. If your computer budget (or, for personal computers, patience) is up to it, this is an excellent application for the downhill simplex minimization

algorithm exemplified in `amoeba` §10.4 or `amebsa` in §10.9. Those algorithms make no assumptions about continuity; they just ooze downhill and will work for virtually any sane choice of the function ρ .

It is very much to your (financial) advantage to find good starting values, however. Often this is done by first fitting the model by the standard χ^2 (nonrobust) techniques, e.g., as described in §15.4 or §15.5. The fitted parameters thus obtained are then used as starting values in `amoeba`, now using the robust choice of ρ and minimizing the expression (15.7.3).

Fitting a Line by Minimizing Absolute Deviation

Occasionally there is a special case that happens to be much easier than is suggested by the general strategy outlined above. The case of equations (15.7.7)–(15.7.8), when the model is a simple straight line

$$y(x; a, b) = a + bx \quad (15.7.13)$$

and where the weights σ_i are all equal, happens to be such a case. The problem is precisely the robust version of the problem posed in equation (15.2.1) above, namely fit a straight line through a set of data points. The merit function to be minimized is

$$\sum_{i=1}^N |y_i - a - bx_i| \quad (15.7.14)$$

rather than the χ^2 given by equation (15.2.2).

The key simplification is based on the following fact: The median c_M of a set of numbers c_i is also that value which minimizes the sum of the absolute deviations

$$\sum_i |c_i - c_M|$$

(Proof: Differentiate the above expression with respect to c_M and set it to zero.)

It follows that, for fixed b , the value of a that minimizes (15.7.14) is

$$a = \text{median}\{y_i - bx_i\} \quad (15.7.15)$$

Equation (15.7.5) for the parameter b is

$$0 = \sum_{i=1}^N x_i \operatorname{sgn}(y_i - a - bx_i) \quad (15.7.16)$$

(where $\operatorname{sgn}(0)$ is to be interpreted as zero). If we replace a in this equation by the implied function $a(b)$ of (15.7.15), then we are left with an equation in a single variable which can be solved by bracketing and bisection, as described in §9.1. (In fact, it is dangerous to use any fancier method of root-finding, because of the discontinuities in equation 15.7.16.)

Here is a routine that does all this. It calls `select` (§8.5) to find the median. The bracketing and bisection are built in to the routine, as is the χ^2 solution that generates the initial guesses for a and b . Notice that the evaluation of the right-hand side of (15.7.16) occurs in the function `rofunc`, with communication via a common block. To save memory, you could generate your data arrays directly into that common block, deleting them from this routine's calling sequence.

```

SUBROUTINE medfit(x,y,ndata,a,b,abdev)

Other Robust Techniques

Sometimes you may have *a priori* knowledge about the probable values and probable uncertainties of some parameters that you are trying to estimate from a data set. In such cases you may want to perform a fit that takes this advance information properly into account, neither completely freezing a parameter at a predetermined value (as in `lfit` §15.4) nor completely leaving it to be determined by the data set. The formalism for doing this is called “use of *a priori* covariances.”

A related problem occurs in signal processing and control theory, where it is sometimes desired to “track” (i.e., maintain an estimate of) a time-varying signal in the presence of noise. If the signal is known to be characterized by some number of parameters that vary only slowly, then the formalism of *Kalman filtering* tells how the incoming, raw measurements of the signal should be processed to produce best parameter estimates as a function of time. For example, if the signal is a frequency-modulated sine wave, then the slowly varying parameter might be the instantaneous frequency. The Kalman filter for this case is called a *phase-locked loop* and is implemented in the circuitry of good radio receivers [3,4].

Chapter 16. Integration of Ordinary Differential Equations

16.0 Introduction

Problems involving ordinary differential equations (ODEs) can always be reduced to the study of sets of first-order differential equations. For example the second-order equation

$$\frac{d^2y}{dx^2} + q(x)\frac{dy}{dx} = r(x) \quad (16.0.1)$$

can be rewritten as two first-order equations

$$\begin{aligned} \frac{dy}{dx} &= z(x) \\ \frac{dz}{dx} &= r(x) - q(x)z(x) \end{aligned} \quad (16.0.2)$$

where z is a new variable. This exemplifies the procedure for an arbitrary ODE. The usual choice for the new variables is to let them be just derivatives of each other (and of the original variable). Occasionally, it is useful to incorporate into their definition some other factors in the equation, or some powers of the independent variable, for the purpose of mitigating singular behavior that could result in overflows or increased roundoff error. Let common sense be your guide: If you find that the original variables are smooth in a solution, while your auxiliary variables are doing crazy things, then figure out why and choose different auxiliary variables.

The generic problem in ordinary differential equations is thus reduced to the study of a set of N coupled *first-order* differential equations for the functions y_i , $i = 1, 2, \dots, N$, having the general form

$$\frac{dy_i(x)}{dx} = f_i(x, y_1, \dots, y_N), \quad i = 1, \dots, N \quad (16.0.3)$$

where the functions f_i on the right-hand side are known.

A problem involving ODEs is not completely specified by its equations. Even more crucial in determining how to attack the problem numerically is the nature of the problem's boundary conditions. Boundary conditions are algebraic conditions on the values of the functions y_i in (16.0.3). In general they can be satisfied at

discrete specified points, but do not hold between those points, i.e., are not preserved automatically by the differential equations. Boundary conditions can be as simple as requiring that certain variables have certain numerical values, or as complicated as a set of nonlinear algebraic equations among the variables.

Usually, it is the nature of the boundary conditions that determines which numerical methods will be feasible. Boundary conditions divide into two broad categories.

- In *initial value problems* all the y_i are given at some starting value x_s , and it is desired to find the y_i 's at some final point x_f , or at some discrete list of points (for example, at tabulated intervals).
- In *two-point boundary value problems*, on the other hand, boundary conditions are specified at more than one x . Typically, some of the conditions will be specified at x_s and the remainder at x_f .

This chapter will consider exclusively the initial value problem, deferring two-point boundary value problems, which are generally more difficult, to Chapter 17.

The underlying idea of any routine for solving the initial value problem is always this: Rewrite the dy 's and dx 's in (16.0.3) as finite steps Δy and Δx , and multiply the equations by Δx . This gives algebraic formulas for the change in the functions when the independent variable x is “stepped” by one “stepsize” Δx . In the limit of making the stepsize very small, a good approximation to the underlying differential equation is achieved. Literal implementation of this procedure results in *Euler's method* (16.1.1, below), which is, however, *not* recommended for any practical use. Euler's method is conceptually important, however; one way or another, practical methods all come down to this same idea: Add small increments to your functions corresponding to derivatives (right-hand sides of the equations) multiplied by stepsizes.

In this chapter we consider three major types of practical numerical methods for solving initial value problems for ODEs:

- Runge-Kutta methods
- Richardson extrapolation and its particular implementation as the Bulirsch-Stoer method
- predictor-corrector methods.

A brief description of each of these types follows.

1. *Runge-Kutta* methods propagate a solution over an interval by combining the information from several Euler-style steps (each involving one evaluation of the right-hand f 's), and then using the information obtained to match a Taylor series expansion up to some higher order.

2. *Richardson extrapolation* uses the powerful idea of extrapolating a computed result to the value that *would* have been obtained if the stepsize had been very much smaller than it actually was. In particular, extrapolation to zero stepsize is the desired goal. The first practical ODE integrator that implemented this idea was developed by Bulirsch and Stoer, and so extrapolation methods are often called Bulirsch-Stoer methods.

3. *Predictor-corrector* methods store the solution along the way, and use those results to extrapolate the solution one step advanced; they then correct the extrapolation using derivative information at the new point. These are best for very smooth functions.

Runge-Kutta is what you use when (i) you don't know any better, or (ii) you have an intransigent problem where Bulirsch-Stoer is failing, or (iii) you have a trivial

problem where computational efficiency is of no concern. Runge-Kutta succeeds virtually always; but it is not usually fastest, except when evaluating f_i is cheap and moderate accuracy ($\lesssim 10^{-5}$) is required. Predictor-corrector methods, since they use past information, are somewhat more difficult to start up, but, for many smooth problems, they are computationally more efficient than Runge-Kutta. In recent years Bulirsch-Stoer has been replacing predictor-corrector in many applications, but it is too soon to say that predictor-corrector is dominated in all cases. However, it appears that only rather sophisticated predictor-corrector routines are competitive. Accordingly, we have chosen *not* to give an implementation of predictor-corrector in this book. We discuss predictor-corrector further in §16.7, so that you can use a canned routine should you encounter a suitable problem. In our experience, the relatively simple Runge-Kutta and Bulirsch-Stoer routines we give are adequate for most problems.

Each of the three types of methods can be organized to monitor internal consistency. This allows numerical errors which are inevitably introduced into the solution to be controlled by automatic, (*adaptive*) changing of the fundamental stepsize. We always recommend that adaptive stepsize control be implemented, and we will do so below.

In general, all three types of methods can be applied to any initial value problem. Each comes with its own set of debits and credits that must be understood before it is used.

We have organized the routines in this chapter into three nested levels. The lowest or “nitty-gritty” level is the piece we call the *algorithm* routine. This implements the basic formulas of the method, starts with dependent variables y_i at x , and returns new values of the dependent variables at the value $x + h$. The algorithm routine also yields up some information about the quality of the solution after the step. The routine is dumb, however, and it is unable to make any adaptive decision about whether the solution is of acceptable quality or not.

That quality-control decision we encode in a *stepper* routine. The stepper routine calls the algorithm routine. It may reject the result, set a smaller stepsize, and call the algorithm routine again, until compatibility with a predetermined accuracy criterion has been achieved. The stepper’s fundamental task is to take the largest stepsize consistent with specified performance. Only when this is accomplished does the true power of an algorithm come to light.

Above the stepper is the *driver* routine, which starts and stops the integration, stores intermediate results, and generally acts as an interface with the user. There is nothing at all canonical about our driver routines. You should consider them to be examples, and you can customize them for your particular application.

Of the routines that follow, `rk4`, `rkck`, `mmid`, `stoerm`, and `simpr` are algorithm routines; `rkqs`, `bsstep`, `stiff`, and `stifbs` are steppers; `rkdumb` and `odeint` are drivers.

Section 16.6 of this chapter treats the subject of *stiff equations*, relevant both to ordinary differential equations and also to partial differential equations (Chapter 19).

16.1 Runge-Kutta Method

The formula for the Euler method is

$$y_{n+1} = y_n + h f(x_n, y_n) \quad (16.1.1)$$

which advances a solution from x_n to $x_{n+1} \equiv x_n + h$. The formula is unsymmetrical: It advances the solution through an interval h , but uses derivative information only at the beginning of that interval (see Figure 16.1.1). That means (and you can verify by expansion in power series) that the step's error is only one power of h smaller than the correction, i.e. $O(h^2)$ added to (16.1.1).

There are several reasons that Euler's method is not recommended for practical use, among them, (i) the method is not very accurate when compared to other, fancier, methods run at the equivalent stepsize, and (ii) neither is it very stable (see §16.6 below).

Consider, however, the use of a step like (16.1.1) to take a “trial” step to the midpoint of the interval. Then use the value of both x and y at that midpoint to compute the “real” step across the whole interval. Figure 16.1.2 illustrates the idea. In equations,

$$\begin{aligned} k_1 &= h f(x_n, y_n) \\ k_2 &= h f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}k_1\right) \\ y_{n+1} &= y_n + k_2 + O(h^3) \end{aligned} \quad (16.1.2)$$

As indicated in the error term, this symmetrization cancels out the first-order error term, making the method *second order*. [A method is conventionally called n th order if its error term is $O(h^{n+1})$.] In fact, (16.1.2) is called the *second-order Runge-Kutta or midpoint* method.

We needn't stop there. There are many ways to evaluate the right-hand side $f(x, y)$ that all agree to first order, but that have different coefficients of higher-order error terms. Adding up the right combination of these, we can eliminate the error terms order by order. That is the basic idea of the Runge-Kutta method. Abramowitz and Stegun [1], and Gear [2], give various specific formulas that derive from this basic

16.1 Runge-Kutta Method

The formula for the Euler method is

$$y_{n+1} = y_n + h f(x_n, y_n) \quad (16.1.1)$$

which advances a solution from x_n to $x_{n+1} \equiv x_n + h$. The formula is unsymmetrical: It advances the solution through an interval h , but uses derivative information only at the beginning of that interval (see Figure 16.1.1). That means (and you can verify by expansion in power series) that the step's error is only one power of h smaller than the correction, i.e. $O(h^2)$ added to (16.1.1).

There are several reasons that Euler's method is not recommended for practical use, among them, (i) the method is not very accurate when compared to other, fancier, methods run at the equivalent stepsize, and (ii) neither is it very stable (see §16.6 below).

Consider, however, the use of a step like (16.1.1) to take a “trial” step to the midpoint of the interval. Then use the value of both x and y at that midpoint to compute the “real” step across the whole interval. Figure 16.1.2 illustrates the idea. In equations,

$$\begin{aligned} k_1 &= h f(x_n, y_n) \\ k_2 &= h f\left(x_n + \frac{1}{2}h, y_n + \frac{1}{2}k_1\right) \\ y_{n+1} &= y_n + k_2 + O(h^3) \end{aligned} \quad (16.1.2)$$

As indicated in the error term, this symmetrization cancels out the first-order error term, making the method *second order*. [A method is conventionally called n th order if its error term is $O(h^{n+1})$.] In fact, (16.1.2) is called the *second-order Runge-Kutta or midpoint* method.

We needn't stop there. There are many ways to evaluate the right-hand side $f(x, y)$ that all agree to first order, but that have different coefficients of higher-order error terms. Adding up the right combination of these, we can eliminate the error terms order by order. That is the basic idea of the Runge-Kutta method. Abramowitz and Stegun [1], and Gear [2], give various specific formulas that derive from this basic

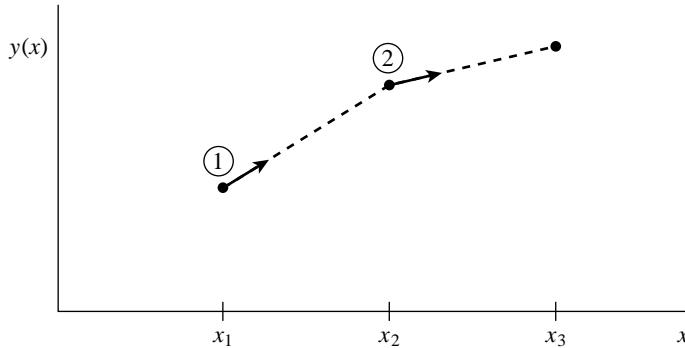

Figure 16.1.1. Euler's method. In this simplest (and least accurate) method for integrating an ODE, the derivative at the starting point of each interval is extrapolated to find the next function value. The method has first-order accuracy.

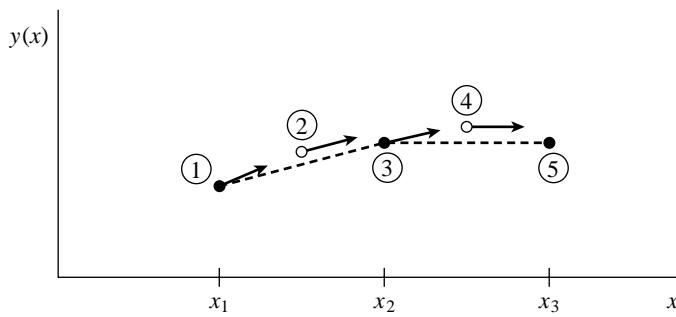

Figure 16.1.2. Midpoint method. Second-order accuracy is obtained by using the initial derivative at each step to find a point halfway across the interval, then using the midpoint derivative across the full width of the interval. In the figure, filled dots represent final function values, while open dots represent function values that are discarded once their derivatives have been calculated and used.

idea. By far the most often used is the classical *fourth-order Runge-Kutta formula*, which has a certain sleekness of organization about it:

$$\begin{aligned}
 k_1 &= hf(x_n, y_n) \\
 k_2 &= hf\left(x_n + \frac{h}{2}, y_n + \frac{k_1}{2}\right) \\
 k_3 &= hf\left(x_n + \frac{h}{2}, y_n + \frac{k_2}{2}\right) \\
 k_4 &= hf(x_n + h, y_n + k_3) \\
 y_{n+1} &= y_n + \frac{k_1}{6} + \frac{k_2}{3} + \frac{k_3}{3} + \frac{k_4}{6} + O(h^5)
 \end{aligned} \tag{16.1.3}$$

The fourth-order Runge-Kutta method requires four evaluations of the right-hand side per step h (see Figure 16.1.3). This will be superior to the midpoint method (16.1.2) if at least twice as large a step is possible with (16.1.3) for the same accuracy. Is that so? The answer is: often, perhaps even usually, but surely not always! This takes us back to a central theme, namely that *high order* does not always mean *high accuracy*. The statement “fourth-order Runge-Kutta is generally superior to second-order” is a true one, but you should recognize it as a statement about the

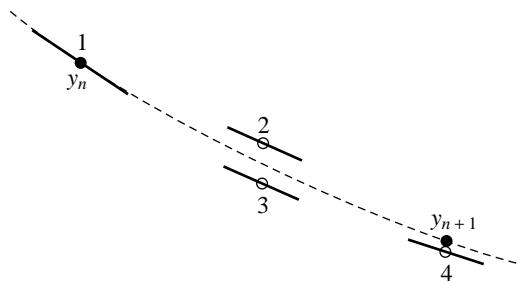

Figure 16.1.3. Fourth-order Runge-Kutta method. In each step the derivative is evaluated four times: once at the initial point, twice at trial midpoints, and once at a trial endpoint. From these derivatives the final function value (shown as a filled dot) is calculated. (See text for details.)

contemporary practice of science rather than as a statement about strict mathematics. That is, it reflects the nature of the problems that contemporary scientists like to solve.

For many scientific users, fourth-order Runge-Kutta is not just the first word on ODE integrators, but the last word as well. In fact, you can get pretty far on this old workhorse, especially if you combine it with an adaptive stepsize algorithm. Keep in mind, however, that the old workhorse's last trip may well be to take you to the poorhouse: Bulirsch-Stoer or predictor-corrector methods can be very much more efficient for problems where very high accuracy is a requirement. Those methods are the high-strung racehorses. Runge-Kutta is for ploughing the fields. However, even the old workhorse is more nimble with new horseshoes. In §16.2 we will give a modern implementation of a Runge-Kutta method that is quite competitive as long as very high accuracy is not required. An excellent discussion of the pitfalls in constructing a good Runge-Kutta code is given in [3].

Here is the routine for carrying out one classical Runge-Kutta step on a set of n differential equations. You input the values of the independent variables, and you get out new values which are stepped by a stepsize h (which can be positive or negative). You will notice that the routine requires you to supply not only function `derivs` for calculating the right-hand side, but also values of the derivatives at the starting point. Why not let the routine call `derivs` for this first value? The answer will become clear only in the next section, but in brief is this: This call may not be your only one with these starting conditions. You may have taken a previous step with too large a stepsize, and this is your replacement. In that case, you do not want to call `derivs` unnecessarily at the start. Note that the routine that follows has, therefore, only three calls to `derivs`.

```
SUBROUTINE rk4(y,dydx,n,x,h,yout,derivs)
INTEGER n,NMAX
REAL h,x,dydx(n),y(n),yout(n)
EXTERNAL derivs
PARAMETER (NMAX=50)           Set to the maximum number of functions.
Given values for the variables y(1:n) and their derivatives dydx(1:n) known at x, use
the fourth-order Runge-Kutta method to advance the solution over an interval h and return
the incremented variables as yout(1:n), which need not be a distinct array from y. The
user supplies the subroutine derivs(x,y,dydx), which returns derivatives dydx at x.
INTEGER i
REAL h6,hh,xh,dym(NMAX),dyt(NMAX),yt(NMAX)
hh=h*0.5
h6=h/6.
xh=x+hh
```

```

do 11 i=1,n           First step.
    yt(i)=y(i)+hh*dydx(i)
  enddo 11
  call derivs(xh,yt,dyt)   Second step.
  do 12 i=1,n
    yt(i)=y(i)+hh*dyt(i)
  enddo 12
  call derivs(xh,yt,dym)   Third step.
  do 13 i=1,n
    yt(i)=y(i)+h*dym(i)
    dym(i)=dyt(i)+dym(i)
  enddo 13
  call derivs(x+h,yt,dyt)   Fourth step.
  do 14 i=1,n           Accumulate increments with proper weights.
    yout(i)=y(i)+h6*(dydx(i)+dyt(i)+2.*dym(i))
  enddo 14
  return
END

```

The Runge-Kutta method treats every step in a sequence of steps in identical manner. Prior behavior of a solution is not used in its propagation. This is mathematically proper, since any point along the trajectory of an ordinary differential equation can serve as an initial point. The fact that all steps are treated identically also makes it easy to incorporate Runge-Kutta into relatively simple “driver” schemes.

We consider adaptive stepsize control, discussed in the next section, an essential for serious computing. Occasionally, however, you just want to tabulate a function at equally spaced intervals, and without particularly high accuracy. In the most common case, you want to produce a graph of the function. Then all you need may be a simple driver program that goes from an initial x_s to a final x_f in a specified number of steps. To check accuracy, double the number of steps, repeat the integration, and compare results. This approach surely does not minimize computer time, and it can fail for problems whose nature *requires* a variable stepsize, but it may well minimize user effort. On small problems, this may be the paramount consideration.

Here is such a driver, self-explanatory, which tabulates the integrated functions in a common block path.

```

SUBROUTINE rkdumb(vstart,nvar,x1,x2,nstep,derivs)
INTEGER nstep,nvar,NMAX,NSTPMX
PARAMETER (NMAX=50,NSTPMX=200)           Maximum number of functions and
REAL x1,x2,vstart(nvar),xx(NSTPMX),y(NMAX,NSTPMX)   maximum number of values to
EXTERNAL derivs                           be stored.
COMMON /path/ xx,y                      Storage of results.
C USES rk4
      Starting from initial values vstart(1:nvar) known at x1 use fourth-order Runge-Kutta to
      advance nstep equal increments to x2. The user-supplied subroutine derivs(x,v,dvdx)
      evaluates derivatives. Results are stored in the common block path. Be sure to dimension
      the common block appropriately.
      INTEGER i,k
      REAL h,x,dv(NMAX),v(NMAX)
      do 11 i=1,nvar                         Load starting values.
        v(i)=vstart(i)
        y(i,1)=v(i)
      enddo 11
      xx(1)=x1
      x=x1
      h=(x2-x1)/nstep
      do 13 k=1,nstep                        Take nstep steps.
        call derivs(x,v,dv)

```

```

call rk4(v,dv,nvar,x,h,v,derivs)
if(x+h.eq.x)pause 'stepsize not significant in rkdumb'
x=x+h
xx(k+1)=x          Store intermediate steps.
do i2 i=1,nvar
    y(i,k+1)=v(i)
enddo i2
enddo i3
return
END

```

16.2 Adaptive Stepsize Control for Runge-Kutta

A good ODE integrator should exert some adaptive control over its own progress, making frequent changes in its stepsize. Usually the purpose of this adaptive stepsize control is to achieve some predetermined accuracy in the solution with minimum computational effort. Many small steps should tiptoe through treacherous terrain, while a few great strides should speed through smooth uninteresting countryside. The resulting gains in efficiency are not mere tens of percents or factors of two; they can sometimes be factors of ten, a hundred, or more. Sometimes accuracy may be demanded not directly in the solution itself, but in some related conserved quantity that can be monitored.

Implementation of adaptive stepsize control requires that the stepping algorithm return information about its performance, most important, an estimate of its truncation error. In this section we will learn how such information can be obtained. Obviously, the calculation of this information will add to the computational overhead, but the investment will generally be repaid handsomely.

With fourth-order Runge-Kutta, the most straightforward technique by far is *step doubling* (see, e.g., [1]). We take each step twice, once as a full step, then, independently, as two half steps (see Figure 16.2.1). How much overhead is this, say in terms of the number of evaluations of the right-hand sides? Each of the three separate Runge-Kutta steps in the procedure requires 4 evaluations, but the single and double sequences share a starting point, so the total is 11. This is to be compared not to 4, but to 8 (the two half-steps), since — stepsize control aside — we are achieving the accuracy of the smaller (half) stepsize. The overhead cost is therefore a factor 1.375. What does it buy us?

```

call rk4(v,dv,nvar,x,h,v,derivs)
if(x+h.eq.x)pause 'stepsize not significant in rkdumb'
x=x+h
xx(k+1)=x          Store intermediate steps.
do i2 i=1,nvar
    y(i,k+1)=v(i)
enddo i2
enddo i3
return
END

```

16.2 Adaptive Stepsize Control for Runge-Kutta

A good ODE integrator should exert some adaptive control over its own progress, making frequent changes in its stepsize. Usually the purpose of this adaptive stepsize control is to achieve some predetermined accuracy in the solution with minimum computational effort. Many small steps should tiptoe through treacherous terrain, while a few great strides should speed through smooth uninteresting countryside. The resulting gains in efficiency are not mere tens of percents or factors of two; they can sometimes be factors of ten, a hundred, or more. Sometimes accuracy may be demanded not directly in the solution itself, but in some related conserved quantity that can be monitored.

Implementation of adaptive stepsize control requires that the stepping algorithm return information about its performance, most important, an estimate of its truncation error. In this section we will learn how such information can be obtained. Obviously, the calculation of this information will add to the computational overhead, but the investment will generally be repaid handsomely.

With fourth-order Runge-Kutta, the most straightforward technique by far is *step doubling* (see, e.g., [1]). We take each step twice, once as a full step, then, independently, as two half steps (see Figure 16.2.1). How much overhead is this, say in terms of the number of evaluations of the right-hand sides? Each of the three separate Runge-Kutta steps in the procedure requires 4 evaluations, but the single and double sequences share a starting point, so the total is 11. This is to be compared not to 4, but to 8 (the two half-steps), since — stepsize control aside — we are achieving the accuracy of the smaller (half) stepsize. The overhead cost is therefore a factor 1.375. What does it buy us?

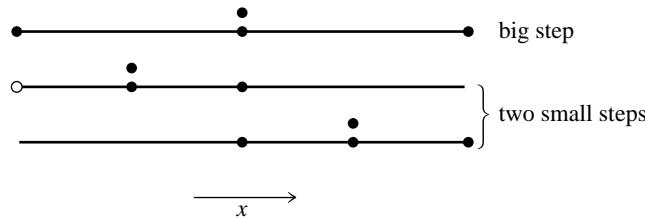

Figure 16.2.1. Step-doubling as a means for adaptive stepsize control in fourth-order Runge-Kutta. Points where the derivative is evaluated are shown as filled circles. The open circle represents the same derivatives as the filled circle immediately above it, so the total number of evaluations is 11 per two steps. Comparing the accuracy of the big step with the two small steps gives a criterion for adjusting the stepsize on the next step, or for rejecting the current step as inaccurate.

Let us denote the exact solution for an advance from x to $x + 2h$ by $y(x + 2h)$ and the two approximate solutions by y_1 (one step $2h$) and y_2 (2 steps each of size h). Since the basic method is fourth order, the true solution and the two numerical approximations are related by

$$\begin{aligned} y(x + 2h) &= y_1 + (2h)^5 \phi + O(h^6) + \dots \\ y(x + 2h) &= y_2 + 2(h^5) \phi + O(h^6) + \dots \end{aligned} \quad (16.2.1)$$

where, to order h^5 , the value ϕ remains constant over the step. [Taylor series expansion tells us the ϕ is a number whose order of magnitude is $y^{(5)}(x)/5!$.] The first expression in (16.2.1) involves $(2h)^5$ since the stepsize is $2h$, while the second expression involves $2(h^5)$ since the error on each step is $h^5\phi$. The difference between the two numerical estimates is a convenient indicator of truncation error

$$\Delta \equiv y_2 - y_1 \quad (16.2.2)$$

It is this difference that we shall endeavor to keep to a desired degree of accuracy, neither too large nor too small. We do this by adjusting h .

It might also occur to you that, ignoring terms of order h^6 and higher, we can solve the two equations in (16.2.1) to improve our numerical estimate of the true solution $y(x + 2h)$, namely,

$$y(x + 2h) = y_2 + \frac{\Delta}{15} + O(h^6) \quad (16.2.3)$$

This estimate is accurate to *fifth order*, one order higher than the original Runge-Kutta steps. However, we can't have our cake and eat it: (16.2.3) may be fifth-order accurate, but we have no way of monitoring its truncation error. Higher order is not always higher accuracy! Use of (16.2.3) rarely does harm, but we have no way of directly knowing whether it is doing any good. Therefore we should use Δ as the error estimate and take as "gravy" any additional accuracy gain derived from (16.2.3). In the technical literature, use of a procedure like (16.2.3) is called "local extrapolation."

An alternative stepsize adjustment algorithm is based on the *embedded Runge-Kutta formulas*, originally invented by Fehlberg. An interesting fact about Runge-Kutta formulas is that for orders M higher than four, more than M function

evaluations (though never more than $M + 2$) are required. This accounts for the popularity of the classical fourth-order method: It seems to give the most bang for the buck. However, Fehlberg discovered a fifth-order method with six function evaluations where another combination of the six functions gives a fourth-order method. The difference between the two estimates of $y(x + h)$ can then be used as an estimate of the truncation error to adjust the stepsize. Since Fehlberg's original formula, several other embedded Runge-Kutta formulas have been found.

Many practitioners were at one time wary of the robustness of Runge-Kutta-Fehlberg methods. The feeling was that using the same evaluation points to advance the function and to estimate the error was riskier than step-doubling, where the error estimate is based on independent function evaluations. However, experience has shown that this concern is not a problem in practice. Accordingly, embedded Runge-Kutta formulas, which are roughly a factor of two more efficient, have superseded algorithms based on step-doubling.

The general form of a fifth-order Runge-Kutta formula is

$$\begin{aligned} k_1 &= hf(x_n, y_n) \\ k_2 &= hf(x_n + a_2 h, y_n + b_{21} k_1) \\ &\dots \\ k_6 &= hf(x_n + a_6 h, y_n + b_{61} k_1 + \dots + b_{65} k_5) \\ y_{n+1} &= y_n + c_1 k_1 + c_2 k_2 + c_3 k_3 + c_4 k_4 + c_5 k_5 + c_6 k_6 + O(h^6) \end{aligned} \quad (16.2.4)$$

The embedded fourth-order formula is

$$y_{n+1}^* = y_n + c_1^* k_1 + c_2^* k_2 + c_3^* k_3 + c_4^* k_4 + c_5^* k_5 + c_6^* k_6 + O(h^5) \quad (16.2.5)$$

and so the error estimate is

$$\Delta \equiv y_{n+1} - y_{n+1}^* = \sum_{i=1}^6 (c_i - c_i^*) k_i \quad (16.2.6)$$

The particular values of the various constants that we favor are those found by Cash and Karp [2], and given in the accompanying table. These give a more efficient method than Fehlberg's original values, with somewhat better error properties.

Now that we know, at least approximately, what our error is, we need to consider how to keep it within desired bounds. What is the relation between Δ and h ? According to (16.2.4) – (16.2.5), Δ scales as h^5 . If we take a step h_1 and produce an error Δ_1 , therefore, the step h_0 that would have given some other value Δ_0 is readily estimated as

$$h_0 = h_1 \left| \frac{\Delta_0}{\Delta_1} \right|^{0.2} \quad (16.2.7)$$

Henceforth we will let Δ_0 denote the *desired* accuracy. Then equation (16.2.7) is used in two ways: If Δ_1 is larger than Δ_0 in magnitude, the equation tells how much to decrease the stepsize *when we retry the present (failed) step*. If Δ_1 is

Cash-Karp Parameters for Embedded Runge-Kutta Method						
i	a_i	b_{ij}			c_i	c_i^*

$j =$		1	2	3	4	5

smaller than Δ_0 , on the other hand, then the equation tells how much we can safely increase the stepsize *for the next step*. Local extrapolation consists in accepting the fifth order value y_{n+1} , even though the error estimate actually applies to the fourth order value y_{n+1}^* .

Our notation hides the fact that Δ_0 is actually a vector of desired accuracies, one for each equation in the set of ODEs. In general, our accuracy requirement will be that all equations are within their respective allowed errors. In other words, we will rescale the stepsize according to the needs of the “worst-offender” equation.

How is Δ_0 , the desired accuracy, related to some looser prescription like “get a solution good to one part in 10^6 ”? That can be a subtle question, and it depends on exactly what your application is! You may be dealing with a set of equations whose dependent variables differ enormously in magnitude. In that case, you probably want to use fractional errors, $\Delta_0 = \epsilon y$, where ϵ is the number like 10^{-6} or whatever. On the other hand, you may have oscillatory functions that pass through zero but are bounded by some maximum values. In that case you probably want to set Δ_0 equal to ϵ times those maximum values.

A convenient way to fold these considerations into a generally useful stepper routine is this: One of the arguments of the routine will of course be the vector of dependent variables at the beginning of a proposed step. Call that $y(1:n)$. Let us require the user to specify for each step another, corresponding, vector argument $yscal(1:n)$, and also an overall tolerance level eps . Then the desired accuracy for the i th equation will be taken to be

$$\Delta_0 = eps \times yscal(i) \quad (16.2.8)$$

If you desire constant fractional errors, plug y into the $yscal$ calling slot (no need to copy the values into a different array). If you desire constant absolute errors relative to some maximum values, set the elements of $yscal$ equal to those maximum values. A useful “trick” for getting constant fractional errors *except* “very” near zero crossings is to set $yscal(i)$ equal to $|y(i)| + |h \times dydx(i)|$. (The routine `odeint`, below, does this.)

Here is a more technical point. We have to consider one additional possibility for $yscal$. The error criteria mentioned thus far are “local,” in that they bound the error of each step individually. In some applications you may be unusually sensitive

about a “global” accumulation of errors, from beginning to end of the integration and in the worst possible case where the errors all are presumed to add with the same sign. Then, the smaller the stepsize h , the smaller the value Δ_0 that you will need to impose. Why? Because there will be *more steps* between your starting and ending values of x . In such cases you will want to set $y\text{scal}$ proportional to h , typically to something like

$$\Delta_0 = \epsilon h \times \text{dydx}(i) \quad (16.2.9)$$

This enforces fractional accuracy ϵ not on the values of y but (much more stringently) on the *increments* to those values at each step. But now look back at (16.2.7). If Δ_0 has an implicit scaling with h , then the exponent 0.20 is no longer correct: When the stepsize is reduced from a too-large value, the new predicted value h_1 will fail to meet the desired accuracy when $y\text{scal}$ is also altered to this new h_1 value. Instead of $0.20 = 1/5$, we must scale by the exponent $0.25 = 1/4$ for things to work out.

The exponents 0.20 and 0.25 are not really very different. This motivates us to adopt the following pragmatic approach, one that frees us from having to know in advance whether or not you, the user, plan to scale your $y\text{scal}$ ’s with stepsize. Whenever we decrease a stepsize, let us use the larger value of the exponent (whether we need it or not!), and whenever we increase a stepsize, let us use the smaller exponent. Furthermore, because our estimates of error are not exact, but only accurate to the leading order in h , we are advised to put in a safety factor S which is a few percent smaller than unity. Equation (16.2.7) is thus replaced by

$$h_0 = \begin{cases} Sh_1 \left| \frac{\Delta_0}{\Delta_1} \right|^{0.20} & \Delta_0 \geq \Delta_1 \\ Sh_1 \left| \frac{\Delta_0}{\Delta_1} \right|^{0.25} & \Delta_0 < \Delta_1 \end{cases} \quad (16.2.10)$$

We have found this prescription to be a reliable one in practice.

Here, then, is a stepper program that takes one “quality-controlled” Runge-Kutta step.

```

SUBROUTINE rkqs(y,dydx,n,x,htry,eps,yscal,hdid,hnext,derivs)
INTEGER n,NMAX
REAL eps,hdid,hnext,htry,x,dydx(n),y(n),yscal(n)
EXTERNAL derivs
PARAMETER (NMAX=50)                                Maximum number of equations.
C USES derivs,rkck
Fifth-order Runge-Kutta step with monitoring of local truncation error to ensure accuracy
and adjust stepsize. Input are the dependent variable vector y(1:n) and its derivative
dydx(1:n) at the starting value of the independent variable x. Also input are the stepsize
to be attempted htry, the required accuracy eps, and the vector yscal(1:n) against
which the error is scaled. On output, y and x are replaced by their new values, hdid is the
stepsize that was actually accomplished, and hnext is the estimated next stepsize. derivs
is the user-supplied subroutine that computes the right-hand side derivatives.
INTEGER i
REAL errmax,h,htemp,xnew,yerr(NMAX),ytemp(NMAX),SAFETY,PGROW,
*      PSHRNK,ERRCON
PARAMETER (SAFETY=0.9,PGROW=-.2,PSHRNK=-.25,ERRCON=1.89e-4)
The value ERRCON equals (5/SAFETY)**(1/PGROW), see use below.
h=htry                                         Set stepsize to the initial trial value.
1  call rkck(y,dydx,n,x,h,ytemp,yerr,derivs)      Take a step.

```

```

errmax=0.                                Evaluate accuracy.
do 11 i=1,n
  errmax=max(errmax,abs(yerr(i)/yscal(i)))
endo 11
errmax=errmax/eps                         Scale relative to required tolerance.
if(errmax.gt.1.)then                      Truncation error too large, reduce stepsize.
  htemp=SAFETY*h*(errmax**PSHRNK)
  h=sign(max(abs(htemp),0.1*abs(h)),h)    No more than a factor of 10.
  xnew=x+h
  if(xnew.eq.x)pause 'stepsize underflow in rkqs'
  goto 1                                  For another try.
else                                         Step succeeded. Compute size of next step.
  if(errmax.gt.ERRCON)then
    hnnext=SAFETY*h*(errmax**PGROW)
  else
    hnnext=5.*h                            No more than a factor of 5 increase.
  endif
  hdid=h
  x=x+h
  do 12 i=1,n
    y(i)=ytemp(i)
  enddo 12
  return
endif
END

```

The routine rkqs calls the routine rkck to take a Cash-Karp Runge-Kutta step:

```

SUBROUTINE rkck(y,dydx,n,x,h,yout,yerr,derivs)
INTEGER n,NMAX
REAL h,x,dydx(n),y(n),yerr(n),yout(n)
EXTERNAL derivs
PARAMETER (NMAX=50)                         Set to the maximum number of functions.
C USES derivs
      Given values for n variables y and their derivatives dydx known at x, use the fifth-order
      Cash-Karp Runge-Kutta method to advance the solution over an interval h and return
      the incremented variables as yout. Also return an estimate of the local truncation er-
      ror in yout using the embedded fourth-order method. The user supplies the subroutine
      derivs(x,y,dydx), which returns derivatives dydx at x.
      INTEGER i
      REAL ak2(NMAX),ak3(NMAX),ak4(NMAX),ak5(NMAX),ak6(NMAX),
*          ytemp(NMAX),A2,A3,A4,A5,A6,B21,B31,B32,B41,B42,B43,B51,

*                                +DC6*ak6(i))
enddo 17
return
END

```

Noting that the above routines are all in single precision, don't be too greedy in specifying `eps`. The punishment for excessive greediness is interesting and worthy of Gilbert and Sullivan's *Mikado*: The routine can always achieve an apparent *zero* error by making the stepsize so small that quantities of order hy' add to quantities of order y as if they were zero. Then the routine chugs happily along taking infinitely many infinitesimal steps and never changing the dependent variables one iota. (You guard against this catastrophic loss of your computer budget by signaling on abnormally small stepsizes or on the dependent variable vector remaining unchanged from step to step. On a personal workstation you guard against it by not taking too long a lunch hour while your program is running.)

Here is a full-fledged "driver" for Runge-Kutta with adaptive stepsize control. We warmly recommend this routine, or one like it, for a variety of problems, notably including garden-variety ODEs or sets of ODEs, and definite integrals (augmenting the methods of Chapter 4). For storage of intermediate results (if you desire to inspect them) we assume a common block path, which can hold up to KMAXX steps. Because steps occur at unequal intervals results are stored only at intervals greater than `dxsav`. Also in the block is `kmax`, indicating the number of steps that can be stored. If `kmax=0` there is no intermediate storage, and the rest of the common block need not exist. Otherwise you should set `kmax = KMAXX`. Storage of steps stops if `kmax` is exceeded, except that the ending values are always stored. Again, these controls are merely indicative of what you might need. The routine `odeint` should be customized to the problem at hand.

```

SUBROUTINE odeint(ystart,nvar,x1,x2,eps,h1,hmin,nok,nbad,derivs,rkqs)
INTEGER nbad,nok,nvar,KMAXX,MAXSTP,NMAX
REAL eps,h1,hmin,x1,x2,ystart(nvar),TINY
EXTERNAL derivs,rkqs
PARAMETER (MAXSTP=10000,NMAX=50,KMAXX=200,TINY=1.e-30)
Runge-Kutta driver with adaptive stepsize control. Integrate the starting values ystart(1:nvar)
from x1 to x2 with accuracy eps, storing intermediate results in the common block /path/.
h1 should be set as a guessed first stepsize, hmin as the minimum allowed stepsize (can be zero). On output nok and nbad are the number of good and bad (but retried and

```

fixed) steps taken, and *ystart* is replaced by values at the end of the integration interval. *derivs* is the user-supplied subroutine for calculating the right-hand side derivative, while *rkqs* is the name of the stepper routine to be used. */path/* contains its own information about how often an intermediate value is to be stored.

```

INTEGER i,kmax,kount,nstp
REAL dxsav,h,hdid,hnext,x,xsav,dydx(NMAX),xp(KMAXX),y(NMAX),
      yp(NMAX,KMAXX),yscal(NMAX)
COMMON /path/ kmax,kount,dxsav,xp,yp
      User storage for intermediate results. Preset dxsav and kmax.

x=x1
h=sign(h1,x2-x1)
nok=0
nbad=0
kount=0
do 11 i=1,nvar

16.3 Modified Midpoint Method

This section discusses the *modified midpoint method*, which advances a vector of dependent variables $y(x)$ from a point x to a point $x + H$ by a sequence of n substeps each of size h ,

$$h = H/n \quad (16.3.1)$$

In principle, one could use the modified midpoint method in its own right as an ODE integrator. In practice, the method finds its most important application as a part of the more powerful Bulirsch-Stoer technique, treated in §16.4. You can therefore consider this section as a preamble to §16.4.

The number of right-hand side evaluations required by the modified midpoint method is $n + 1$. The formulas for the method are

$$\begin{aligned} z_0 &\equiv y(x) \\ z_1 &= z_0 + hf(x, z_0) \\ z_{m+1} &= z_{m-1} + 2hf(x + mh, z_m) \quad \text{for } m = 1, 2, \dots, n-1 \\ y(x + H) \approx y_n &\equiv \frac{1}{2}[z_n + z_{n-1} + hf(x + H, z_n)] \end{aligned} \quad (16.3.2)$$

Here the z 's are intermediate approximations which march along in steps of h , while y_n is the final approximation to $y(x + H)$. The method is basically a “centered difference” or “midpoint” method (compare equation 16.1.2), except at the first and last points. Those give the qualifier “modified.”

The modified midpoint method is a second-order method, like (16.1.2), but with the advantage of requiring (asymptotically for large n) only one derivative evaluation per step h instead of the two required by second-order Runge-Kutta. Perhaps there are applications where the simplicity of (16.3.2), easily coded in-line in some other program, recommends it. In general, however, use of the modified midpoint method by itself will be dominated by the embedded Runge-Kutta method with adaptive stepsize control, as implemented in the preceding section.

The usefulness of the modified midpoint method to the Bulirsch-Stoer technique (§16.4) derives from a “deep” result about equations (16.3.2), due to Gragg. It turns

16.3 Modified Midpoint Method

This section discusses the *modified midpoint method*, which advances a vector of dependent variables $y(x)$ from a point x to a point $x + H$ by a sequence of n substeps each of size h ,

$$h = H/n \quad (16.3.1)$$

In principle, one could use the modified midpoint method in its own right as an ODE integrator. In practice, the method finds its most important application as a part of the more powerful Bulirsch-Stoer technique, treated in §16.4. You can therefore consider this section as a preamble to §16.4.

The number of right-hand side evaluations required by the modified midpoint method is $n + 1$. The formulas for the method are

$$\begin{aligned} z_0 &\equiv y(x) \\ z_1 &= z_0 + hf(x, z_0) \\ z_{m+1} &= z_{m-1} + 2hf(x + mh, z_m) \quad \text{for } m = 1, 2, \dots, n-1 \\ y(x + H) \approx y_n &\equiv \frac{1}{2}[z_n + z_{n-1} + hf(x + H, z_n)] \end{aligned} \quad (16.3.2)$$

Here the z 's are intermediate approximations which march along in steps of h , while y_n is the final approximation to $y(x + H)$. The method is basically a “centered difference” or “midpoint” method (compare equation 16.1.2), except at the first and last points. Those give the qualifier “modified.”

The modified midpoint method is a second-order method, like (16.1.2), but with the advantage of requiring (asymptotically for large n) only one derivative evaluation per step h instead of the two required by second-order Runge-Kutta. Perhaps there are applications where the simplicity of (16.3.2), easily coded in-line in some other program, recommends it. In general, however, use of the modified midpoint method by itself will be dominated by the embedded Runge-Kutta method with adaptive stepsize control, as implemented in the preceding section.

The usefulness of the modified midpoint method to the Bulirsch-Stoer technique (§16.4) derives from a “deep” result about equations (16.3.2), due to Gragg. It turns

out that the error of (16.3.2), expressed as a power series in h , the stepsize, contains only *even* powers of h ,

$$y_n - y(x + H) = \sum_{i=1}^{\infty} \alpha_i h^{2i} \quad (16.3.3)$$

where H is held constant, but h changes by varying n in (16.3.1). The importance of this even power series is that, if we play our usual tricks of combining steps to knock out higher-order error terms, we can gain *two* orders at a time!

For example, suppose n is even, and let $y_{n/2}$ denote the result of applying (16.3.1) and (16.3.2) with half as many steps, $n \rightarrow n/2$. Then the estimate

$$y(x + H) \approx \frac{4y_n - y_{n/2}}{3} \quad (16.3.4)$$

is *fourth-order* accurate, the same as fourth-order Runge-Kutta, but requires only about 1.5 derivative evaluations per step h instead of Runge-Kutta's 4 evaluations. Don't be too anxious to implement (16.3.4), since we will soon do even better.

Now would be a good time to look back at the routine `qsimp` in §4.2, and especially to compare equation (4.2.4) with equation (16.3.4) above. You will see that the transition in Chapter 4 to the idea of Richardson extrapolation, as embodied in Romberg integration of §4.3, is exactly analogous to the transition in going from this section to the next one.

Here is the routine that implements the modified midpoint method, which will be used below.

```
SUBROUTINE mmid(y,dydx,nvar,xs,htot,nstep,yout,derivs)
INTEGER nstep,nvar,NMAX
REAL htot,xs,dydx(nvar),y(nvar),yout(nvar)
EXTERNAL derivs
PARAMETER (NMAX=50)
Modified midpoint step. Dependent variable vector y(1:nvar) and its derivative vector
dydx(1:nvar) are input at xs. Also input is htot, the total step to be made, and nstep,
the number of substeps to be used. The output is returned as yout(1:nvar), which need
not be a distinct array from y; if it is distinct, however, then y and dydx are returned
undamaged.
INTEGER i,n
REAL h,h2,swap,x,ym(NMAX),yn(NMAX)
h=htot/nstep           Stepsize this trip.
do 11 i=1,nvar
    ym(i)=y(i)
    yn(i)=y(i)+h*dydx(i)   First step.
11 do 13 n=2,nstep
    do 12 i=1,nvar
        swap=ym(i)+h2*yout(i)
        ym(i)=yn(i)
        yn(i)=swap
    12 enddo
    x=x+h
    call derivs(x,yn,yout)   Will use yout for temporary storage of derivatives.
    h2=2.*h
13 do 14 n=2,nstep
    do 15 i=1,nvar
        swap=ym(i)+h2*yout(i)
        ym(i)=yn(i)
        yn(i)=swap
    15 enddo
    x=x+h
    call derivs(x,yn,yout)
```

```

enddo 13
do 14 i=1,nvar           Last step.
    yout(i)=0.5*(ym(i)+yn(i)+h*yout(i))
enddo 14
return
END

```

16.4 Richardson Extrapolation and the Bulirsch-Stoer Method

The techniques described in this section are not for differential equations containing nonsmooth functions. For example, you might have a differential equation whose right-hand side involves a function that is evaluated by table look-up and interpolation. If so, go back to Runge-Kutta with adaptive stepsize choice: That method does an excellent job of feeling its way through rocky or discontinuous terrain. It is also an excellent choice for quick-and-dirty, low-accuracy solution of a set of equations. A second warning is that the techniques in this section are not particularly good for differential equations that have singular points *inside* the interval of integration. A regular solution must tiptoe very carefully across such points. Runge-Kutta with adaptive stepsize can sometimes effect this; more generally, there are special techniques available for such problems, beyond our scope here.

Apart from those two caveats, we believe that the Bulirsch-Stoer method, discussed in this section, is the best known way to obtain high-accuracy solutions to ordinary differential equations with minimal computational effort. (A possible exception, infrequently encountered in practice, is discussed in §16.7.)

Three key ideas are involved. The first is *Richardson's deferred approach to the limit*, which we already met in §4.3 on Romberg integration. The idea is to consider the final answer of a numerical calculation as itself being an analytic function (if a complicated one) of an adjustable parameter like the stepsize h . That analytic function can be probed by performing the calculation with various values of h , *none* of them being necessarily small enough to yield the accuracy that we desire. When we know enough about the function, we *fit* it to some analytic form, and then *evaluate* it at that mythical and golden point $h = 0$ (see Figure 16.4.1). Richardson extrapolation is a method for turning straw into gold! (Lead into gold for alchemist readers.)

The second idea has to do with what kind of fitting function is used. Bulirsch and Stoer first recognized the strength of *rational function extrapolation* in Richardson-type applications. That strength is to break the shackles of the power series and its limited radius of convergence, out only to the distance of the first pole in the complex

16.4 Richardson Extrapolation and the Bulirsch-Stoer Method

The techniques described in this section are not for differential equations containing nonsmooth functions. For example, you might have a differential equation whose right-hand side involves a function that is evaluated by table look-up and interpolation. If so, go back to Runge-Kutta with adaptive stepsize choice: That method does an excellent job of feeling its way through rocky or discontinuous terrain. It is also an excellent choice for quick-and-dirty, low-accuracy solution of a set of equations. A second warning is that the techniques in this section are not particularly good for differential equations that have singular points *inside* the interval of integration. A regular solution must tiptoe very carefully across such points. Runge-Kutta with adaptive stepsize can sometimes effect this; more generally, there are special techniques available for such problems, beyond our scope here.

Apart from those two caveats, we believe that the Bulirsch-Stoer method, discussed in this section, is the best known way to obtain high-accuracy solutions to ordinary differential equations with minimal computational effort. (A possible exception, infrequently encountered in practice, is discussed in §16.7.)

Three key ideas are involved. The first is *Richardson's deferred approach to the limit*, which we already met in §4.3 on Romberg integration. The idea is to consider the final answer of a numerical calculation as itself being an analytic function (if a complicated one) of an adjustable parameter like the stepsize h . That analytic function can be probed by performing the calculation with various values of h , *none* of them being necessarily small enough to yield the accuracy that we desire. When we know enough about the function, we *fit* it to some analytic form, and then *evaluate* it at that mythical and golden point $h = 0$ (see Figure 16.4.1). Richardson extrapolation is a method for turning straw into gold! (Lead into gold for alchemist readers.)

The second idea has to do with what kind of fitting function is used. Bulirsch and Stoer first recognized the strength of *rational function extrapolation* in Richardson-type applications. That strength is to break the shackles of the power series and its limited radius of convergence, out only to the distance of the first pole in the complex

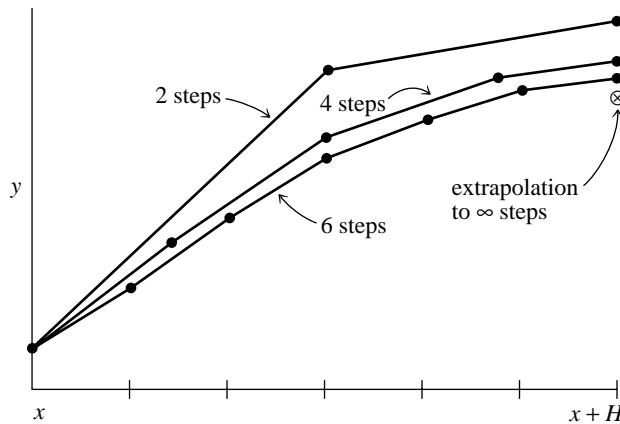

Figure 16.4.1. Richardson extrapolation as used in the Bulirsch-Stoer method. A large interval H is spanned by different sequences of finer and finer substeps. Their results are extrapolated to an answer that is supposed to correspond to infinitely fine substeps. In the Bulirsch-Stoer method, the integrations are done by the modified midpoint method, and the extrapolation technique is rational function or polynomial extrapolation.

plane. Rational function fits can remain good approximations to analytic functions even after the various terms in powers of h all have comparable magnitudes. In other words, h can be so large as to make the whole notion of the “order” of the method meaningless — and the method can still work superbly. Nevertheless, more recent experience suggests that for smooth problems straightforward polynomial extrapolation is slightly more efficient than rational function extrapolation. We will accordingly adopt polynomial extrapolation as the default, but the routine `bsstep` below allows easy substitution of one kind of extrapolation for the other. You might wish at this point to review §3.1–§3.2, where polynomial and rational function extrapolation were already discussed.

The third idea was discussed in the section before this one, namely to use a method whose error function is strictly even, allowing the rational function or polynomial approximation to be in terms of the variable h^2 instead of just h .

Put these ideas together and you have the *Bulirsch-Stoer method* [1]. A single Bulirsch-Stoer step takes us from x to $x + H$, where H is supposed to be quite a large — not at all infinitesimal — distance. That single step is a grand leap consisting of many (e.g., dozens to hundreds) substeps of modified midpoint method, which are then extrapolated to zero stepsize.

The sequence of separate attempts to cross the interval H is made with increasing values of n , the number of substeps. Bulirsch and Stoer originally proposed the sequence

$$n = 2, 4, 6, 8, 12, 16, 24, 32, 48, 64, 96, \dots, [n_j = 2n_{j-2}], \dots \quad (16.4.1)$$

More recent work by Deuflhard [2,3] suggests that the sequence

$$n = 2, 4, 6, 8, 10, 12, 14, \dots, [n_j = 2j], \dots \quad (16.4.2)$$

is usually more efficient. For each step, we do not know in advance how far up this sequence we will go. After each successive n is tried, a polynomial extrapolation is

attempted. That extrapolation returns both extrapolated values and error estimates. If the errors are not satisfactory, we go higher in n . If they are satisfactory, we go on to the next step and begin anew with $n = 2$.

Of course there must be some upper limit, beyond which we conclude that there is some obstacle in our path in the interval H , so that we must reduce H rather than just subdivide it more finely. In the implementations below, the maximum number of n 's to be tried is called KMAXX. For reasons described below we usually take this equal to 8; the 8th value of the sequence (16.4.2) is 16, so this is the maximum number of subdivisions of H that we allow.

We enforce error control, as in the Runge-Kutta method, by monitoring internal consistency, and adapting stepsize to match a prescribed bound on the local truncation error. Each new result from the sequence of modified midpoint integrations allows a tableau like that in §3.1 to be extended by one additional set of diagonals. The size of the new correction added at each stage is taken as the (conservative) error estimate. How should we use this error estimate to adjust the stepsize? The best strategy now known is due to Deuflhard [2,3]. For completeness we describe it here:

Suppose the absolute value of the error estimate returned from the k th column (and hence the $k + 1$ st row) of the extrapolation tableau is $\epsilon_{k+1,k}$. Error control is enforced by requiring

$$\epsilon_{k+1,k} < \epsilon \quad (16.4.3)$$

as the criterion for accepting the current step, where ϵ is the required tolerance. For the even sequence (16.4.2) the order of the method is $2k + 1$:

$$\epsilon_{k+1,k} \sim H^{2k+1} \quad (16.4.4)$$

Thus a simple estimate of a new stepsize H_k to obtain convergence in a fixed column k would be

$$H_k = H \left(\frac{\epsilon}{\epsilon_{k+1,k}} \right)^{1/(2k+1)} \quad (16.4.5)$$

Which column k should we aim to achieve convergence in? Let's compare the work required for different k . Suppose A_k is the work to obtain row k of the extrapolation tableau, so A_{k+1} is the work to obtain column k . We will assume the work is dominated by the cost of evaluating the functions defining the right-hand sides of the differential equations. For n_k subdivisions in H , the number of function evaluations can be found from the recurrence

$$\begin{aligned} A_1 &= n_1 + 1 \\ A_{k+1} &= A_k + n_{k+1} \end{aligned} \quad (16.4.6)$$

The work per unit step to get column k is A_{k+1}/H_k , which we nondimensionalize with a factor of H and write as

$$W_k = \frac{A_{k+1}}{H_k} H \quad (16.4.7)$$

$$= A_{k+1} \left(\frac{\epsilon_{k+1,k}}{\epsilon} \right)^{1/(2k+1)} \quad (16.4.8)$$

The quantities W_k can be calculated during the integration. The optimal column index q is then defined by

$$W_q = \min_{k=1,\dots,k_f} W_k \quad (16.4.9)$$

where k_f is the final column, in which the error criterion (16.4.3) was satisfied. The q determined from (16.4.9) defines the stepsize H_q to be used as the next basic stepsize, so that we can expect to get convergence in the optimal column q .

Two important refinements have to be made to the strategy outlined so far:

- If the current H is “too small,” then k_f will be “too small,” and so q remains “too small.” It may be desirable to increase H and aim for convergence in a column $q > k_f$.
- If the current H is “too big,” we may not converge at all on the current step and we will have to decrease H . We would like to detect this by monitoring the quantities $\epsilon_{k+1,k}$ for each k so we can stop the current step as soon as possible.

Deuflhard’s prescription for dealing with these two problems uses ideas from communication theory to determine the “average expected convergence behavior” of the extrapolation. His model produces certain correction factors $\alpha(k, q)$ by which H_k is to be multiplied to try to get convergence in column q . The factors $\alpha(k, q)$ depend only on ϵ and the sequence $\{n_k\}$ and so can be computed once during initialization:

$$\alpha(k, q) = \epsilon^{\frac{A_{k+1} - A_{q+1}}{(2k+1)(A_{q+1} - A_1 + 1)}} \quad \text{for } k < q \quad (16.4.10)$$

with $\alpha(q, q) = 1$.

Now to handle the first problem, suppose convergence occurs in column $q = k_f$. Then rather than taking H_q for the next step, we might aim to increase the stepsize to get convergence in column $q + 1$. Since we don’t have H_{q+1} available from the computation, we estimate it as

$$H_{q+1} = H_q \alpha(q, q + 1) \quad (16.4.11)$$

By equation (16.4.7) this replacement is efficient, i.e., reduces the work per unit step, if

$$\frac{A_{q+1}}{H_q} > \frac{A_{q+2}}{H_{q+1}} \quad (16.4.12)$$

or

$$A_{q+1} \alpha(q, q + 1) > A_{q+2} \quad (16.4.13)$$

During initialization, this inequality can be checked for $q = 1, 2, \dots$ to determine k_{\max} , the largest allowed column. Then when (16.4.12) is satisfied it will always be efficient to use H_{q+1} . (In practice we limit k_{\max} to 8 even when ϵ is very small as there is very little further gain in efficiency whereas roundoff can become a problem.)

The problem of stepsize reduction is handled by computing stepsize estimates

$$\bar{H}_k \equiv H_k \alpha(k, q), \quad k = 1, \dots, q - 1 \quad (16.4.14)$$

during the current step. The \bar{H} ’s are estimates of the stepsize to get convergence in the optimal column q . If any \bar{H}_k is “too small,” we abandon the current step and restart using \bar{H}_k . The criterion of being “too small” is taken to be

$$H_k \alpha(k, q + 1) < H \quad (16.4.15)$$

The α ’s satisfy $\alpha(k, q + 1) > \alpha(k, q)$.

During the first step, when we have no information about the solution, the stepsize reduction check is made for all k . Afterwards, we test for convergence and for possible stepsize reduction only in an “order window”

$$\max(1, q - 1) \leq k \leq \min(k_{\max}, q + 1) \quad (16.4.16)$$

The rationale for the order window is that if convergence appears to occur for $k < q - 1$ it is often spurious, resulting from some fortuitously small error estimate in the extrapolation. On the other hand, if you need to go beyond $k = q + 1$ to obtain convergence, your local model of the convergence behavior is obviously not very good and you need to cut the stepsize and reestablish it.

In the routine `bsstep`, these various tests are actually carried out using quantities

$$\epsilon(k) \equiv \frac{H}{H_k} = \left(\frac{\epsilon_{k+1,k}}{\epsilon} \right)^{1/(2k+1)} \quad (16.4.17)$$

called `err(k)` in the code. As usual, we include a “safety factor” in the stepsize selection. This is implemented by replacing ϵ by 0.25ϵ . Other safety factors are explained in the program comments.

Note that while the optimal convergence column is restricted to increase by at most one on each step, a sudden drop in order is allowed by equation (16.4.9). This gives the method a degree of robustness for problems with discontinuities.

Let us remind you once again that *scaling* of the variables is often crucial for successful integration of differential equations. The scaling “trick” suggested in the discussion following equation (16.2.8) is a good general purpose choice, but not foolproof. Scaling by the maximum values of the variables is more robust, but requires you to have some prior information.

The following implementation of a Bulirsch-Stoer step has exactly the same calling sequence as the quality-controlled Runge-Kutta stepper `rkqs`. This means that the driver `odeint` in §16.2 can be used for Bulirsch-Stoer as well as Runge-Kutta: Just substitute `bsstep` for `rkqs` in `odeint`’s argument list. The routine `bsstep` calls `mmid` to take the modified midpoint sequences, and calls `pzextr`, given below, to do the polynomial extrapolation.

```
SUBROUTINE bsstep(y,dydx,nv,x,htry,eps,yscal,hdid,hnext,derivs)
INTEGER nv,NMAX,KMAXX,IMAX
REAL eps,hdid,hnext,htry,x,dydx(nv),y(nv),yscal(nv),SAFE1,
*      SAFE2,REDMAX,REDMIN,TINY,SCALMX
PARAMETER (NMAX=50,KMAXX=8,IMAX=KMAXX+1,SAFE1=.25,SAFE2=.7,
*      REDMAX=1.e-5,REDMIN=.7,TINY=1.e-30,SCALMX=.1)
C USES derivs,mmid,pzextr
      Bulirsch-Stoer step with monitoring of local truncation error to ensure accuracy and adjust
      stepsize. Input are the dependent variable vector y(1:nv) and its derivative dydx(1:nv)
      at the starting value of the independent variable x. Also input are the stepsize to be at-
      tempted htry, the required accuracy eps, and the vector yscal(1:nv) against which the
      error is scaled. On output, y and x are replaced by their new values, hdid is the stepsize
      that was actually accomplished, and hnext is the estimated next stepsize. derivs is the
      user-supplied subroutine that computes the right-hand side derivatives. Be sure to set htry
      on successive steps to the value of hnext returned from the previous step, as is the case
      if the routine is called by odeint.
      Parameters: NMAX is the maximum value of nv; KMAXX is the maximum row number used
      in the extrapolation; IMAX is the next row number; SAFE1 and SAFE2 are safety factors;
      REDMAX is the maximum factor used when a stepsize is reduced, REDMIN the minimum;
      TINY prevents division by zero; 1/SCALMX is the maximum factor by which a stepsize can
      be increased.
      INTEGER i,iq,k,kk,km,kmax,kopt,nseq(IMAX)

Check for possible order increase, but not if step-size was just reduced.

The polynomial extrapolation routine is based on the same algorithm as `polint` §3.1. It is simpler in that it is always extrapolating to zero, rather than to an arbitrary value. However, it is more complicated in that it must individually extrapolate each component of a vector of quantities.

```

SUBROUTINE pzextr(iest,xest,yest,yz,dy,nv)
INTEGER iest,nv,IMAX,NMAX
REAL xest,dy(nv),yest(nv),yz(nv)
PARAMETER (IMAX=13,NMAX=50)
      Use polynomial extrapolation to evaluate nv functions at  $x = 0$  by fitting a polynomial to a
      sequence of estimates with progressively smaller values  $x = xest$ , and corresponding func-
      tion vectors  $yest(1:nv)$ . This call is number iest in the sequence of calls. Extrapolated
      function values are output as  $yz(1:nv)$ , and their estimated error is output as  $dy(1:nv)$ .
      Parameters: Maximum expected value of iest is IMAX; of nv is NMAX.
INTEGER j,k1

        qcol(j,iest)=dy(j)
    enddo 16
endif
return
END

```

Current wisdom favors polynomial extrapolation over rational function extrapolation in the Bulirsch-Stoer method. However, our feeling is that this view is guided more by the kinds of problems used for tests than by one method being actually “better.” Accordingly, we provide the optional routine `rzextr` for rational function extrapolation, an exact substitution for `pzextr` above.

```
SUBROUTINE rzextr(iest,xest,yest,yz,dy,nv)
INTEGER iest,nv,IMAX,NMAX
REAL xest,dy(nv),yest(nv),yz(nv)
PARAMETER (IMAX=13,NMAX=50)
Exact substitute for pzextr, but uses diagonal rational function extrapolation instead of
polynomial extrapolation.
INTEGER j,k
REAL b,b1,c,ddy,v,yy,d(NMAX,IMAX),fx(IMAX),x(IMAX)
SAVE d,x
x(iest)=xest                               Save current independent variable.
if(iest.eq.1) then
  do 11 j=1,nv
    yz(j)=yest(j)
    d(j,1)=yest(j)
    dy(j)=yest(j)
  enddo 11
else
  do 12 k=1,iest-1
    fx(k+1)=x(iest-k)/xest
  enddo 12
  do 14 j=1,nv                           Evaluate next diagonal in tableau.
    yy=yest(j)

16.5 Second-Order Conservative Equations

Usually when you have a system of high-order differential equations to solve it is best to reformulate them as a system of first-order equations, as discussed in §16.0. There is a particular class of equations that occurs quite frequently in practice where you can gain about a factor of two in efficiency by differencing the equations directly. The equations are second-order systems where the derivative does not appear on the right-hand side:

$$y'' = f(x, y), \quad y(x_0) = y_0, \quad y'(x_0) = z_0 \quad (16.5.1)$$

As usual, y can denote a vector of values.

Stoermer's rule, dating back to 1907, has been a popular method for discretizing such systems. With $h = H/m$ we have

$$\begin{aligned} y_1 &= y_0 + h[z_0 + \frac{1}{2}hf(x_0, y_0)] \\ y_{k+1} - 2y_k + y_{k-1} &= h^2f(x_0 + kh, y_k), \quad k = 1, \dots, m-1 \\ z_m &= (y_m - y_{m-1})/h + \frac{1}{2}hf(x_0 + H, y_m) \end{aligned} \quad (16.5.2)$$

Here z_m is $y'(x_0 + H)$. Henrici showed how to rewrite equations (16.5.2) to reduce roundoff error by using the quantities $\Delta_k \equiv y_{k+1} - y_k$. Start with

$$\begin{aligned} \Delta_0 &= h[z_0 + \frac{1}{2}hf(x_0, y_0)] \\ y_1 &= y_0 + \Delta_0 \end{aligned} \quad (16.5.3)$$

Then for $k = 1, \dots, m-1$, set

$$\begin{aligned} \Delta_k &= \Delta_{k-1} + h^2f(x_0 + kh, y_k) \\ y_{k+1} &= y_k + \Delta_k \end{aligned} \quad (16.5.4)$$

Finally compute the derivative from

$$z_m = \Delta_{m-1}/h + \frac{1}{2}hf(x_0 + H, y_m) \quad (16.5.5)$$

Gragg again showed that the error series for equations (16.5.3)–(16.5.5) contains only even powers of h , and so the method is a logical candidate for extrapolation à la Bulirsch-Stoer. We replace `mmid` by the following routine `stoerm`:

```
SUBROUTINE stoerm(y,d2y,nv,xs,htot,nstep,yout,derivs)
INTEGER nstep,nv,NMAX
REAL htot,xs,d2y(nv),y(nv),yout(nv)
EXTERNAL derivs
PARAMETER (NMAX=50)                                Maximum value of nv.
C USES derivs
      Stoermer's rule for integrating  $y'' = f(x, y)$  for a system of  $n = nv/2$  equations. On input  $y(1:nv)$  contains  $y$  in its first  $n$  elements and  $y'$  in its second  $n$  elements, all evaluated at  $xs$ .  $d2y(1:nv)$  contains the right-hand side function  $f$  (also evaluated at  $xs$ ) in its first  $n$  elements. Its second  $n$  elements are not referenced. Also input is  $htot$ , the total step to be taken, and  $nstep$ , the number of substeps to be used. The output is returned as  $yout(1:nv)$ , with the same storage arrangement as  $y$ .  $derivs$  is the user-supplied subroutine that calculates  $f$ .
      INTEGER i,n,neqns,nn
      REAL h,h2,halfh,x,ytemp(NMAX)
      h=htot/nstep                                         Stepsize this trip.
      halfh=0.5*h
      neqns=nv/2                                         Number of equations.
      do i=1,neqns                                         First step.
      n=neqns+i
      ytemp(n)=h*(y(n)+halfh*d2y(i))
```

16.5 Second-Order Conservative Equations

Usually when you have a system of high-order differential equations to solve it is best to reformulate them as a system of first-order equations, as discussed in §16.0. There is a particular class of equations that occurs quite frequently in practice where you can gain about a factor of two in efficiency by differencing the equations directly. The equations are second-order systems where the derivative does not appear on the right-hand side:

$$y'' = f(x, y), \quad y(x_0) = y_0, \quad y'(x_0) = z_0 \quad (16.5.1)$$

As usual, y can denote a vector of values.

Stoermer's rule, dating back to 1907, has been a popular method for discretizing such systems. With $h = H/m$ we have

$$\begin{aligned} y_1 &= y_0 + h[z_0 + \frac{1}{2}hf(x_0, y_0)] \\ y_{k+1} - 2y_k + y_{k-1} &= h^2f(x_0 + kh, y_k), \quad k = 1, \dots, m-1 \\ z_m &= (y_m - y_{m-1})/h + \frac{1}{2}hf(x_0 + H, y_m) \end{aligned} \quad (16.5.2)$$

Here z_m is $y'(x_0 + H)$. Henrici showed how to rewrite equations (16.5.2) to reduce roundoff error by using the quantities $\Delta_k \equiv y_{k+1} - y_k$. Start with

$$\begin{aligned} \Delta_0 &= h[z_0 + \frac{1}{2}hf(x_0, y_0)] \\ y_1 &= y_0 + \Delta_0 \end{aligned} \quad (16.5.3)$$

Then for $k = 1, \dots, m-1$, set

$$\begin{aligned} \Delta_k &= \Delta_{k-1} + h^2f(x_0 + kh, y_k) \\ y_{k+1} &= y_k + \Delta_k \end{aligned} \quad (16.5.4)$$

Finally compute the derivative from

$$z_m = \Delta_{m-1}/h + \frac{1}{2}hf(x_0 + H, y_m) \quad (16.5.5)$$

Gragg again showed that the error series for equations (16.5.3)–(16.5.5) contains only even powers of h , and so the method is a logical candidate for extrapolation à la Bulirsch-Stoer. We replace `mmid` by the following routine `stoerm`:

```

Note that for compatibility with `bsstep` the arrays `y` and `d2y` are of length $2n$ for a system of n second-order equations. The values of y are stored in the first n elements of `y`, while the first derivatives are stored in the second n elements. The right-hand side f is stored in the first n elements of the array `d2y`; the second n elements are unused. With this storage arrangement you can use `bsstep` simply by replacing the call to `mmid` with one to `stoerm` using the same arguments; just be sure that the argument `nv` of `bsstep` is set to $2n$. You should also use the more efficient sequence of stepsizes suggested by Deuflhard:

$$n = 1, 2, 3, 4, 5, \dots \quad (16.5.6)$$

and set `KMAXX = 12` in `bsstep`.

16.6 Stiff Sets of Equations

As soon as one deals with more than one first-order differential equation, the possibility of a *stiff* set of equations arises. Stiffness occurs in a problem where there are two or more very different scales of the independent variable on which the dependent variables are changing. For example, consider the following set of equations [1]:

$$\begin{aligned} u' &= 998u + 1998v \\ v' &= -999u - 1999v \end{aligned} \quad (16.6.1)$$

with boundary conditions

$$u(0) = 1 \quad v(0) = 0 \quad (16.6.2)$$

```

ytemp(i)=y(i)+ytemp(n)
enddo 11
x=xs+h
call derivs(x,ytemp,yout)           Use yout for temporary storage of derivatives.

16.6 Stiff Sets of Equations

As soon as one deals with more than one first-order differential equation, the possibility of a *stiff* set of equations arises. Stiffness occurs in a problem where there are two or more very different scales of the independent variable on which the dependent variables are changing. For example, consider the following set of equations [1]:

$$\begin{aligned} u' &= 998u + 1998v \\ v' &= -999u - 1999v \end{aligned} \quad (16.6.1)$$

with boundary conditions

$$u(0) = 1 \quad v(0) = 0 \quad (16.6.2)$$

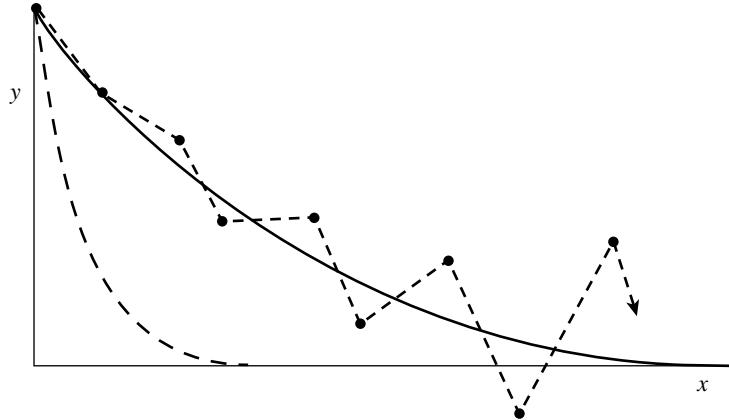

Figure 16.6.1. Example of an instability encountered in integrating a stiff equation (schematic). Here it is supposed that the equation has two solutions, shown as solid and dashed lines. Although the initial conditions are such as to give the solid solution, the stability of the integration (shown as the unstable dotted sequence of segments) is determined by the more rapidly varying dashed solution, even after that solution has effectively died away to zero. Implicit integration methods are the cure.

By means of the transformation

$$u = 2y - z \quad v = -y + z \quad (16.6.3)$$

we find the solution

$$\begin{aligned} u &= 2e^{-x} - e^{-1000x} \\ v &= -e^{-x} + e^{-1000x} \end{aligned} \quad (16.6.4)$$

If we integrated the system (16.6.1) with any of the methods given so far in this chapter, the presence of the e^{-1000x} term would require a stepsize $h \ll 1/1000$ for the method to be stable (the reason for this is explained below). This is so even though the e^{-1000x} term is completely negligible in determining the values of u and v as soon as one is away from the origin (see Figure 16.6.1).

This is the generic disease of stiff equations: we are required to follow the variation in the solution on the shortest length scale to maintain stability of the integration, even though accuracy requirements allow a much larger stepsize.

To see how we might cure this problem, consider the single equation

$$y' = -cy \quad (16.6.5)$$

where $c > 0$ is a constant. The explicit (or *forward*) Euler scheme for integrating this equation with stepsize h is

$$y_{n+1} = y_n + hy'_n = (1 - ch)y_n \quad (16.6.6)$$

The method is called explicit because the new value y_{n+1} is given explicitly in terms of the old value y_n . Clearly the method is unstable if $h > 2/c$, for then $|y_n| \rightarrow \infty$ as $n \rightarrow \infty$.

The simplest cure is to resort to *implicit* differencing, where the right-hand side is evaluated at the *new* y location. In this case, we get the *backward Euler* scheme:

$$y_{n+1} = y_n + hy'_{n+1} \quad (16.6.7)$$

or

$$y_{n+1} = \frac{y_n}{1 + ch} \quad (16.6.8)$$

The method is absolutely stable: even as $h \rightarrow \infty$, $y_{n+1} \rightarrow 0$, which is in fact the correct solution of the differential equation. If we think of x as representing time, then the implicit method converges to the true equilibrium solution (i.e., the solution at late times) for large stepsizes. This nice feature of implicit methods holds only for linear systems, but even in the general case implicit methods give better stability. Of course, we give up *accuracy* in following the evolution towards equilibrium if we use large stepsizes, but we maintain *stability*.

These considerations can easily be generalized to sets of linear equations with constant coefficients:

$$\mathbf{y}' = -\mathbf{C} \cdot \mathbf{y} \quad (16.6.9)$$

where \mathbf{C} is a positive definite matrix. Explicit differencing gives

$$\mathbf{y}_{n+1} = (\mathbf{1} - \mathbf{C}h) \cdot \mathbf{y}_n \quad (16.6.10)$$

Now a matrix \mathbf{A}^n tends to zero as $n \rightarrow \infty$ only if the largest eigenvalue of \mathbf{A} has magnitude less than unity. Thus \mathbf{y}_n is bounded as $n \rightarrow \infty$ only if the largest eigenvalue of $\mathbf{1} - \mathbf{C}h$ is less than 1, or in other words

$$h < \frac{2}{\lambda_{\max}} \quad (16.6.11)$$

where λ_{\max} is the largest eigenvalue of \mathbf{C} .

On the other hand, implicit differencing gives

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h\mathbf{y}'_{n+1} \quad (16.6.12)$$

or

$$\mathbf{y}_{n+1} = (\mathbf{1} + \mathbf{C}h)^{-1} \cdot \mathbf{y}_n \quad (16.6.13)$$

If the eigenvalues of \mathbf{C} are λ , then the eigenvalues of $(\mathbf{1} + \mathbf{C}h)^{-1}$ are $(1 + \lambda h)^{-1}$, which has magnitude less than one for all h . (Recall that all the eigenvalues of a positive definite matrix are nonnegative.) Thus the method is stable for all stepsizes h . The penalty we pay for this stability is that we are required to invert a matrix at each step.

Not all equations are linear with constant coefficients, unfortunately! For the system

$$\mathbf{y}' = \mathbf{f}(\mathbf{y}) \quad (16.6.14)$$

implicit differencing gives

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h\mathbf{f}(\mathbf{y}_{n+1}) \quad (16.6.15)$$

In general this is some nasty set of nonlinear equations that has to be solved iteratively at each step. Suppose we try linearizing the equations, as in Newton's method:

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h \left[\mathbf{f}(\mathbf{y}_n) + \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \Big|_{\mathbf{y}_n} \cdot (\mathbf{y}_{n+1} - \mathbf{y}_n) \right] \quad (16.6.16)$$

Here $\partial \mathbf{f} / \partial \mathbf{y}$ is the matrix of the partial derivatives of the right-hand side (the Jacobian matrix). Rearrange equation (16.6.16) into the form

$$\mathbf{y}_{n+1} = \mathbf{y}_n + h \left[\mathbf{1} - h \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \right]^{-1} \cdot \mathbf{f}(\mathbf{y}_n) \quad (16.6.17)$$

If h is not too big, only one iteration of Newton's method may be accurate enough to solve equation (16.6.15) using equation (16.6.17). In other words, at each step we have to invert the matrix

$$\mathbf{1} - h \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \quad (16.6.18)$$

to find \mathbf{y}_{n+1} . Solving implicit methods by linearization is called a “semi-implicit” method, so equation (16.6.17) is the *semi-implicit Euler method*. It is not guaranteed to be stable, but it usually is, because the behavior is locally similar to the case of a constant matrix \mathbf{C} described above.

So far we have dealt only with implicit methods that are first-order accurate. While these are very robust, most problems will benefit from higher-order methods. There are three important classes of higher-order methods for stiff systems:

- Generalizations of the Runge-Kutta method, of which the most useful are the Rosenbrock methods. The first practical implementation of these ideas was by Kaps and Rentrop, and so these methods are also called Kaps-Rentrop methods.
- Generalizations of the Bulirsch-Stoer method, in particular a semi-implicit extrapolation method due to Bader and Deuflhard.
- Predictor-corrector methods, most of which are descendants of Gear's backward differentiation method.

We shall give implementations of the first two methods. Note that systems where the right-hand side depends explicitly on x , $\mathbf{f}(\mathbf{y}, x)$, can be handled by adding x to the list of dependent variables so that the system to be solved is

$$\begin{pmatrix} \mathbf{y} \\ x \end{pmatrix}' = \begin{pmatrix} \mathbf{f} \\ 1 \end{pmatrix} \quad (16.6.19)$$

In both the routines to be given in this section, we have explicitly carried out this replacement for you, so the routines can handle right-hand sides of the form $\mathbf{f}(\mathbf{y}, x)$ without any special effort on your part.

We now mention an important point: *It is absolutely crucial to scale your variables properly when integrating stiff problems with automatic stepsize adjustment.* As in our nonstiff routines, you will be asked to supply a vector \mathbf{y}_{scal} with which the error is to be scaled. For example, to get constant fractional errors, simply set $\mathbf{y}_{\text{scal}} = |\mathbf{y}|$. You can get constant absolute errors relative to some maximum values

by setting \mathbf{y}_{scal} equal to those maximum values. In stiff problems, there are often strongly decreasing pieces of the solution which you are not particularly interested in following once they are small. You can control the relative error above some threshold \mathbf{C} and the absolute error below the threshold by setting

$$\mathbf{y}_{\text{scal}} = \max(\mathbf{C}, |\mathbf{y}|) \quad (16.6.20)$$

If you are using appropriate nondimensional units, then each component of \mathbf{C} should be of order unity. If you are not sure what values to take for \mathbf{C} , simply try setting each component equal to unity. *We strongly advocate the choice (16.6.20) for stiff problems.*

One final warning: Solving stiff problems can sometimes lead to catastrophic precision loss. Be alert for situations where double precision is necessary.

Rosenbrock Methods

These methods have the advantage of being relatively simple to understand and implement. For moderate accuracies ($\epsilon \lesssim 10^{-4} - 10^{-5}$ in the error criterion) and moderate-sized systems ($N \lesssim 10$), they are competitive with the more complicated algorithms. For more stringent parameters, Rosenbrock methods remain reliable; they merely become less efficient than competitors like the semi-implicit extrapolation method (see below).

A Rosenbrock method seeks a solution of the form

$$\mathbf{y}(x_0 + h) = \mathbf{y}_0 + \sum_{i=1}^s c_i \mathbf{k}_i \quad (16.6.21)$$

where the corrections \mathbf{k}_i are found by solving s linear equations that generalize the structure in (16.6.17):

$$(\mathbf{1} - \gamma h \mathbf{f}') \cdot \mathbf{k}_i = h \mathbf{f} \left(\mathbf{y}_0 + \sum_{j=1}^{i-1} \alpha_{ij} \mathbf{k}_j \right) + h \mathbf{f}' \cdot \sum_{j=1}^{i-1} \gamma_{ij} \mathbf{k}_j, \quad i = 1, \dots, s \quad (16.6.22)$$

Here we denote the Jacobian matrix by \mathbf{f}' . The coefficients γ , c_i , α_{ij} , and γ_{ij} are fixed constants independent of the problem. If $\gamma = \gamma_{ij} = 0$, this is simply a Runge-Kutta scheme. Equations (16.6.22) can be solved successively for $\mathbf{k}_1, \mathbf{k}_2, \dots$.

Crucial to the success of a stiff integration scheme is an automatic stepsize adjustment algorithm. Kaps and Rentrop [2] discovered an *embedded* or Runge-Kutta-Fehlberg method as described in §16.2: Two estimates of the form (16.6.21) are computed, the “real” one \mathbf{y} and a lower-order estimate $\hat{\mathbf{y}}$ with different coefficients \hat{c}_i , $i = 1, \dots, \hat{s}$, where $\hat{s} < s$ but the \mathbf{k}_i are the same. The difference between \mathbf{y} and $\hat{\mathbf{y}}$ leads to an estimate of the local truncation error, which can then be used for stepsize control. Kaps and Rentrop showed that the smallest value of s for which embedding is possible is $s = 4$, $\hat{s} = 3$, leading to a fourth-order method.

To minimize the matrix-vector multiplications on the right-hand side of (16.6.22), we rewrite the equations in terms of quantities

$$\mathbf{g}_i = \sum_{j=1}^{i-1} \gamma_{ij} \mathbf{k}_j + \gamma \mathbf{k}_i \quad (16.6.23)$$

The equations then take the form

$$\begin{aligned} (\mathbf{1}/\gamma h - \mathbf{f}') \cdot \mathbf{g}_1 &= \mathbf{f}(\mathbf{y}_0) \\ (\mathbf{1}/\gamma h - \mathbf{f}') \cdot \mathbf{g}_2 &= \mathbf{f}(\mathbf{y}_0 + a_{21} \mathbf{g}_1) + c_{21} \mathbf{g}_1/h \\ (\mathbf{1}/\gamma h - \mathbf{f}') \cdot \mathbf{g}_3 &= \mathbf{f}(\mathbf{y}_0 + a_{31} \mathbf{g}_1 + a_{32} \mathbf{g}_2) + (c_{31} \mathbf{g}_1 + c_{32} \mathbf{g}_2)/h \\ (\mathbf{1}/\gamma h - \mathbf{f}') \cdot \mathbf{g}_4 &= \mathbf{f}(\mathbf{y}_0 + a_{41} \mathbf{g}_1 + a_{42} \mathbf{g}_2 + a_{43} \mathbf{g}_3) + (c_{41} \mathbf{g}_1 + c_{42} \mathbf{g}_2 + c_{43} \mathbf{g}_3)/h \end{aligned} \quad (16.6.24)$$

In our implementation **stiff** of the Kaps-Rentrop algorithm, we have carried out the replacement (16.6.19) explicitly in equations (16.6.24), so you need not concern yourself about it. Simply provide a subroutine (called **derivs** in **stiff**) that returns \mathbf{f} (called **dydx**) as a function of x and \mathbf{y} . Also supply a subroutine **jacobn** that returns \mathbf{f}' (**dfdy**) and $\partial \mathbf{f} / \partial x$ (**dfdx**) as functions of x and \mathbf{y} . If x does not occur explicitly on the right-hand side, then **dfdx** will be zero. Usually the Jacobian matrix will be available to you by analytic differentiation of the right-hand side \mathbf{f} . If not, your subroutine will have to compute it by numerical differencing with appropriate increments Δy .

Kaps and Rentrop gave two different sets of parameters, which have slightly different stability properties. Several other sets have been proposed. Our default choice is that of Shampine [3], but we also give you one of the Kaps-Rentrop sets as an option. Some proposed parameter sets require function evaluations outside the domain of integration; we prefer to avoid that complication.

The calling sequence of **stiff** is exactly the same as the nonstiff routines given earlier in this chapter. It is thus “plug-compatible” with them in the general ODE integrating routine **odeint**. This compatibility requires, unfortunately, one slight anomaly: While the user-supplied routine **derivs** is a dummy argument (which can therefore have any actual name), the other user-supplied routine is *not* an argument and must be named (exactly) **jacobn**.

stiff begins by saving the initial values, in case the step has to be repeated because the error tolerance is exceeded. The linear equations (16.6.24) are solved by first computing the *LU* decomposition of the matrix $1/\gamma h - \mathbf{f}'$ using the routine **ludcmp**. Then the four \mathbf{g}_i are found by back-substitution of the four different right-hand sides using **lubksb**. Note that each step of the integration requires one call to **jacobn** and three calls to **derivs** (one call to get **dydx** before calling **stiff**, and two calls inside **stiff**). The reason only three calls are needed and not four is that the parameters have been chosen so that the last two calls in equation (16.6.24) are done with the same arguments. Counting the evaluation of the Jacobian matrix as roughly equivalent to N evaluations of the right-hand side \mathbf{f} , we see that the Kaps-Rentrop scheme involves about $N + 3$ function evaluations per step. Note that if N is large and the Jacobian matrix is sparse, you should replace the *LU* decomposition by a suitable sparse matrix procedure.

Stepsize control depends on the fact that

$$\begin{aligned}\mathbf{y}_{\text{exact}} &= \mathbf{y} + O(h^5) \\ \mathbf{y}_{\text{exact}} &= \hat{\mathbf{y}} + O(h^4)\end{aligned}\tag{16.6.25}$$

Thus

$$|\mathbf{y} - \hat{\mathbf{y}}| = O(h^4)\tag{16.6.26}$$

Referring back to the steps leading from equation (16.2.4) to equation (16.2.10), we see that the new stepsize should be chosen as in equation (16.2.10) but with the exponents 1/4 and 1/5 replaced by 1/3 and 1/4, respectively. Also, experience shows that it is wise to prevent too large a stepsize change in one step, otherwise we will probably have to undo the large change in the next step. We adopt 0.5 and 1.5 as the maximum allowed decrease and increase of h in one step.

```

As an example of how `stiff` is used, one can solve the system

$$\begin{aligned} y'_1 &= -0.013y_1 - 1000y_1y_3 \\ y'_2 &= -2500y_2y_3 \\ y'_3 &= -0.013y_1 - 1000y_1y_3 - 2500y_2y_3 \end{aligned} \tag{16.6.27}$$

with initial conditions

$$y_1(0) = 1, \quad y_2(0) = 1, \quad y_3(0) = 0 \tag{16.6.28}$$

(This is test problem D4 in [4].) We integrate the system up to $x = 50$ with an initial stepsize of $h = 2.9 \times 10^{-4}$ using `odeint`. The components of \mathbf{C} in (16.6.20) are all set to unity. The routines `derivs` and `jacobn` for this problem are given below. Even though the ratio of largest to smallest decay constants for this problem is around 10^6 , `stiff` succeeds in integrating this set in only 29 steps with $\epsilon = 10^{-4}$. By contrast, the Runge-Kutta routine `rkqs` requires 51,012 steps!

```

SUBROUTINE jacobn(x,y,dfdx,dfdy,n,nmax)

dydx(1)=-.013*y(1)-1000.*y(1)*y(3)
dydx(2)=-2500.*y(2)*y(3)
dydx(3)=-.013*y(1)-1000.*y(1)*y(3)-2500.*y(2)*y(3)
return
END

```

Semi-implicit Extrapolation Method

The Bulirsch-Stoer method, which discretizes the differential equation using the modified midpoint rule, does not work for stiff problems. Bader and Deuflhard [5] discovered a semi-implicit discretization that works very well and that lends itself to extrapolation exactly as in the original Bulirsch-Stoer method.

The starting point is an implicit form of the midpoint rule:

$$\mathbf{y}_{n+1} - \mathbf{y}_{n-1} = 2h\mathbf{f}\left(\frac{\mathbf{y}_{n+1} + \mathbf{y}_{n-1}}{2}\right) \quad (16.6.29)$$

Convert this equation into semi-implicit form by linearizing the right-hand side about $\mathbf{f}(\mathbf{y}_n)$. The result is the *semi-implicit midpoint rule*:

$$\left[\mathbf{1} - h\frac{\partial\mathbf{f}}{\partial\mathbf{y}}\right] \cdot \mathbf{y}_{n+1} = \left[\mathbf{1} + h\frac{\partial\mathbf{f}}{\partial\mathbf{y}}\right] \cdot \mathbf{y}_{n-1} + 2h \left[\mathbf{f}(\mathbf{y}_n) - \frac{\partial\mathbf{f}}{\partial\mathbf{y}} \cdot \mathbf{y}_n\right] \quad (16.6.30)$$

It is used with a special first step, the semi-implicit Euler step (16.6.17), and a special “smoothing” last step in which the last \mathbf{y}_n is replaced by

$$\bar{\mathbf{y}}_n \equiv \frac{1}{2}(\mathbf{y}_{n+1} + \mathbf{y}_{n-1}) \quad (16.6.31)$$

Bader and Deuflhard showed that the error series for this method once again involves only even powers of h .

For practical implementation, it is better to rewrite the equations using $\Delta_k \equiv \mathbf{y}_{k+1} - \mathbf{y}_k$. With $h = H/m$, start by calculating

$$\begin{aligned} \Delta_0 &= \left[\mathbf{1} - h\frac{\partial\mathbf{f}}{\partial\mathbf{y}}\right]^{-1} \cdot h\mathbf{f}(\mathbf{y}_0) \\ \mathbf{y}_1 &= \mathbf{y}_0 + \Delta_0 \end{aligned} \quad (16.6.32)$$

Then for $k = 1, \dots, m-1$, set

$$\begin{aligned} \Delta_k &= \Delta_{k-1} + 2 \left[\mathbf{1} - h\frac{\partial\mathbf{f}}{\partial\mathbf{y}}\right]^{-1} \cdot [h\mathbf{f}(\mathbf{y}_k) - \Delta_{k-1}] \\ \mathbf{y}_{k+1} &= \mathbf{y}_k + \Delta_k \end{aligned} \quad (16.6.33)$$

Finally compute

$$\begin{aligned}\Delta_m &= \left[\mathbf{1} - h \frac{\partial \mathbf{f}}{\partial \mathbf{y}} \right]^{-1} \cdot [h\mathbf{f}(\mathbf{y}_m) - \Delta_{m-1}] \\ \bar{\mathbf{y}}_m &= \mathbf{y}_m + \Delta_m\end{aligned}\quad (16.6.34)$$

It is easy to incorporate the replacement (16.6.19) in the above formulas. The additional terms in the Jacobian that come from $\partial f / \partial x$ all cancel out of the semi-implicit midpoint rule (16.6.30). In the special first step (16.6.17), and in the corresponding equation (16.6.32), the term $h\mathbf{f}$ becomes $h\mathbf{f} + h^2 \partial \mathbf{f} / \partial x$. The remaining equations are all unchanged.

This algorithm is implemented in the routine `simpr`:

```
SUBROUTINE simpr(y,dydx,dfdx,dfdy,nmax,n,xs,htot,nstep,yout,
*      derivs)
INTEGER n,nmax,nstep,NMAXX
REAL htot,xs,dfdx(n),dfdy(nmax,nmax),dydx(n),y(n),yout(n)
EXTERNAL derivs
PARAMETER (NMAXX=50)           Maximum expected value of n.
C USES derivs,lubksb,ludcmp
Performs one step of semi-implicit midpoint rule. Input are the dependent variable y(1:n),
its derivative dydx(1:n), the derivative of the right-hand side with respect to x, dfdx(1:n),
and the Jacobian dfdy(1:nmax, 1:nmax) at xs. Also input are htot, the total step
to be taken, and nstep, the number of substeps to be used. The output is returned as
yout(1:n). derivs is the user-supplied subroutine that calculates dydx.
INTEGER i,j,nn,indx(NMAXX)
REAL d,h,x,a(NMAXX,NMAXX),del(NMAXX),ytemp(NMAXX)
h=htot/nstep                  Stepsize this trip.
do 12 i=1,n                   Set up the matrix  $\mathbf{1} - hf'$ .
    do 11 j=1,n
        a(i,j)=-h*dfdy(i,j)
    enddo 11
    a(i,i)=a(i,i)+1.
  enddo 12
  call ludcmp(a,n,NMAXX,indx,d)   LU decomposition of the matrix.
  do 13 i=1,n                   Set up right-hand side for first step. Use yout for
      yout(i)=h*(dydx(i)+h*dfdx(i)) temporary storage.
  enddo 13
  call lubksb(a,n,NMAXX,indx,yout)  First step.
  do 14 i=1,n
      del(i)=yout(i)
      ytemp(i)=y(i)+del(i)
  enddo 14
  x=xs+h
  call derivs(x,ytemp,yout)       Use yout for temporary storage of derivatives.
  do 17 nn=2,nstep               General step.
      do 15 i=1,n
          yout(i)=h*yout(i)-del(i)
      enddo 15
      call lubksb(a,n,NMAXX,indx,yout)
      do 16 i=1,n
          del(i)=del(i)+2.*yout(i)
          ytemp(i)=ytemp(i)+del(i)
      enddo 16
      x=x+h
      call derivs(x,ytemp,yout)
  enddo 17
  do 18 i=1,n                   Set up right-hand side for last step.
      yout(i)=h*yout(i)-del(i)
  enddo 18
  call lubksb(a,n,NMAXX,indx,yout)
  do 19 i=1,n                   Take last step.
      yout(i)=ytemp(i)+yout(i)
```

```
enddo 19
return
END
```

The routine `simpr` is intended to be used in a routine `stifbs` that is almost exactly the same as `bsstep`. The only differences are:

- The stepsize sequence is

$$n = 2, 6, 10, 14, 22, 34, 50, \dots, \quad (16.6.35)$$

where each member differs from its predecessor by the smallest multiple of 4 that makes the ratio of successive terms be $\leq \frac{5}{7}$. The parameter `KMAXX` is taken to be 7.

- The work per unit step now includes the cost of Jacobian evaluations as well as function evaluations. We count one Jacobian evaluation as equivalent to N function evaluations, where N is the number of equations.
- Once again the user-supplied routine `derivs` is a dummy argument and so can have any name. However, to maintain “plug-compatibility” with `rkqs`, `bsstep` and `stiff`, the routine `jacobn` is not an argument and *must* have exactly this name. It is called once per step to return $\mathbf{f}'(\mathbf{dfdy})$ and $\partial\mathbf{f}/\partial x(\mathbf{dfdx})$ as functions of x and y .

Here is the routine, with comments pointing out only the differences from `bsstep`:

```
SUBROUTINE stifbs(y,dydx,nv,x,htry,eps,yscal,hdid,hnext,derivs)
INTEGER nv,NMAX,KMAXX,IMAX
REAL eps,hdid,hnext,htry,x,dydx(nv),y(nv),yscal(nv),SAFE1,
*      SAFE2,REDMAX,REDMIN,TINY,SCALMX
EXTERNAL derivs
PARAMETER (NMAX=50,KMAXX=7,IMAX=KMAXX+1,SAFE1=.25,SAFE2=.7,
*      REDMAX=1.e-5,REDMIN=.7,TINY=1.e-30,SCALMX=.1)
C USES derivs,jacobn,simpr,pzextr
      Semi-implicit extrapolation step for integrating stiff o.d.e.'s, with monitoring of local truncation error to adjust stepsize. Input are the dependent variable vector y(1:nv) and its derivative dydx(1:nv) at the starting value of the independent variable x. Also input are the stepsize to be attempted htry, the required accuracy eps, and the vector yscal(1:nv) against which the error is scaled. On output, y and x are replaced by their new values, hdid is the stepsize that was actually accomplished, and hnext is the estimated next stepsize. derivs is a user-supplied subroutine that computes the derivatives of the right-hand side with respect to x, while jacobn (a fixed name) is a user-supplied subroutine that computes the Jacobi matrix of derivatives of the right-hand side with respect to the components of y. Be sure to set htry on successive steps to the value of hnext returned from the previous step, as is the case if the routine is called by odeint.

The routine `stifbs` is an excellent routine for all stiff problems, competitive with the best Gear-type routines. `stiff` is comparable in execution time for moderate N and $\epsilon \lesssim 10^{-4}$. By the time $\epsilon \sim 10^{-8}$, `stifbs` is roughly an order of magnitude faster. There are further improvements that could be applied to `stifbs` to make it even more robust. For example, very occasionally `ludcmp` in `simpz` will encounter a singular matrix. You could arrange for the stepsize to be reduced, say by a factor of the current `nseq(k)`. There are also certain stability restrictions on the stepsize that come into play on some problems. For a discussion of how to implement these automatically, see [6].

16.7 Multistep, Multivalue, and Predictor-Corrector Methods

The terms multistep and multivalue describe two different ways of implementing essentially the same integration technique for ODEs. Predictor-corrector is a particular subcategory of these methods — in fact, the most widely used. Accordingly, the name predictor-corrector is often loosely used to denote all these methods.

We suspect that predictor-corrector integrators have had their day, and that they are no longer the method of choice for most problems in ODEs. For high-precision applications, or applications where evaluations of the right-hand sides are expensive, Bulirsch-Stoer dominates. For convenience, or for low precision, adaptive-stepsize Runge-Kutta dominates. Predictor-corrector methods have been, we think, squeezed out in the middle. There is possibly only one exceptional case: high-precision solution of very smooth equations with very complicated right-hand sides, as we will describe later.

Nevertheless, these methods have had a long historical run. Textbooks are full of information on them, and there are a lot of standard ODE programs around that are based on predictor-corrector methods. Many capable researchers have a lot of experience with predictor-corrector routines, and they see no reason to make a precipitous change of habit. It is not a bad idea for you to be familiar with the principles involved, and even with the sorts of bookkeeping details that are the bane of these methods. Otherwise there will be a big surprise in store when you first have to fix a problem in a predictor-corrector routine.

Let us first consider the multistep approach. Think about how integrating an ODE is different from finding the integral of a function: For a function, the integrand has a known dependence on the independent variable x , and can be evaluated at will. For an ODE, the “integrand” is the right-hand side, which depends both on x and on the dependent variables y . Thus to advance the solution of $y' = f(x, y)$ from x_n to x , we have

$$y(x) = y_n + \int_{x_n}^x f(x', y) dx' \quad (16.7.1)$$

In a single-step method like Runge-Kutta or Bulirsch-Stoer, the value y_{n+1} at x_{n+1} depends only on y_n . In a multistep method, we approximate $f(x, y)$ by a polynomial passing through *several* previous points x_n, x_{n-1}, \dots and possibly also through x_{n+1} . The result of evaluating the integral (16.7.1) at $x = x_{n+1}$ is then of the form

$$y_{n+1} = y_n + h(\beta_0 y'_{n+1} + \beta_1 y'_{n-1} + \beta_2 y'_{n-2} + \dots) \quad (16.7.2)$$

where y'_n denotes $f(x_n, y_n)$, and so on. If $\beta_0 = 0$, the method is explicit; otherwise it is implicit. The order of the method depends on how many previous steps we use to get each new value of y .

Consider how we might solve an implicit formula of the form (16.7.2) for y_{n+1} . Two methods suggest themselves: *functional iteration* and *Newton's method*. In functional iteration, we take some initial guess for y_{n+1} , insert it into the right-hand side of (16.7.2) to get an updated value of y_{n+1} , insert this updated value back into the right-hand side, and continue iterating. But how are we to get an initial guess for

16.7 Multistep, Multivalue, and Predictor-Corrector Methods

The terms multistep and multivalue describe two different ways of implementing essentially the same integration technique for ODEs. Predictor-corrector is a particular subcategory of these methods — in fact, the most widely used. Accordingly, the name predictor-corrector is often loosely used to denote all these methods.

We suspect that predictor-corrector integrators have had their day, and that they are no longer the method of choice for most problems in ODEs. For high-precision applications, or applications where evaluations of the right-hand sides are expensive, Bulirsch-Stoer dominates. For convenience, or for low precision, adaptive-stepsize Runge-Kutta dominates. Predictor-corrector methods have been, we think, squeezed out in the middle. There is possibly only one exceptional case: high-precision solution of very smooth equations with very complicated right-hand sides, as we will describe later.

Nevertheless, these methods have had a long historical run. Textbooks are full of information on them, and there are a lot of standard ODE programs around that are based on predictor-corrector methods. Many capable researchers have a lot of experience with predictor-corrector routines, and they see no reason to make a precipitous change of habit. It is not a bad idea for you to be familiar with the principles involved, and even with the sorts of bookkeeping details that are the bane of these methods. Otherwise there will be a big surprise in store when you first have to fix a problem in a predictor-corrector routine.

Let us first consider the multistep approach. Think about how integrating an ODE is different from finding the integral of a function: For a function, the integrand has a known dependence on the independent variable x , and can be evaluated at will. For an ODE, the “integrand” is the right-hand side, which depends both on x and on the dependent variables y . Thus to advance the solution of $y' = f(x, y)$ from x_n to x , we have

$$y(x) = y_n + \int_{x_n}^x f(x', y) dx' \quad (16.7.1)$$

In a single-step method like Runge-Kutta or Bulirsch-Stoer, the value y_{n+1} at x_{n+1} depends only on y_n . In a multistep method, we approximate $f(x, y)$ by a polynomial passing through *several* previous points x_n, x_{n-1}, \dots and possibly also through x_{n+1} . The result of evaluating the integral (16.7.1) at $x = x_{n+1}$ is then of the form

$$y_{n+1} = y_n + h(\beta_0 y'_{n+1} + \beta_1 y'_{n-1} + \beta_2 y'_{n-2} + \dots) \quad (16.7.2)$$

where y'_n denotes $f(x_n, y_n)$, and so on. If $\beta_0 = 0$, the method is explicit; otherwise it is implicit. The order of the method depends on how many previous steps we use to get each new value of y .

Consider how we might solve an implicit formula of the form (16.7.2) for y_{n+1} . Two methods suggest themselves: *functional iteration* and *Newton's method*. In functional iteration, we take some initial guess for y_{n+1} , insert it into the right-hand side of (16.7.2) to get an updated value of y_{n+1} , insert this updated value back into the right-hand side, and continue iterating. But how are we to get an initial guess for

y_{n+1} ? Easy! Just use some *explicit* formula of the same form as (16.7.2). This is called the *predictor step*. In the predictor step we are essentially *extrapolating* the polynomial fit to the derivative from the previous points to the new point x_{n+1} and then doing the integral (16.7.1) in a Simpson-like manner from x_n to x_{n+1} . The subsequent Simpson-like integration, using the prediction step's value of y_{n+1} to *interpolate* the derivative, is called the *corrector step*. The difference between the predicted and corrected function values supplies information on the local truncation error that can be used to control accuracy and to adjust stepsize.

If one corrector step is good, aren't many better? Why not use each corrector as an improved predictor and iterate to convergence on each step? Answer: Even if you had a *perfect* predictor, the step would still be accurate only to the finite order of the corrector. This incurable error term is on the same order as that which your iteration is supposed to cure, so you are at best changing only the coefficient in front of the error term by a fractional amount. So dubious an improvement is certainly not worth the effort. Your extra effort would be better spent in taking a smaller stepsize.

As described so far, you might think it desirable or necessary to predict several intervals ahead at each step, then to use all these intervals, with various weights, in a Simpson-like corrector step. That is not a good idea. Extrapolation is the least stable part of the procedure, and it is desirable to minimize its effect. Therefore, the integration steps of a predictor-corrector method are overlapping, each one involving several stepsize intervals h , but extending just one such interval farther than the previous ones. Only that one extended interval is extrapolated by each predictor step.

The most popular predictor-corrector methods are probably the Adams-Bashforth-Moulton schemes, which have good stability properties. The Adams-Bashforth part is the predictor. For example, the third-order case is

$$\text{predictor: } y_{n+1} = y_n + \frac{h}{12}(23y'_n - 16y'_{n-1} + 5y'_{n-2}) + O(h^4) \quad (16.7.3)$$

Here information at the current point x_n , together with the two previous points x_{n-1} and x_{n-2} (assumed equally spaced), is used to predict the value y_{n+1} at the next point, x_{n+1} . The Adams-Moulton part is the corrector. The third-order case is

$$\text{corrector: } y_{n+1} = y_n + \frac{h}{12}(5y'_{n+1} + 8y'_n - y'_{n-1}) + O(h^4) \quad (16.7.4)$$

Without the trial value of y_{n+1} from the predictor step to insert on the right-hand side, the corrector would be a nasty implicit equation for y_{n+1} .

There are actually three separate processes occurring in a predictor-corrector method: the predictor step, which we call P, the evaluation of the derivative y'_{n+1} from the latest value of y , which we call E, and the corrector step, which we call C. In this notation, iterating m times with the corrector (a practice we inveighed against earlier) would be written $P(EC)^m$. One also has the choice of finishing with a C or an E step. The lore is that a final E is superior, so the strategy usually recommended is PECE.

Notice that a PC method with a fixed number of iterations (say, one) is an explicit method! When we fix the number of iterations in advance, then the final value of y_{n+1} can be written as some complicated function of known quantities. Thus fixed iteration PC methods lose the strong stability properties of implicit methods and *should only be used for nonstiff problems*.

For stiff problems we *must* use an implicit method if we want to avoid having tiny stepsizes. (Not all implicit methods are good for stiff problems, but fortunately some good ones such as the Gear formulas are known.) We then appear to have two choices for solving the implicit equations: functional iteration to convergence, or Newton iteration. However, it turns out that for stiff problems functional iteration will not even converge unless we use tiny stepsizes, no matter how close our prediction is! Thus Newton iteration is usually an essential part of a multistep stiff solver. For convergence, Newton's method doesn't particularly care what the stepsize is, as long as the prediction is accurate enough.

Multistep methods, as we have described them so far, suffer from two serious difficulties when one tries to implement them:

- Since the formulas require results from equally spaced steps, adjusting the stepsize is difficult.
- Starting and stopping present problems. For starting, we need the initial values plus several previous steps to prime the pump. Stopping is a problem because equal steps are unlikely to land directly on the desired termination point.

Older implementations of PC methods have various cumbersome ways of dealing with these problems. For example, they might use Runge-Kutta to start and stop. Changing the stepsize requires considerable bookkeeping to do some kind of interpolation procedure. Fortunately both these drawbacks disappear with the multivalue approach.

For multivalue methods the basic data available to the integrator are the first few terms of the Taylor series expansion of the solution at the current point x_n . The aim is to advance the solution and obtain the expansion coefficients at the next point x_{n+1} . This is in contrast to multistep methods, where the data are the values of the solution at x_n, x_{n-1}, \dots . We'll illustrate the idea by considering a four-value method, for which the basic data are

$$\mathbf{y}_n \equiv \begin{pmatrix} y_n \\ hy'_n \\ (h^2/2)y''_n \\ (h^3/6)y'''_n \end{pmatrix} \quad (16.7.5)$$

It is also conventional to scale the derivatives with the powers of $h = x_{n+1} - x_n$ as shown. Note that here we use the vector notation \mathbf{y} to denote the solution and its first few derivatives at a point, not the fact that we are solving a system of equations with many components y .

In terms of the data in (16.7.5), we can approximate the value of the solution y at some point x :

$$y(x) = y_n + (x - x_n)y'_n + \frac{(x - x_n)^2}{2}y''_n + \frac{(x - x_n)^3}{6}y'''_n \quad (16.7.6)$$

Set $x = x_{n+1}$ in equation (16.7.6) to get an approximation to y_{n+1} . Differentiate equation (16.7.6) and set $x = x_{n+1}$ to get an approximation to y'_{n+1} , and similarly for y''_{n+1} and y'''_{n+1} . Call the resulting approximation $\tilde{\mathbf{y}}_{n+1}$, where the tilde is a reminder

that all we have done so far is a polynomial extrapolation of the solution and its derivatives; we have not yet used the differential equation. You can easily verify that

$$\tilde{\mathbf{y}}_{n+1} = \mathbf{B} \cdot \mathbf{y}_n \quad (16.7.7)$$

where the matrix \mathbf{B} is

$$\mathbf{B} = \begin{pmatrix} 1 & 1 & 1 & 1 \\ 0 & 1 & 2 & 3 \\ 0 & 0 & 1 & 3 \\ 0 & 0 & 0 & 1 \end{pmatrix} \quad (16.7.8)$$

We now write the actual approximation to \mathbf{y}_{n+1} that we will use by adding a correction to $\tilde{\mathbf{y}}_{n+1}$:

$$\mathbf{y}_{n+1} = \tilde{\mathbf{y}}_{n+1} + \alpha \mathbf{r} \quad (16.7.9)$$

Here \mathbf{r} will be a fixed vector of numbers, in the same way that \mathbf{B} is a fixed matrix. We fix α by requiring that the differential equation

$$y'_{n+1} = f(x_{n+1}, y_{n+1}) \quad (16.7.10)$$

be satisfied. The second of the equations in (16.7.9) is

$$hy'_{n+1} = h\tilde{y}'_{n+1} + \alpha r_2 \quad (16.7.11)$$

and this will be consistent with (16.7.10) provided

$$r_2 = 1, \quad \alpha = hf(x_{n+1}, y_{n+1}) - h\tilde{y}'_{n+1} \quad (16.7.12)$$

The values of r_1 , r_3 , and r_4 are free for the inventor of a given four-value method to choose. Different choices give different orders of method (i.e., through what order in h the final expression 16.7.9 actually approximates the solution), and different stability properties.

An interesting result, not obvious from our presentation, is that multivalue and multistep methods are entirely equivalent. In other words, the value y_{n+1} given by a multivalue method with given \mathbf{B} and \mathbf{r} is exactly the same value given by some multistep method with given β 's in equation (16.7.2). For example, it turns out that the Adams-Basforth formula (16.7.3) corresponds to a four-value method with $r_1 = 0$, $r_3 = 3/4$, and $r_4 = 1/6$. The method is explicit because $r_1 = 0$. The Adams-Moulton method (16.7.4) corresponds to the implicit four-value method with $r_1 = 5/12$, $r_3 = 3/4$, and $r_4 = 1/6$. Implicit multivalue methods are solved the same way as implicit multistep methods: either by a predictor-corrector approach using an explicit method for the predictor, or by Newton iteration for stiff systems.

Why go to all the trouble of introducing a whole new method that turns out to be equivalent to a method you already knew? The reason is that multivalue methods allow an easy solution to the two difficulties we mentioned above in actually implementing multistep methods.

Consider first the question of stepsize adjustment. To change stepsize from h to h' at some point x_n , simply multiply the components of \mathbf{y}_n in (16.7.5) by the appropriate powers of h'/h , and you are ready to continue to $x_n + h'$.

Multivalue methods also allow a relatively easy change in the *order* of the method: Simply change r . The usual strategy for this is first to determine the new stepsize with the current order from the error estimate. Then check what stepsize would be predicted using an order one greater and one smaller than the current order. Choose the order that allows you to take the biggest next step. Being able to change order also allows an easy solution to the starting problem: Simply start with a first-order method and let the order automatically increase to the appropriate level.

For low accuracy requirements, a Runge-Kutta routine like `rkqs` is almost always the most efficient choice. For high accuracy, `bsstep` is both robust and efficient. For very smooth functions, a variable-order PC method can invoke very high orders. If the right-hand side of the equation is relatively complicated, so that the expense of evaluating it outweighs the bookkeeping expense, then the best PC packages can outperform Bulirsch-Stoer on such problems. As you can imagine, however, such a variable-stepsize, variable-order method is not trivial to program. If you suspect that your problem is suitable for this treatment, we recommend use of a canned PC package. For further details consult Gear [1] or Shampine and Gordon [2].

Our prediction, nevertheless, is that, as extrapolation methods like Bulirsch-Stoer continue to gain sophistication, they will eventually beat out PC methods in all applications. We are willing, however, to be corrected.

Chapter 17. Two Point Boundary Value Problems

17.0 Introduction

When ordinary differential equations are required to satisfy boundary conditions at more than one value of the independent variable, the resulting problem is called a *two point boundary value problem*. As the terminology indicates, the most common case by far is where boundary conditions are supposed to be satisfied at two points — usually the starting and ending values of the integration. However, the phrase “two point boundary value problem” is also used loosely to include more complicated cases, e.g., where some conditions are specified at endpoints, others at interior (usually singular) points.

The crucial distinction between initial value problems (Chapter 16) and two point boundary value problems (this chapter) is that in the former case we are able to start an acceptable solution at its beginning (initial values) and just march it along by numerical integration to its end (final values); while in the present case, the boundary conditions at the starting point do not determine a unique solution to start with — and a “random” choice among the solutions that satisfy these (incomplete) starting boundary conditions is almost certain *not* to satisfy the boundary conditions at the other specified point(s).

It should not surprise you that iteration is in general required to meld these spatially scattered boundary conditions into a single global solution of the differential equations. For this reason, two point boundary value problems require considerably more effort to solve than do initial value problems. You have to integrate your differential equations over the interval of interest, or perform an analogous “relaxation” procedure (see below), at least several, and sometimes very many, times. Only in the special case of linear differential equations can you say in advance just how many such iterations will be required.

The “standard” two point boundary value problem has the following form: We desire the solution to a set of N coupled first-order ordinary differential equations, satisfying n_1 boundary conditions at the starting point x_1 , and a remaining set of $n_2 = N - n_1$ boundary conditions at the final point x_2 . (Recall that all differential equations of order higher than first can be written as coupled sets of first-order equations, cf. §16.0.)

The differential equations are

$$\frac{dy_i(x)}{dx} = g_i(x, y_1, y_2, \dots, y_N) \quad i = 1, 2, \dots, N \quad (17.0.1)$$

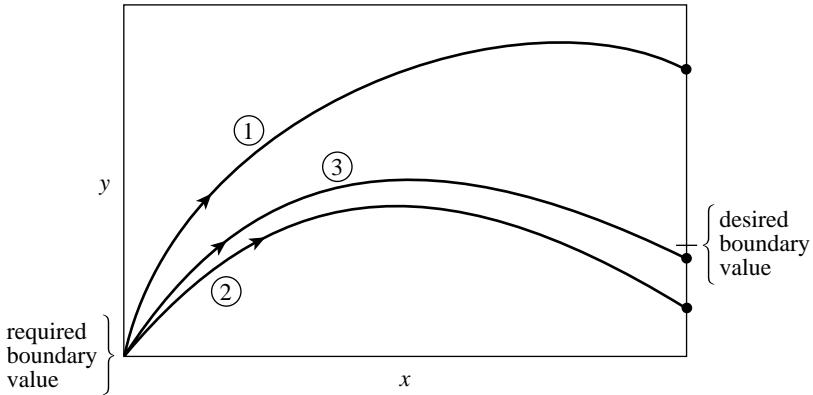

Figure 17.0.1. Shooting method (schematic). Trial integrations that satisfy the boundary condition at one endpoint are “launched.” The discrepancies from the desired boundary condition at the other endpoint are used to adjust the starting conditions, until boundary conditions at both endpoints are ultimately satisfied.

At x_1 , the solution is supposed to satisfy

$$B_{1j}(x_1, y_1, y_2, \dots, y_N) = 0 \quad j = 1, \dots, n_1 \quad (17.0.2)$$

while at x_2 , it is supposed to satisfy

$$B_{2k}(x_2, y_1, y_2, \dots, y_N) = 0 \quad k = 1, \dots, n_2 \quad (17.0.3)$$

There are two distinct classes of numerical methods for solving two point boundary value problems. In the *shooting method* (§17.1) we choose values for all of the dependent variables at one boundary. These values must be consistent with any boundary conditions for *that* boundary, but otherwise are arranged to depend on arbitrary free parameters whose values we initially “randomly” guess. We then integrate the ODEs by initial value methods, arriving at the other boundary (and/or any interior points with boundary conditions specified). In general, we find discrepancies from the desired boundary values there. Now we have a multidimensional root-finding problem, as was treated in §9.6 and §9.7: Find the adjustment of the free parameters at the starting point that zeros the discrepancies at the other boundary point(s). If we liken integrating the differential equations to following the trajectory of a shot from gun to target, then picking the initial conditions corresponds to aiming (see Figure 17.0.1). The shooting method provides a systematic approach to taking a set of “ranging” shots that allow us to improve our “aim” systematically.

As another variant of the shooting method (§17.2), we can guess unknown free parameters at both ends of the domain, integrate the equations to a common midpoint, and seek to adjust the guessed parameters so that the solution joins “smoothly” at the fitting point. In all shooting methods, trial solutions satisfy the differential equations “exactly” (or as exactly as we care to make our numerical integration), but the trial solutions come to satisfy the required boundary conditions only after the iterations are finished.

Relaxation methods use a different approach. The differential equations are replaced by finite-difference equations on a mesh of points that covers the range of

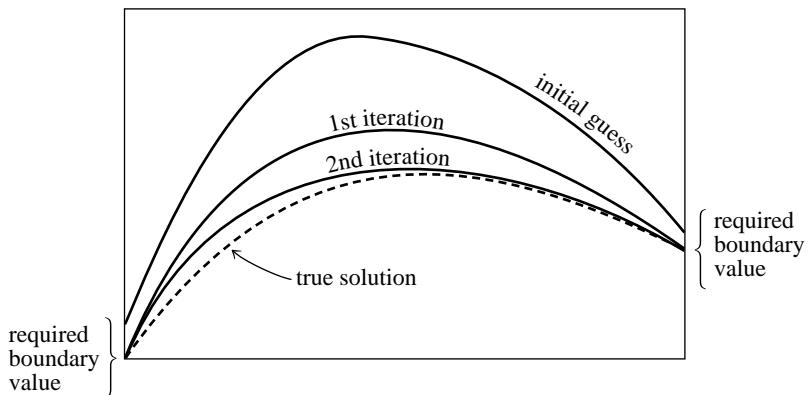

Figure 17.0.2. Relaxation method (schematic). An initial solution is guessed that approximately satisfies the differential equation and boundary conditions. An iterative process adjusts the function to bring it into close agreement with the true solution.

the integration. A trial solution consists of values for the dependent variables at each mesh point, *not* satisfying the desired finite-difference equations, nor necessarily even satisfying the required boundary conditions. The iteration, now called *relaxation*, consists of adjusting all the values on the mesh so as to bring them into successively closer agreement with the finite-difference equations and, simultaneously, with the boundary conditions (see Figure 17.0.2). For example, if the problem involves three coupled equations and a mesh of one hundred points, we must guess and improve three hundred variables representing the solution.

With all this adjustment, you may be surprised that relaxation is ever an efficient method, but (for the right problems) it really is! Relaxation works better than shooting when the boundary conditions are especially delicate or subtle, or where they involve complicated algebraic relations that cannot easily be solved in closed form. Relaxation works best when the solution is smooth and not highly oscillatory. Such oscillations would require many grid points for accurate representation. The number and position of required points may not be known *a priori*. Shooting methods are usually preferred in such cases, because their variable stepsize integrations adjust naturally to a solution's peculiarities.

Relaxation methods are often preferred when the ODEs have extraneous solutions which, while not appearing in the final solution satisfying all boundary conditions, may wreak havoc on the initial value integrations required by shooting. The typical case is that of trying to maintain a dying exponential in the presence of growing exponentials.

Good initial guesses are the secret of efficient relaxation methods. Often one has to solve a problem many times, each time with a slightly different value of some parameter. In that case, the previous solution is usually a good initial guess when the parameter is changed, and relaxation will work well.

Until you have enough experience to make your own judgment between the two methods, you might wish to follow the advice of your authors, who are notorious computer gunslingers: We always shoot first, and only then relax.

Problems Reducible to the Standard Boundary Problem

There are two important problems that can be reduced to the standard boundary value problem described by equations (17.0.1) – (17.0.3). The first is the *eigenvalue problem for differential equations*. Here the right-hand side of the system of differential equations depends on a parameter λ ,

$$\frac{dy_i(x)}{dx} = g_i(x, y_1, \dots, y_N, \lambda) \quad (17.0.4)$$

and one has to satisfy $N + 1$ boundary conditions instead of just N . The problem is overdetermined and in general there is no solution for arbitrary values of λ . For certain special values of λ , the eigenvalues, equation (17.0.4) does have a solution.

We reduce this problem to the standard case by introducing a new dependent variable

$$y_{N+1} \equiv \lambda \quad (17.0.5)$$

and another differential equation

$$\frac{dy_{N+1}}{dx} = 0 \quad (17.0.6)$$

An example of this trick is given in §17.4.

The other case that can be put in the standard form is a *free boundary problem*. Here only one boundary abscissa x_1 is specified, while the other boundary x_2 is to be determined so that the system (17.0.1) has a solution satisfying a total of $N + 1$ boundary conditions. Here we again add an extra constant dependent variable:

$$y_{N+1} \equiv x_2 - x_1 \quad (17.0.7)$$

$$\frac{dy_{N+1}}{dx} = 0 \quad (17.0.8)$$

We also define a new *independent* variable t by setting

$$x - x_1 \equiv t y_{N+1}, \quad 0 \leq t \leq 1 \quad (17.0.9)$$

The system of $N + 1$ differential equations for dy_i/dt is now in the standard form, with t varying between the known limits 0 and 1.

17.1 The Shooting Method

In this section we discuss “pure” shooting, where the integration proceeds from x_1 to x_2 , and we try to match boundary conditions at the end of the integration. In the next section, we describe shooting to an intermediate fitting point, where the solution to the equations and boundary conditions is found by launching “shots” from both sides of the interval and trying to match continuity conditions at some intermediate point.

Our implementation of the shooting method exactly implements multidimensional, globally convergent Newton-Raphson (§9.7). It seeks to zero n_2 functions of n_2 variables. The functions are obtained by integrating N differential equations from x_1 to x_2 . Let us see how this works:

At the starting point x_1 there are N starting values y_i to be specified, but subject to n_1 conditions. Therefore there are $n_2 = N - n_1$ freely specifiable starting values. Let us imagine that these freely specifiable values are the components of a vector \mathbf{V} that lives in a vector space of dimension n_2 . Then you, the user, knowing the functional form of the boundary conditions (17.0.2), can write a subroutine that generates a complete set of N starting values \mathbf{y} , satisfying the boundary conditions at x_1 , from an arbitrary vector value of \mathbf{V} in which there are no restrictions on the n_2 component values. In other words, (17.0.2) converts to a prescription

$$y_i(x_1) = y_i(x_1; V_1, \dots, V_{n_2}) \quad i = 1, \dots, N \quad (17.1.1)$$

Below, the subroutine that implements (17.1.1) will be called `load`.

Notice that the components of \mathbf{V} might be exactly the values of certain “free” components of \mathbf{y} , with the other components of \mathbf{y} determined by the boundary conditions. Alternatively, the components of \mathbf{V} might parametrize the solutions that satisfy the starting boundary conditions in some other convenient way. Boundary conditions often impose algebraic relations among the y_i , rather than specific values for each of them. Using some auxiliary set of parameters often makes it easier to “solve” the boundary relations for a consistent set of y_i ’s. It makes no difference which way you go, as long as your vector space of \mathbf{V} ’s generates (through 17.1.1) all allowed starting vectors \mathbf{y} .

Given a particular \mathbf{V} , a particular $\mathbf{y}(x_1)$ is thus generated. It can then be turned into a $\mathbf{y}(x_2)$ by integrating the ODEs to x_2 as an initial value problem (e.g., using Chapter 16’s `odeint`). Now, at x_2 , let us define a *discrepancy vector* \mathbf{F} , also of dimension n_2 , whose components measure how far we are from satisfying the n_2 boundary conditions at x_2 (17.0.3). Simplest of all is just to use the right-hand sides of (17.0.3),

$$F_k = B_{2k}(x_2, \mathbf{y}) \quad k = 1, \dots, n_2 \quad (17.1.2)$$

As in the case of \mathbf{V} , however, you can use any other convenient parametrization, as long as your space of \mathbf{F} ’s spans the space of possible discrepancies from the desired boundary conditions, with all components of \mathbf{F} equal to zero if and only if the boundary conditions at x_2 are satisfied. Below, you will be asked to supply a user-written subroutine `score` which uses (17.0.3) to convert an N -vector of ending values $\mathbf{y}(x_2)$ into an n_2 -vector of discrepancies \mathbf{F} .

17.1 The Shooting Method

In this section we discuss “pure” shooting, where the integration proceeds from x_1 to x_2 , and we try to match boundary conditions at the end of the integration. In the next section, we describe shooting to an intermediate fitting point, where the solution to the equations and boundary conditions is found by launching “shots” from both sides of the interval and trying to match continuity conditions at some intermediate point.

Our implementation of the shooting method exactly implements multidimensional, globally convergent Newton-Raphson (§9.7). It seeks to zero n_2 functions of n_2 variables. The functions are obtained by integrating N differential equations from x_1 to x_2 . Let us see how this works:

At the starting point x_1 there are N starting values y_i to be specified, but subject to n_1 conditions. Therefore there are $n_2 = N - n_1$ freely specifiable starting values. Let us imagine that these freely specifiable values are the components of a vector \mathbf{V} that lives in a vector space of dimension n_2 . Then you, the user, knowing the functional form of the boundary conditions (17.0.2), can write a subroutine that generates a complete set of N starting values \mathbf{y} , satisfying the boundary conditions at x_1 , from an arbitrary vector value of \mathbf{V} in which there are no restrictions on the n_2 component values. In other words, (17.0.2) converts to a prescription

$$y_i(x_1) = y_i(x_1; V_1, \dots, V_{n_2}) \quad i = 1, \dots, N \quad (17.1.1)$$

Below, the subroutine that implements (17.1.1) will be called `load`.

Notice that the components of \mathbf{V} might be exactly the values of certain “free” components of \mathbf{y} , with the other components of \mathbf{y} determined by the boundary conditions. Alternatively, the components of \mathbf{V} might parametrize the solutions that satisfy the starting boundary conditions in some other convenient way. Boundary conditions often impose algebraic relations among the y_i , rather than specific values for each of them. Using some auxiliary set of parameters often makes it easier to “solve” the boundary relations for a consistent set of y_i ’s. It makes no difference which way you go, as long as your vector space of \mathbf{V} ’s generates (through 17.1.1) all allowed starting vectors \mathbf{y} .

Given a particular \mathbf{V} , a particular $\mathbf{y}(x_1)$ is thus generated. It can then be turned into a $\mathbf{y}(x_2)$ by integrating the ODEs to x_2 as an initial value problem (e.g., using Chapter 16’s `odeint`). Now, at x_2 , let us define a *discrepancy vector* \mathbf{F} , also of dimension n_2 , whose components measure how far we are from satisfying the n_2 boundary conditions at x_2 (17.0.3). Simplest of all is just to use the right-hand sides of (17.0.3),

$$F_k = B_{2k}(x_2, \mathbf{y}) \quad k = 1, \dots, n_2 \quad (17.1.2)$$

As in the case of \mathbf{V} , however, you can use any other convenient parametrization, as long as your space of \mathbf{F} ’s spans the space of possible discrepancies from the desired boundary conditions, with all components of \mathbf{F} equal to zero if and only if the boundary conditions at x_2 are satisfied. Below, you will be asked to supply a user-written subroutine `score` which uses (17.0.3) to convert an N -vector of ending values $\mathbf{y}(x_2)$ into an n_2 -vector of discrepancies \mathbf{F} .

Now, as far as Newton-Raphson is concerned, we are nearly in business. We want to find a vector value of \mathbf{V} that zeros the vector value of \mathbf{F} . We do this by invoking the globally convergent Newton's method implemented in the routine `newt` of §9.7. Recall that the heart of Newton's method involves solving the set of n_2 linear equations

$$\mathbf{J} \cdot \delta\mathbf{V} = -\mathbf{F} \quad (17.1.3)$$

and then adding the correction back,

$$\mathbf{V}^{\text{new}} = \mathbf{V}^{\text{old}} + \delta\mathbf{V} \quad (17.1.4)$$

In (17.1.3), the Jacobian matrix \mathbf{J} has components given by

$$J_{ij} = \frac{\partial F_i}{\partial V_j} \quad (17.1.5)$$

It is not feasible to compute these partial derivatives analytically. Rather, each requires a *separate* integration of the N ODEs, followed by the evaluation of

$$\frac{\partial F_i}{\partial V_j} \approx \frac{F_i(V_1, \dots, V_j + \Delta V_j, \dots) - F_i(V_1, \dots, V_j, \dots)}{\Delta V_j} \quad (17.1.6)$$

This is done automatically for you in the routine `fdjac` that comes with `newt`. The only input to `newt` that you have to provide is the routine `funcv` that calculates \mathbf{F} by integrating the ODEs. Here is the appropriate routine:

```
C SUBROUTINE shoot(n2,v,f) is named "funcv" for use with "newt"
SUBROUTINE funcv(n2,v,f)
INTEGER n2,nvar,kmax,kount,KMAXX,NMAX
REAL f(n2),v(n2),x1,x2,dxsav,xp,yp,EPS
PARAMETER (NMAX=50,KMAXX=200,EPS=1.e-6) At most NMAX coupled ODEs.
COMMON /caller/ x1,x2,nvar
COMMON /path/ kmax,kount,dxsav,xp(KMAXX),yp(NMAX,KMAXX)
C USES derivs,load,odeint,rkqs,score
Routine for use with newt to solve a two point boundary value problem for nvar coupled
ODEs by shooting from x1 to x2. Initial values for the nvar ODEs at x1 are generated
from the n2 input coefficients v(1:n2), using the user-supplied routine load. The routine
integrates the ODEs to x2 using the Runge-Kutta method with tolerance EPS, initial stepsize
h1, and minimum stepsize hmin. At x2 it calls the user-supplied subroutine score to
evaluate the n2 functions f(1:n2) that ought to be zero to satisfy the boundary conditions
at x2. The functions f are returned on output. newt uses a globally convergent Newton's
method to adjust the values of v until the functions f are zero. The user-supplied subroutine
derivs(x,y,dydx) supplies derivative information to the ODE integrator (see Chapter
16). The common block caller receives its values from the main program so that funcv
can have the syntax required by newt. The common block path is included for compatibility
with odeint.
INTEGER nbad,nok
REAL h1,hmin,y(NMAX)
EXTERNAL derivs,rkqs
kmax=0
h1=(x2-x1)/100.
hmin=0.
call load(x1,v,y)
call odeint(y,nvar,x1,x2,EPS,h1,hmin,nok,nbad,derivs,rkqs)
call score(x2,y,f)
return
END
```

For some problems the initial stepsize ΔV might depend sensitively upon the initial conditions. It is straightforward to alter `load` to include a suggested stepsize `h1` as another returned argument and feed it to `fdjac` via a common block.

A complete cycle of the shooting method thus requires $n_2 + 1$ integrations of the N coupled ODEs: one integration to evaluate the current degree of mismatch, and n_2 for the partial derivatives. Each new cycle requires a new round of $n_2 + 1$ integrations. This illustrates the enormous extra effort involved in solving two point boundary value problems compared with initial value problems.

If the differential equations are *linear*, then only one complete cycle is required, since (17.1.3)–(17.1.4) should take us right to the solution. A second round can be useful, however, in mopping up some (never all) of the roundoff error.

As given here, `shoot` uses the quality controlled Runge-Kutta method of §16.2 to integrate the ODEs, but any of the other methods of Chapter 16 could just as well be used.

You, the user, must supply `shoot` with: (i) a subroutine `load(x1, v, y)` which returns the n-vector `y(1:n)` (satisfying the starting boundary conditions, of course), given the freely specifiable variables of `v(1:n2)` at the initial point `x1`; (ii) a subroutine `score(x2, y, f)` which returns the discrepancy vector `f(1:n2)` of the ending boundary conditions, given the vector `y(1:n)` at the endpoint `x2`; (iii) a starting vector `v(1:n2)`; (iv) a subroutine `derivs` for the ODE integration; and other obvious parameters as described in the header comment above.

In §17.4 we give a sample program illustrating how to use `shoot`.

17.2 Shooting to a Fitting Point

The shooting method described in §17.1 tacitly assumed that the “shots” would be able to traverse the entire domain of integration, even at the early stages of convergence to a correct solution. In some problems it can happen that, for very wrong starting conditions, an initial solution can’t even get from x_1 to x_2 without encountering some incalculable, or catastrophic, result. For example, the argument of a square root might go negative, causing the numerical code to crash. Simple shooting would be stymied.

A different, but related, case is where the endpoints are both singular points of the set of ODEs. One frequently needs to use special methods to integrate near the singular points, analytic asymptotic expansions, for example. In such cases it is feasible to integrate in the direction *away* from a singular point, using the special method to get through the first little bit and then reading off “initial” values for further numerical integration. However it is usually not feasible to integrate *into* a singular point, if only because one has not usually expended the same analytic

For some problems the initial stepsize ΔV might depend sensitively upon the initial conditions. It is straightforward to alter `load` to include a suggested stepsize `h1` as another returned argument and feed it to `fdjac` via a common block.

A complete cycle of the shooting method thus requires $n_2 + 1$ integrations of the N coupled ODEs: one integration to evaluate the current degree of mismatch, and n_2 for the partial derivatives. Each new cycle requires a new round of $n_2 + 1$ integrations. This illustrates the enormous extra effort involved in solving two point boundary value problems compared with initial value problems.

If the differential equations are *linear*, then only one complete cycle is required, since (17.1.3)–(17.1.4) should take us right to the solution. A second round can be useful, however, in mopping up some (never all) of the roundoff error.

As given here, `shoot` uses the quality controlled Runge-Kutta method of §16.2 to integrate the ODEs, but any of the other methods of Chapter 16 could just as well be used.

You, the user, must supply `shoot` with: (i) a subroutine `load(x1, v, y)` which returns the n-vector `y(1:n)` (satisfying the starting boundary conditions, of course), given the freely specifiable variables of `v(1:n2)` at the initial point `x1`; (ii) a subroutine `score(x2, y, f)` which returns the discrepancy vector `f(1:n2)` of the ending boundary conditions, given the vector `y(1:n)` at the endpoint `x2`; (iii) a starting vector `v(1:n2)`; (iv) a subroutine `derivs` for the ODE integration; and other obvious parameters as described in the header comment above.

In §17.4 we give a sample program illustrating how to use `shoot`.

17.2 Shooting to a Fitting Point

The shooting method described in §17.1 tacitly assumed that the “shots” would be able to traverse the entire domain of integration, even at the early stages of convergence to a correct solution. In some problems it can happen that, for very wrong starting conditions, an initial solution can’t even get from x_1 to x_2 without encountering some incalculable, or catastrophic, result. For example, the argument of a square root might go negative, causing the numerical code to crash. Simple shooting would be stymied.

A different, but related, case is where the endpoints are both singular points of the set of ODEs. One frequently needs to use special methods to integrate near the singular points, analytic asymptotic expansions, for example. In such cases it is feasible to integrate in the direction *away* from a singular point, using the special method to get through the first little bit and then reading off “initial” values for further numerical integration. However it is usually not feasible to integrate *into* a singular point, if only because one has not usually expended the same analytic

effort to obtain expansions of “wrong” solutions near the singular point (those not satisfying the desired boundary condition).

The solution to the above mentioned difficulties is *shooting to a fitting point*. Instead of integrating from x_1 to x_2 , we integrate first from x_1 to some point x_f that is *between* x_1 and x_2 ; and second from x_2 (in the opposite direction) to x_f .

If (as before) the number of boundary conditions imposed at x_1 is n_1 , and the number imposed at x_2 is n_2 , then there are n_2 freely specifiable starting values at x_1 and n_1 freely specifiable starting values at x_2 . (If you are confused by this, go back to §17.1.) We can therefore define an n_2 -vector $\mathbf{V}_{(1)}$ of starting parameters at x_1 , and a prescription `load1(x1,v1,y)` for mapping $\mathbf{V}_{(1)}$ into a \mathbf{y} that satisfies the boundary conditions at x_1 ,

$$y_i(x_1) = y_i(x_1; V_{(1)1}, \dots, V_{(1)n_2}) \quad i = 1, \dots, N \quad (17.2.1)$$

Likewise we can define an n_1 -vector $\mathbf{V}_{(2)}$ of starting parameters at x_2 , and a prescription `load2(x2,v2,y)` for mapping $\mathbf{V}_{(2)}$ into a \mathbf{y} that satisfies the boundary conditions at x_2 ,

$$y_i(x_2) = y_i(x_2; V_{(2)1}, \dots, V_{(2)n_1}) \quad i = 1, \dots, N \quad (17.2.2)$$

We thus have a total of N freely adjustable parameters in the combination of $\mathbf{V}_{(1)}$ and $\mathbf{V}_{(2)}$. The N conditions that must be satisfied are that there be agreement in N components of \mathbf{y} at x_f between the values obtained integrating from one side and from the other,

$$y_i(x_f; \mathbf{V}_{(1)}) = y_i(x_f; \mathbf{V}_{(2)}) \quad i = 1, \dots, N \quad (17.2.3)$$

In some problems, the N matching conditions can be better described (physically, mathematically, or numerically) by using N different functions F_i , $i = 1 \dots N$, each possibly depending on the N components y_i . In those cases, (17.2.3) is replaced by

$$F_i[\mathbf{y}(x_f; \mathbf{V}_{(1)})] = F_i[\mathbf{y}(x_f; \mathbf{V}_{(2)})] \quad i = 1, \dots, N \quad (17.2.4)$$

In the program below, the user-supplied subroutine `score(xf,y,f)` is supposed to map an input N -vector \mathbf{y} into an output N -vector \mathbf{F} . In most cases, you can dummy this subroutine as the identity mapping.

Shooting to a fitting point uses globally convergent Newton-Raphson exactly as in §17.1. Comparing closely with the routine `shoot` of the previous section, you should have no difficulty in understanding the following routine `shootf`. The main differences in use are that you have to supply both `load1` and `load2`. Also, in the calling program you must supply initial guesses for `v1(1:n2)` and `v2(1:n1)`. Once again a sample program illustrating shooting to a fitting point is given in §17.4.

```
C SUBROUTINE shootf(n,v,f) is named "funcv" for use with "newt"
SUBROUTINE funcv(n,v,f)
INTEGER n,nvar,nn2,kmax,kount,KMAXX,NMAX
REAL f(n),v(n),x1,x2,xf,dxsav,xp,yp,EPS
PARAMETER (NMAX=50,KMAXX=200,EPS=1.e-6) At most NMAX equations.
COMMON /caller/ x1,x2,xf,nvar,nn2
COMMON /path/ kmax,kount,dxsav,xp(KMAXX),yp(NMAX,KMAXX)
C USES derivs,load1,load2,odeint,rkqs,score
      Routine for use with newt to solve a two point boundary value problem for nvar coupled ODEs by shooting from x1 and x2 to a fitting point xf. Initial values for the nvar
```

ODEs at x_1 (x_2) are generated from the n_2 (n_1) coefficients v_1 (v_2), using the user-supplied routine `load1` (`load2`). The coefficients v_1 and v_2 should be stored in a single array $v(1:n1+n2)$ in the main program by an EQUIVALENCE statement of the form $(v1(1),v(1)),(v2(1),v(n2+1))$. The input parameter $n = n_1 + n_2 = nvar$. The routine integrates the ODEs to xf using the Runge-Kutta method with tolerance EPS , initial stepsize h_1 , and minimum stepsize h_{\min} . At xf it calls the user-supplied subroutine `score` to evaluate the $nvar$ functions f_1 and f_2 that ought to match at xf . The differences f are returned on output. `newt` uses a globally convergent Newton's method to adjust the values of v until the functions f are zero. The user-supplied subroutine `derivs(x,y,dydx)` supplies derivative information to the ODE integrator (see Chapter 16). The common block `caller` receives its values from the main program so that `funcv` can have the syntax required by `newt`. Set $nn2 = n_2$ in the main program. The common block `path` is for compatibility with `odeint`.

```

INTEGER i,nbad,nok
REAL h1,hmin,f1(NMAX),f2(NMAX),y(NMAX)
EXTERNAL derivs,rkqs
kmax=0
h1=(x2-x1)/100.
hmin=0.
call load1(x1,v,y)                               Path from x1 to xf with best trial values v1.
call odeint(y,nvar,x1,xf,eps,h1,hmin,nok,nbad,derivs,rkqs)
call score(xf,y,f1)
call load2(x2,v(nn2+1),y)                         Path from x2 to xf with best trial values v2.
call odeint(y,nvar,x2,xf,eps,h1,hmin,nok,nbad,derivs,rkqs)
call score(xf,y,f2)
do :: i=1,n
    f(i)=f1(i)-f2(i)
enddo :: i
return
END

```

There are boundary value problems where even shooting to a fitting point fails — the integration interval has to be partitioned by several fitting points with the solution being matched at each such point. For more details see [1].

17.3 Relaxation Methods

In *relaxation methods* we replace ODEs by approximate *finite-difference equations* (FDEs) on a grid or mesh of points that spans the domain of interest. As a typical example, we could replace a general first-order differential equation

$$\frac{dy}{dx} = g(x, y) \quad (17.3.1)$$

with an algebraic equation relating function values at two points $k, k - 1$:

$$y_k - y_{k-1} - (x_k - x_{k-1}) g \left[\frac{1}{2}(x_k + x_{k-1}), \frac{1}{2}(y_k + y_{k-1}) \right] = 0 \quad (17.3.2)$$

ODEs at x_1 (x_2) are generated from the n_2 (n_1) coefficients v_1 (v_2), using the user-supplied routine `load1` (`load2`). The coefficients v_1 and v_2 should be stored in a single array $v(1:n1+n2)$ in the main program by an EQUIVALENCE statement of the form $(v1(1),v(1)),(v2(1),v(n2+1))$. The input parameter $n = n_1 + n_2 = nvar$. The routine integrates the ODEs to xf using the Runge-Kutta method with tolerance EPS , initial stepsize h_1 , and minimum stepsize h_{\min} . At xf it calls the user-supplied subroutine `score` to evaluate the $nvar$ functions f_1 and f_2 that ought to match at xf . The differences f are returned on output. `newt` uses a globally convergent Newton's method to adjust the values of v until the functions f are zero. The user-supplied subroutine `derivs(x,y,dydx)` supplies derivative information to the ODE integrator (see Chapter 16). The common block `caller` receives its values from the main program so that `funcv` can have the syntax required by `newt`. Set $nn2 = n_2$ in the main program. The common block `path` is for compatibility with `odeint`.

```

INTEGER i,nbad,nok
REAL h1,hmin,f1(NMAX),f2(NMAX),y(NMAX)
EXTERNAL derivs,rkqs
kmax=0
h1=(x2-x1)/100.
hmin=0.
call load1(x1,v,y)                               Path from x1 to xf with best trial values v1.
call odeint(y,nvar,x1,xf,eps,h1,hmin,nok,nbad,derivs,rkqs)
call score(xf,y,f1)
call load2(x2,v(nn2+1),y)                         Path from x2 to xf with best trial values v2.
call odeint(y,nvar,x2,xf,eps,h1,hmin,nok,nbad,derivs,rkqs)
call score(xf,y,f2)
do :: i=1,n
    f(i)=f1(i)-f2(i)
enddo :: i
return
END

```

There are boundary value problems where even shooting to a fitting point fails — the integration interval has to be partitioned by several fitting points with the solution being matched at each such point. For more details see [1].

17.3 Relaxation Methods

In *relaxation methods* we replace ODEs by approximate *finite-difference equations* (FDEs) on a grid or mesh of points that spans the domain of interest. As a typical example, we could replace a general first-order differential equation

$$\frac{dy}{dx} = g(x, y) \quad (17.3.1)$$

with an algebraic equation relating function values at two points $k, k - 1$:

$$y_k - y_{k-1} - (x_k - x_{k-1}) g \left[\frac{1}{2}(x_k + x_{k-1}), \frac{1}{2}(y_k + y_{k-1}) \right] = 0 \quad (17.3.2)$$

The form of the FDE in (17.3.2) illustrates the idea, but not uniquely: There are many ways to turn the ODE into an FDE. When the problem involves N coupled first-order ODEs represented by FDEs on a mesh of M points, a solution consists of values for N dependent functions given at each of the M mesh points, or $N \times M$ variables in all. The relaxation method determines the solution by starting with a guess and improving it, iteratively. As the iterations improve the solution, the result is said to *relax* to the true solution.

While several iteration schemes are possible, for most problems our old standby, multi-dimensional Newton's method, works well. The method produces a matrix equation that must be solved, but the matrix takes a special, "block diagonal" form, that allows it to be inverted far more economically both in time and storage than would be possible for a general matrix of size $(MN) \times (MN)$. Since MN can easily be several thousand, this is crucial for the feasibility of the method.

Our implementation couples at most pairs of points, as in equation (17.3.2). More points can be coupled, but then the method becomes more complex. We will provide enough background so that you can write a more general scheme if you have the patience to do so.

Let us develop a general set of algebraic equations that represent the ODEs by FDEs. The ODE problem is exactly identical to that expressed in equations (17.0.1)–(17.0.3) where we had N coupled first-order equations that satisfy n_1 boundary conditions at x_1 and $n_2 = N - n_1$ boundary conditions at x_2 . We first define a mesh or grid by a set of $k = 1, 2, \dots, M$ points at which we supply values for the independent variable x_k . In particular, x_1 is the initial boundary, and x_M is the final boundary. We use the notation \mathbf{y}_k to refer to the entire set of dependent variables y_1, y_2, \dots, y_N at point x_k . At an arbitrary point k in the middle of the mesh, we approximate the set of N first-order ODEs by algebraic relations of the form

$$0 = \mathbf{E}_k \equiv \mathbf{y}_k - \mathbf{y}_{k-1} - (x_k - x_{k-1})\mathbf{g}_k(x_k, x_{k-1}, \mathbf{y}_k, \mathbf{y}_{k-1}), \quad k = 2, 3, \dots, M \quad (17.3.3)$$

The notation signifies that \mathbf{g}_k can be evaluated using information from both points $k, k - 1$. The FDEs labeled by \mathbf{E}_k provide N equations coupling $2N$ variables at points $k, k - 1$. There are $M - 1$ points, $k = 2, 3, \dots, M$, at which difference equations of the form (17.3.3) apply. Thus the FDEs provide a total of $(M - 1)N$ equations for the MN unknowns. The remaining N equations come from the boundary conditions.

At the first boundary we have

$$0 = \mathbf{E}_1 \equiv \mathbf{B}(x_1, \mathbf{y}_1) \quad (17.3.4)$$

while at the second boundary

$$0 = \mathbf{E}_{M+1} \equiv \mathbf{C}(x_M, \mathbf{y}_M) \quad (17.3.5)$$

The vectors \mathbf{E}_1 and \mathbf{B} have only n_1 nonzero components, corresponding to the n_1 boundary conditions at x_1 . It will turn out to be useful to take these nonzero components to be the *last* n_1 components. In other words, $E_{j,1} \neq 0$ only for $j = n_2 + 1, n_2 + 2, \dots, N$. At the other boundary, only the first n_2 components of \mathbf{E}_{M+1} and \mathbf{C} are nonzero: $E_{j,M+1} \neq 0$ only for $j = 1, 2, \dots, n_2$.

The "solution" of the FDE problem in (17.3.3)–(17.3.5) consists of a set of variables $y_{j,k}$, the values of the N variables y_j at the M points x_k . The algorithm we describe below requires an initial guess for the $y_{j,k}$. We then determine increments $\Delta y_{j,k}$ such that $y_{j,k} + \Delta y_{j,k}$ is an improved approximation to the solution.

Equations for the increments are developed by expanding the FDEs in first-order Taylor series with respect to small changes $\Delta \mathbf{y}_k$. At an interior point, $k = 2, 3, \dots, M$ this gives:

$$\begin{aligned} \mathbf{E}_k(\mathbf{y}_k + \Delta \mathbf{y}_k, \mathbf{y}_{k-1} + \Delta \mathbf{y}_{k-1}) &\approx \mathbf{E}_k(\mathbf{y}_k, \mathbf{y}_{k-1}) \\ &+ \sum_{n=1}^N \frac{\partial \mathbf{E}_k}{\partial y_{n,k-1}} \Delta y_{n,k-1} + \sum_{n=1}^N \frac{\partial \mathbf{E}_k}{\partial y_{n,k}} \Delta y_{n,k} \end{aligned} \quad (17.3.6)$$

For a solution we want the updated value $\mathbf{E}(\mathbf{y} + \Delta \mathbf{y})$ to be zero, so the general set of equations at an interior point can be written in matrix form as

$$\sum_{n=1}^N S_{j,n} \Delta y_{n,k-1} + \sum_{n=N+1}^{2N} S_{j,n} \Delta y_{n-N,k} = -E_{j,k}, \quad j = 1, 2, \dots, N \quad (17.3.7)$$

where

$$S_{j,n} = \frac{\partial E_{j,k}}{\partial y_{n,k-1}}, \quad S_{j,n+N} = \frac{\partial E_{j,k}}{\partial y_{n,k}}, \quad n = 1, 2, \dots, N \quad (17.3.8)$$

The quantity $S_{j,n}$ is an $N \times 2N$ matrix at each point k . Each interior point thus supplies a block of N equations coupling $2N$ corrections to the solution variables at the points $k, k - 1$.

Similarly, the algebraic relations at the boundaries can be expanded in a first-order Taylor series for increments that improve the solution. Since \mathbf{E}_1 depends only on \mathbf{y}_1 , we find at the first boundary:

$$\sum_{n=1}^N S_{j,n} \Delta y_{n,1} = -E_{j,1}, \quad j = n_2 + 1, n_2 + 2, \dots, N \quad (17.3.9)$$

where

$$S_{j,n} = \frac{\partial E_{j,1}}{\partial y_{n,1}}, \quad n = 1, 2, \dots, N \quad (17.3.10)$$

At the second boundary,

$$\sum_{n=1}^N S_{j,n} \Delta y_{n,M} = -E_{j,M+1}, \quad j = 1, 2, \dots, n_2 \quad (17.3.11)$$

where

$$S_{j,n} = \frac{\partial E_{j,M+1}}{\partial y_{n,M}}, \quad n = 1, 2, \dots, N \quad (17.3.12)$$

We thus have in equations (17.3.7)–(17.3.12) a set of linear equations to be solved for the corrections $\Delta\mathbf{y}$, iterating until the corrections are sufficiently small. The equations have a special structure, because each $S_{j,n}$ couples only points $k, k - 1$. Figure 17.3.1 illustrates the typical structure of the complete matrix equation for the case of 5 variables and 4 mesh points, with 3 boundary conditions at the first boundary and 2 at the second. The 3×5 block of nonzero entries in the top left-hand corner of the matrix comes from the boundary condition $S_{j,n}$ at point $k = 1$. The next three 5×10 blocks are the $S_{j,n}$ at the interior points, coupling variables at mesh points (2,1), (3,2), and (4,3). Finally we have the block corresponding to the second boundary condition.

We can solve equations (17.3.7)–(17.3.12) for the increments $\Delta\mathbf{y}$ using a form of Gaussian elimination that exploits the special structure of the matrix to minimize the total number of operations, and that minimizes storage of matrix coefficients by packing the elements in a special blocked structure. (You might wish to review Chapter 2, especially §2.2, if you are unfamiliar with the steps involved in Gaussian elimination.) Recall that Gaussian elimination consists of manipulating the equations by elementary operations such as dividing rows of coefficients by a common factor to produce unity in diagonal elements, and adding appropriate multiples of other rows to produce zeros below the diagonal. Here we take advantage of the block structure by performing a bit more reduction than in pure Gaussian elimination, so that the storage of coefficients is minimized. Figure 17.3.2 shows the form that we wish to achieve by elimination, just prior to the backsubstitution step. Only a small subset of the reduced $MN \times MN$ matrix elements needs to be stored as the elimination progresses. Once the matrix elements reach the stage in Figure 17.3.2, the solution follows quickly by a backsubstitution procedure.

Furthermore, the entire procedure, except the backsubstitution step, operates only on one block of the matrix at a time. The procedure contains four types of operations: (1) partial reduction to zero of certain elements of a block using results from a previous step, (2) elimination of the square structure of the remaining block elements such that the square section contains unity along the diagonal, and zero in off-diagonal elements, (3) storage of the remaining nonzero coefficients for use in later steps, and (4) backsubstitution. We illustrate the steps schematically by figures.

Consider the block of equations describing corrections available from the initial boundary conditions. We have n_1 equations for N unknown corrections. We wish to transform the first

Figure 17.3.1. Matrix structure of a set of linear finite-difference equations (FDEs) with boundary conditions imposed at both endpoints. Here \mathbf{X} represents a coefficient of the FDEs, \mathbf{V} represents a component of the unknown solution vector, and \mathbf{B} is a component of the known right-hand side. Empty spaces represent zeros. The matrix equation is to be solved by a special form of Gaussian elimination. (See text for details.)

Figure 17.3.2. Target structure of the Gaussian elimination. Once the matrix of Figure 17.3.1 has been reduced to this form, the solution follows quickly by backsubstitution.

block so that its left-hand $n_1 \times n_1$ square section becomes unity along the diagonal, and zero in off-diagonal elements. Figure 17.3.3 shows the original and final form of the first block of the matrix. In the figure we designate matrix elements that are subject to diagonalization by “D”, and elements that will be altered by “A”; in the final block, elements that are stored are labeled by “S”. We get from start to finish by selecting in turn n_1 “pivot” elements from among the first n_1 columns, normalizing the pivot row so that the value of the “pivot” element is unity, and adding appropriate multiples of this row to the remaining rows so that they contain zeros in the pivot column. In its final form, the reduced block expresses values for the corrections to the first n_1 variables at mesh point 1 in terms of values for the remaining n_2 unknown corrections at point 1, i.e., we now know what the first n_1 elements are in terms of the remaining n_2 elements. We store only the final set of n_2 nonzero columns from the initial block, plus the column for the altered right-hand side of the matrix equation.

We must emphasize here an important detail of the method. To exploit the reduced storage allowed by operating on blocks, it is essential that the ordering of columns in the s matrix of derivatives be such that pivot elements can be found among the first n_1 rows of the matrix. This means that the n_1 boundary conditions at the first point must contain some dependence on the first $j=1, 2, \dots, n_1$ dependent variables, $y(j, 1)$. If not, then the original square $n_1 \times n_1$ subsection of the first block will appear to be singular, and the method will fail. Alternatively, we would have to allow the search for pivot elements to involve all N columns of the block, and this would require column swapping and far more bookkeeping. The code provides a simple method of reordering the variables, i.e., the columns of the s matrix, so that this can be done easily. End of important detail.

Next consider the block of N equations representing the FDEs that describe the relation between the $2N$ corrections at points 2 and 1. The elements of that block, together with results from the previous step, are illustrated in Figure 17.3.4. Note that by adding suitable multiples of rows from the first block we can reduce to zero the first n_1 columns of the block (labeled by “Z”), and, to do so, we will need to alter only the columns from $n_1 + 1$ to N and the vector element on the right-hand side. Of the remaining columns we can diagonalize a square subsection of $N \times N$ elements, labeled by “D” in the figure. In the process we alter the final set of $n_2 + 1$ columns, denoted “A” in the figure. The second half of the figure shows the block when we finish operating on it, with the stored $(n_2 + 1) \times N$ elements labeled by “S.”

If we operate on the next set of equations corresponding to the FDEs coupling corrections at points 3 and 2, we see that the state of available results and new equations exactly reproduces the situation described in the previous paragraph. Thus, we can carry out those steps again for each block in turn through block M . Finally on block $M + 1$ we encounter the remaining boundary conditions.

Figure 17.3.5 shows the final block of n_2 FDEs relating the N corrections for variables at mesh point M , together with the result of reducing the previous block. Again, we can first use the prior results to zero the first n_1 columns of the block. Now, when we diagonalize the remaining square section, we strike gold: We get values for the final n_2 corrections at mesh point M .

With the final block reduced, the matrix has the desired form shown previously in Figure 17.3.2, and the matrix is ripe for backsubstitution. Starting with the bottom row and working up towards the top, at each stage we can simply determine one unknown correction in terms of known quantities.

The subroutine `solvde` organizes the steps described above. The principal procedures used in the algorithm are performed by subroutines called internally by `solvde`. The subroutine `red` eliminates leading columns of the s matrix using results from prior blocks. `pinv` diagonalizes the square subsection of s and stores unreduced coefficients. `bksub` carries out the backsubstitution step. The user of `solvde` must understand the calling arguments, as described below, and supply a subroutine `difeq`, called by `solvde`, that evaluates the s matrix for each block.

Most of the arguments in the call to `solvde` have already been described, but some require discussion. Array $y(j, k)$ contains the initial guess for the solution, with j labeling the dependent variables at mesh points k . The problem involves ne FDEs spanning points $k=1, \dots, m$. nb boundary conditions apply at the first point $k=1$. The array `indexv(j)` establishes the correspondence between columns of the s matrix, equations (17.3.8), (17.3.10),

and (17.3.12), and the dependent variables. As described above it is essential that the `nb` boundary conditions at $k=1$ involve the dependent variables referenced by the first `nb` columns of the `s` matrix. Thus, columns j of the `s` matrix can be ordered by the user in `difeq` to refer to derivatives with respect to the dependent variable `indexv(j)`.

The subroutine only attempts `itmax` correction cycles before returning, even if the solution has not converged. The parameters `conv`, `slowc`, `scalv` relate to convergence. Each inversion of the matrix produces corrections for `ne` variables at `m` mesh points. We want these to become vanishingly small as the iterations proceed, but we must define a measure for the size of corrections. This error “norm” is very problem specific, so the user might wish to rewrite this section of the code as appropriate. In the program below we compute a value for the average correction `err` by summing the absolute value of all corrections, weighted by a scale factor appropriate to each type of variable:

$$\text{err} = \frac{1}{m \times ne} \sum_{k=1}^m \sum_{j=1}^{ne} \frac{|\Delta Y(j,k)|}{\text{scalv}(j)} \quad (17.3.13)$$

When $\text{err} \leq \text{conv}$, the method has converged. Note that the user gets to supply an array `scalv` which measures the typical size of each variable.

Obviously, if `err` is large, we are far from a solution, and perhaps it is a bad idea to believe that the corrections generated from a first-order Taylor series are accurate. The number `slowc` modulates application of corrections. After each iteration we apply only a fraction of the corrections found by matrix inversion:

$$Y(j,k) \rightarrow Y(j,k) + \frac{\text{slowc}}{\max(\text{slowc}, \text{err})} \Delta Y(j,k) \quad (17.3.14)$$

Thus, when $\text{err} > \text{slowc}$ only a fraction of the corrections are used, but when $\text{err} \leq \text{slowc}$ the entire correction gets applied.

The call statement also supplies `solvde` with the array `y(1:nyj, 1:nyk)` containing the initial trial solution, and workspace arrays `c(1:nci, 1:ncj, 1:nck)`, `s(1:nsi, 1:nsj)`. The array `c` is the blockbuster: It stores the unreduced elements of the matrix built up for the backsubstitution step. If there are `m` mesh points, then there will be `nck=m+1` blocks, each requiring `nci=ne` rows and `ncj=ne-nb+1` columns. Although large, this is small compared with $(ne \times m)^2$ elements required for the whole matrix if we did not break it into blocks.

We now describe the workings of the user-supplied subroutine `difeq`. The parameters of the subroutine are given by

```
SUBROUTINE difeq(k,k1,k2,jsf,is1,isf,indexv,ne,s,nsi,nsj,y,nyj,nyk)
```

The only information returned from `difeq` to `solvde` is the matrix of derivatives `s(i,j)`; all other arguments are input to `difeq` and should not be altered. `k` indicates the current mesh point, or block number. `k1, k2` label the first and last point in the mesh. If $k=k_1$ or $k>k_2$, the block involves the boundary conditions at the first or final points; otherwise the block acts on FDEs coupling variables at points $k-1, k$.

The convention on storing information into the array `s(i,j)` follows that used in equations (17.3.8), (17.3.10), and (17.3.12): Rows i label equations, columns j refer to derivatives with respect to dependent variables in the solution. Recall that each equation will depend on the `ne` dependent variables at either one or two points. Thus, j runs from 1 to either `ne` or $2*ne$. The column ordering for dependent variables at each point must agree with the list supplied in `indexv(j)`. Thus, for a block not at a boundary, the first column multiplies $\Delta Y(l=\text{indexv}(1), k-1)$, and the column `ne+1` multiplies $\Delta Y(l=\text{indexv}(1), k)$. `is1, isf` give the numbers of the starting and final *rows* that need to be filled in the `s` matrix for this block. `jsf` labels the column in which the difference equations $E_{j,k}$ of equations (17.3.3)–(17.3.5) are stored. Thus, $-s(i, jsf)$ is the vector on the right-hand side of the matrix. The reason for the minus sign is that `difeq` supplies the actual difference equation, $E_{j,k}$, not its negative. Note that `solvde` supplies a value for `jsf` such that the difference equation is put in the column *just after* all derivatives in the `s` matrix. Thus, `difeq` expects to find values entered into `s(i,j)` for rows $is1 \leq i \leq isf$ and $1 \leq j \leq jsf$.

Finally, $s(1:nsi, 1:nsj)$ and $y(1:nyj, 1:nyk)$ supply `difeq` with storage for s and the solution variables y for this iteration. An example of how to use this routine is given in the next section.

Many ideas in the following code are due to Eggleton [1].

```

SUBROUTINE solve(itmax,conv,slowc,scalv,indexv,ne,nb,m,
*      y,nyj,nyk,c,nci,ncj,nck,s,nsi,nsj)
*      INTEGER itmax,m,nb,nci,ncj,nck,ne,nsi,nsj,
*      nyj,nyk,indexv(nyj),NMAX
*      REAL conv,slowc,c(nci,ncj,nck),s(nsi,nsj),
*      scalv(nyj),y(nyj,nyk)
*      PARAMETER (NMAX=10)          Largest expected value of ne.
C USES bksub,difeq,pinvs,red
      Driver routine for solution of two point boundary value problems by relaxation. itmax is the
      maximum number of iterations. conv is the convergence criterion (see text). slowc con-
      trols the fraction of corrections actually used after each iteration. scalv(1:nyj) contains
      typical sizes for each dependent variable, used to weight errors. indexv(1:nyj) lists the
      column ordering of variables used to construct the matrix s of derivatives. (The nb boundary
      conditions at the first mesh point must contain some dependence on the first nb variables
      listed in indexv.) The problem involves ne equations for ne adjustable dependent variables
      at each point. At the first mesh point there are nb boundary conditions. There are a total
      of m mesh points. y(1:nyj, 1:nyk) is the two-dimensional array that contains the initial
      guess for all the dependent variables at each mesh point. On each iteration, it is updated by
      the calculated correction. The arrays c(1:nci, 1:ncj, 1:nck), s(1:nsi, 1:nsj) sup-
      ply dummy storage used by the relaxation code; the minimum dimensions must satisfy:
      nci=ne, ncj=ne-nb+1, nck=m+1, nsi=ne, nsj=2*ne+1.

“Algebraically Difficult” Sets of Differential Equations

Relaxation methods allow you to take advantage of an additional opportunity that, while not obvious, can speed up some calculations enormously. It is not necessary that the set of variables $y_{j,k}$ correspond exactly with the dependent variables of the original differential equations. They can be related to those variables through algebraic equations. Obviously, it is necessary only that the solution variables allow us to *evaluate* the functions $y, g, \mathbf{B}, \mathbf{C}$ that are used to construct the FDEs from the ODEs. In some problems g depends on functions of y that are known only implicitly, so that iterative solutions are necessary to evaluate functions in the ODEs. Often one can dispense with this “internal” nonlinear problem by defining a new set of variables from which both y, g and the boundary conditions can be obtained directly. A typical example occurs in physical problems where the equations require solution of a complex equation of state that can be expressed in more convenient terms using variables other than the original dependent variables in the ODE. While this approach is analogous to performing an *analytic* change of variables directly on the original ODEs, such an analytic transformation might be prohibitively complicated. The change of variables in the relaxation method is easy and requires no analytic manipulations.

17.4 A Worked Example: Spheroidal Harmonics

The best way to understand the algorithms of the previous sections is to see them employed to solve an actual problem. As a sample problem, we have selected the computation of spheroidal harmonics. (The more common name is spheroidal angle functions, but we prefer the explicit reminder of the kinship with spherical harmonics.) We will show how to find spheroidal harmonics, first by the method of relaxation (§17.3), and then by the methods of shooting (§17.1) and shooting to a fitting point (§17.2).

Spheroidal harmonics typically arise when certain partial differential equations are solved by separation of variables in spheroidal coordinates. They satisfy the following differential equation on the interval $-1 \leq x \leq 1$:

$$\frac{d}{dx} \left[(1 - x^2) \frac{dS}{dx} \right] + \left(\lambda - c^2 x^2 - \frac{m^2}{1 - x^2} \right) S = 0 \quad (17.4.1)$$

Here m is an integer, c is the “oblateness parameter,” and λ is the eigenvalue. Despite the notation, c^2 can be positive or negative. For $c^2 > 0$ the functions are called “prolate,” while if $c^2 < 0$ they are called “oblate.” The equation has singular points at $x = \pm 1$ and is to be solved subject to the boundary conditions that the solution be regular at $x = \pm 1$. Only for certain values of λ , the eigenvalues, will this be possible.

If we consider first the spherical case, where $c = 0$, we recognize the differential equation for Legendre functions $P_n^m(x)$. In this case the eigenvalues are $\lambda_{mn} = n(n+1)$, $n = m, m+1, \dots$. The integer n labels successive eigenvalues for fixed m : When $n = m$ we have the lowest eigenvalue, and the corresponding eigenfunction has no nodes in the interval $-1 < x < 1$; when $n = m+1$ we have the next eigenvalue, and the eigenfunction has one node inside $(-1, 1)$; and so on.

A similar situation holds for the general case $c^2 \neq 0$. We write the eigenvalues of (17.4.1) as $\lambda_{mn}(c)$ and the eigenfunctions as $S_{mn}(x; c)$. For fixed m , $n = m, m+1, \dots$ labels the successive eigenvalues.

The computation of $\lambda_{mn}(c)$ and $S_{mn}(x; c)$ traditionally has been quite difficult. Complicated recurrence relations, power series expansions, etc., can be found in references [1-3]. Cheap computing makes evaluation by direct solution of the differential equation quite feasible.

The first step is to investigate the behavior of the solution near the singular points $x = \pm 1$. Substituting a power series expansion of the form

$$S = (1 \pm x)^\alpha \sum_{k=0}^{\infty} a_k (1 \pm x)^k \quad (17.4.2)$$

in equation (17.4.1), we find that the regular solution has $\alpha = m/2$. (Without loss of generality we can take $m \geq 0$ since $m \rightarrow -m$ is a symmetry of the equation.) We get an equation that is numerically more tractable if we factor out this behavior. Accordingly we set

$$S = (1 - x^2)^{m/2} y \quad (17.4.3)$$

We then find from (17.4.1) that y satisfies the equation

$$(1 - x^2) \frac{d^2y}{dx^2} - 2(m+1)x \frac{dy}{dx} + (\mu - c^2 x^2)y = 0 \quad (17.4.4)$$

17.4 A Worked Example: Spheroidal Harmonics

The best way to understand the algorithms of the previous sections is to see them employed to solve an actual problem. As a sample problem, we have selected the computation of spheroidal harmonics. (The more common name is spheroidal angle functions, but we prefer the explicit reminder of the kinship with spherical harmonics.) We will show how to find spheroidal harmonics, first by the method of relaxation (§17.3), and then by the methods of shooting (§17.1) and shooting to a fitting point (§17.2).

Spheroidal harmonics typically arise when certain partial differential equations are solved by separation of variables in spheroidal coordinates. They satisfy the following differential equation on the interval $-1 \leq x \leq 1$:

$$\frac{d}{dx} \left[(1 - x^2) \frac{dS}{dx} \right] + \left(\lambda - c^2 x^2 - \frac{m^2}{1 - x^2} \right) S = 0 \quad (17.4.1)$$

Here m is an integer, c is the “oblateness parameter,” and λ is the eigenvalue. Despite the notation, c^2 can be positive or negative. For $c^2 > 0$ the functions are called “prolate,” while if $c^2 < 0$ they are called “oblate.” The equation has singular points at $x = \pm 1$ and is to be solved subject to the boundary conditions that the solution be regular at $x = \pm 1$. Only for certain values of λ , the eigenvalues, will this be possible.

If we consider first the spherical case, where $c = 0$, we recognize the differential equation for Legendre functions $P_n^m(x)$. In this case the eigenvalues are $\lambda_{mn} = n(n+1)$, $n = m, m+1, \dots$. The integer n labels successive eigenvalues for fixed m : When $n = m$ we have the lowest eigenvalue, and the corresponding eigenfunction has no nodes in the interval $-1 < x < 1$; when $n = m+1$ we have the next eigenvalue, and the eigenfunction has one node inside $(-1, 1)$; and so on.

A similar situation holds for the general case $c^2 \neq 0$. We write the eigenvalues of (17.4.1) as $\lambda_{mn}(c)$ and the eigenfunctions as $S_{mn}(x; c)$. For fixed m , $n = m, m+1, \dots$ labels the successive eigenvalues.

The computation of $\lambda_{mn}(c)$ and $S_{mn}(x; c)$ traditionally has been quite difficult. Complicated recurrence relations, power series expansions, etc., can be found in references [1-3]. Cheap computing makes evaluation by direct solution of the differential equation quite feasible.

The first step is to investigate the behavior of the solution near the singular points $x = \pm 1$. Substituting a power series expansion of the form

$$S = (1 \pm x)^\alpha \sum_{k=0}^{\infty} a_k (1 \pm x)^k \quad (17.4.2)$$

in equation (17.4.1), we find that the regular solution has $\alpha = m/2$. (Without loss of generality we can take $m \geq 0$ since $m \rightarrow -m$ is a symmetry of the equation.) We get an equation that is numerically more tractable if we factor out this behavior. Accordingly we set

$$S = (1 - x^2)^{m/2} y \quad (17.4.3)$$

We then find from (17.4.1) that y satisfies the equation

$$(1 - x^2) \frac{d^2y}{dx^2} - 2(m+1)x \frac{dy}{dx} + (\mu - c^2 x^2)y = 0 \quad (17.4.4)$$

where

$$\mu \equiv \lambda - m(m+1) \quad (17.4.5)$$

Both equations (17.4.1) and (17.4.4) are invariant under the replacement $x \rightarrow -x$. Thus the functions S and y must also be invariant, except possibly for an overall scale factor. (Since the equations are linear, a constant multiple of a solution is also a solution.) Because the solutions will be normalized, the scale factor can only be ± 1 . If $n - m$ is odd, there are an odd number of zeros in the interval $(-1, 1)$. Thus we must choose the antisymmetric solution $y(-x) = -y(x)$ which has a zero at $x = 0$. Conversely, if $n - m$ is even we must have the symmetric solution. Thus

$$y_{mn}(-x) = (-1)^{n-m} y_{mn}(x) \quad (17.4.6)$$

and similarly for S_{mn} .

The boundary conditions on (17.4.4) require that y be regular at $x = \pm 1$. In other words, near the endpoints the solution takes the form

$$y = a_0 + a_1(1-x^2) + a_2(1-x^2)^2 + \dots \quad (17.4.7)$$

Substituting this expansion in equation (17.4.4) and letting $x \rightarrow 1$, we find that

$$a_1 = -\frac{\mu - c^2}{4(m+1)} a_0 \quad (17.4.8)$$

Equivalently,

$$y'(1) = \frac{\mu - c^2}{2(m+1)} y(1) \quad (17.4.9)$$

A similar equation holds at $x = -1$ with a minus sign on the right-hand side. The irregular solution has a different relation between function and derivative at the endpoints.

Instead of integrating the equation from -1 to 1 , we can exploit the symmetry (17.4.6) to integrate from 0 to 1 . The boundary condition at $x = 0$ is

$$\begin{aligned} y(0) &= 0, & n - m &\text{ odd} \\ y'(0) &= 0, & n - m &\text{ even} \end{aligned} \quad (17.4.10)$$

A third boundary condition comes from the fact that any constant multiple of a solution y is a solution. We can thus *normalize* the solution. We adopt the normalization that the function S_{mn} has the same limiting behavior as P_n^m at $x = 1$:

$$\lim_{x \rightarrow 1} (1-x^2)^{-m/2} S_{mn}(x; c) = \lim_{x \rightarrow 1} (1-x^2)^{-m/2} P_n^m(x) \quad (17.4.11)$$

Various normalization conventions in the literature are tabulated by Flammer [1].

Imposing three boundary conditions for the second-order equation (17.4.4) turns it into an eigenvalue problem for λ or equivalently for μ . We write it in the standard form by setting

$$y_1 = y \quad (17.4.12)$$

$$y_2 = y' \quad (17.4.13)$$

$$y_3 = \mu \quad (17.4.14)$$

Then

$$y'_1 = y_2 \quad (17.4.15)$$

$$y'_2 = \frac{1}{1-x^2} [2x(m+1)y_2 - (y_3 - c^2 x^2)y_1] \quad (17.4.16)$$

$$y'_3 = 0 \quad (17.4.17)$$

The boundary condition at $x = 0$ in this notation is

$$\begin{aligned} y_1 &= 0, & n-m &\text{ odd} \\ y_2 &= 0, & n-m &\text{ even} \end{aligned} \quad (17.4.18)$$

At $x = 1$ we have two conditions:

$$y_2 = \frac{y_3 - c^2}{2(m+1)} y_1 \quad (17.4.19)$$

$$y_1 = \lim_{x \rightarrow 1} (1-x^2)^{-m/2} P_n^m(x) = \frac{(-1)^m (n+m)!}{2^m m! (n-m)!} \equiv \gamma \quad (17.4.20)$$

We are now ready to illustrate the use of the methods of previous sections on this problem.

Relaxation

If we just want a few isolated values of λ or S , shooting is probably the quickest method. However, if we want values for a large sequence of values of c , relaxation is better. Relaxation rewards a good initial guess with rapid convergence, and the previous solution should be a good initial guess if c is changed only slightly.

For simplicity, we choose a uniform grid on the interval $0 \leq x \leq 1$. For a total of M mesh points, we have

$$h = \frac{1}{M-1} \quad (17.4.21)$$

$$x_k = (k-1)h, \quad k = 1, 2, \dots, M \quad (17.4.22)$$

At interior points $k = 2, 3, \dots, M$, equation (17.4.15) gives

$$E_{1,k} = y_{1,k} - y_{1,k-1} - \frac{h}{2}(y_{2,k} + y_{2,k-1}) \quad (17.4.23)$$

Equation (17.4.16) gives

$$E_{2,k} = y_{2,k} - y_{2,k-1} - \beta_k \times \left[\frac{(x_k + x_{k-1})(m+1)(y_{2,k} + y_{2,k-1})}{2} - \alpha_k \frac{(y_{1,k} + y_{1,k-1})}{2} \right] \quad (17.4.24)$$

where

$$\alpha_k = \frac{y_{3,k} + y_{3,k-1}}{2} - \frac{c^2(x_k + x_{k-1})^2}{4} \quad (17.4.25)$$

$$\beta_k = \frac{h}{1 - \frac{1}{4}(x_k + x_{k-1})^2} \quad (17.4.26)$$

Finally, equation (17.4.17) gives

$$E_{3,k} = y_{3,k} - y_{3,k-1} \quad (17.4.27)$$

Now recall that the matrix of partial derivatives $S_{i,j}$ of equation (17.3.8) is defined so that i labels the equation and j the variable. In our case, j runs from 1 to 3 for y_j at $k-1$ and from 4 to 6 for y_j at k . Thus equation (17.4.23) gives

$$\begin{aligned} S_{1,1} &= -1, & S_{1,2} &= -\frac{h}{2}, & S_{1,3} &= 0 \\ S_{1,4} &= 1, & S_{1,5} &= -\frac{h}{2}, & S_{1,6} &= 0 \end{aligned} \quad (17.4.28)$$

Similarly equation (17.4.24) yields

$$\begin{aligned} S_{2,1} &= \alpha_k \beta_k / 2, & S_{2,2} &= -1 - \beta_k (x_k + x_{k-1})(m+1)/2, \\ S_{2,3} &= \beta_k (y_{1,k} + y_{1,k-1})/4 & S_{2,4} &= S_{2,1}, \\ S_{2,5} &= 2 + S_{2,2}, & S_{2,6} &= S_{2,3} \end{aligned} \quad (17.4.29)$$

while from equation (17.4.27) we find

$$\begin{aligned} S_{3,1} &= 0, & S_{3,2} &= 0, & S_{3,3} &= -1 \\ S_{3,4} &= 0, & S_{3,5} &= 0, & S_{3,6} &= 1 \end{aligned} \quad (17.4.30)$$

At $x = 0$ we have the boundary condition

$$E_{3,1} = \begin{cases} y_{1,1}, & n - m \text{ odd} \\ y_{2,1}, & n - m \text{ even} \end{cases} \quad (17.4.31)$$

Recall the convention adopted in the `solvde` routine that for one boundary condition at $k = 1$ only $S_{3,j}$ can be nonzero. Also, j takes on the values 4 to 6 since the boundary condition involves only y_k , not y_{k-1} . Accordingly, the only nonzero values of $S_{3,j}$ at $x = 0$ are

$$\begin{aligned} S_{3,4} &= 1, & n - m &\text{ odd} \\ S_{3,5} &= 1, & n - m &\text{ even} \end{aligned} \quad (17.4.32)$$

At $x = 1$ we have

$$E_{1,M+1} = y_{2,M} - \frac{y_{3,M} - c^2}{2(m+1)} y_{1,M} \quad (17.4.33)$$

$$E_{2,M+1} = y_{1,M} - \gamma \quad (17.4.34)$$

Thus

$$S_{1,4} = -\frac{y_{3,M} - c^2}{2(m+1)}, \quad S_{1,5} = 1, \quad S_{1,6} = -\frac{y_{1,M}}{2(m+1)} \quad (17.4.35)$$

$$S_{2,4} = 1, \quad S_{2,5} = 0, \quad S_{2,6} = 0 \quad (17.4.36)$$

Here now is the sample program that implements the above algorithm. We need a main program, `sfroid`, that calls the routine `solvde`, and we must supply the subroutine `difeq` called by `solvde`. For simplicity we choose an equally spaced mesh of $m = 41$ points, that is, $h = .025$. As we shall see, this gives good accuracy for the eigenvalues up to moderate values of $n - m$.

Since the boundary condition at $x = 0$ does not involve y_1 if $n - m$ is even, we have to use the `indexv` feature of `solvde`. Recall that the value of `indexv(j)` describes which column of $s(i, j)$ the variable $y(j)$ has been put in. If $n - m$ is even, we need to interchange the columns for y_1 and y_2 so that there is not a zero pivot element in $s(i, j)$.

The program prompts for values of m and n . It then computes an initial guess for y based on the Legendre function P_n^m . It next prompts for c^2 , solves for y , prompts for c^2 , solves for y using the previous values as an initial guess, and so on.

You can run the program and check it against values of $\lambda_{mn}(c)$ given in the tables at the back of Flammer's book [1] or in Table 21.1 of Abramowitz and Stegun [2]. Typically it converges in about 3 iterations. The table below gives a few comparisons.

Selected Output of sfroid				
m	n	c^2	λ_{exact}	λ_{sfroid}
2	2	0.1	6.01427	6.01427
		1.0	6.14095	6.14095
		4.0	6.54250	6.54253
2	5	1.0	30.4361	30.4372
		16.0	36.9963	37.0135
4	11	-1.0	131.560	131.554

Shooting

To solve the same problem via shooting (§17.1), we supply a subroutine `derivs` that implements equations (17.4.15)–(17.4.17). We will integrate the equations over the range $-1 \leq x \leq 0$. We provide the subroutine `load` which sets the eigenvalue y_3 to its current best estimate, $v(1)$. It also sets the boundary values of y_1 and

y_2 using equations (17.4.20) and (17.4.19) (with a minus sign corresponding to $x = -1$). Note that the boundary condition is actually applied a distance dx from the boundary to avoid having to evaluate y'_2 right on the boundary. The subroutine `score` follows from equation (17.4.18).

```

Shooting to a Fitting Point

For variety we illustrate `shootf` from §17.2 by integrating over the whole range $-1 + dx \leq x \leq 1 - dx$, with the fitting point chosen to be at $x = 0$. The routine `derivs` is identical to the one for `shoot`. Now, however, there are two load routines. The routine `load1` for $x = -1$ is essentially identical to `load` above. At $x = 1$, `load2` sets the function value y_1 and the eigenvalue y_3 to their best current estimates, $v2(1)$ and $v2(2)$, respectively. If you quite sensibly make your initial guess of the eigenvalue the same in the two intervals, then $v1(1)$ will stay equal to $v2(2)$ during the iteration. The subroutine `score` simply checks whether all three function values match at the fitting point.

```

17.5 Automated Allocation of Mesh Points

In relaxation problems, you have to choose values for the independent variable at the mesh points. This is called *allocating* the grid or mesh. The usual procedure is to pick a plausible set of values and, if it works, to be content. If it doesn't work, increasing the number of points usually cures the problem.

If we know ahead of time where our solutions will be rapidly varying, we can put more grid points there and less elsewhere. Alternatively, we can solve the problem first on a uniform mesh and then examine the solution to see where we should add more points. We then repeat the solution with the improved grid. The object of the exercise is to allocate points in such a way as to represent the solution accurately.

It is also possible to automate the allocation of mesh points, so that it is done "dynamically" during the relaxation process. This powerful technique not only improves the accuracy of the relaxation method, but also (as we will see in the next section) allows internal singularities to be handled in quite a neat way. Here we learn how to accomplish the automatic allocation.

We want to focus attention on the independent variable x , and consider two alternative reparametrizations of it. The first, we term q ; this is just the coordinate corresponding to the mesh points themselves, so that $q = 1$ at $k = 1$, $q = 2$ at $k = 2$, and so on. Between any two mesh points we have $\Delta q = 1$. In the change of independent variable in the ODEs from x to q ,

$$\frac{dy}{dx} = \mathbf{g} \quad (17.5.1)$$

becomes

$$\frac{dy}{dq} = \mathbf{g} \frac{dx}{dq} \quad (17.5.2)$$

In terms of q , equation (17.5.2) as an FDE might be written

$$\mathbf{y}_k - \mathbf{y}_{k-1} - \frac{1}{2} \left[\left(\mathbf{g} \frac{dx}{dq} \right)_k + \left(\mathbf{g} \frac{dx}{dq} \right)_{k-1} \right] = 0 \quad (17.5.3)$$

or some related version. Note that dx/dq should accompany \mathbf{g} . The transformation between x and q depends only on the Jacobian dx/dq . Its reciprocal dq/dx is proportional to the density of mesh points.

Now, given the function $\mathbf{y}(x)$, or its approximation at the current stage of relaxation, we are supposed to have some idea of how we want to specify the density of mesh points. For example, we might want dq/dx to be larger where \mathbf{y} is changing rapidly, or near to the boundaries, or both. In fact, we can probably make up a formula for what we would like dq/dx to be proportional to. The problem is that we do not know the proportionality constant. That is, the formula that we might invent would not have the correct integral over the whole range of x so as to make q vary from 1 to M , according to its definition. To solve this problem we introduce a second reparametrization $Q(q)$, where Q is a new independent variable. The relation between Q and q is taken to be *linear*, so that a mesh spacing formula for dQ/dx differs only in its unknown proportionality constant. A linear relation implies

$$\frac{d^2Q}{dq^2} = 0 \quad (17.5.4)$$

or, expressed in the usual manner as coupled first-order equations,

$$\frac{dQ(x)}{dq} = \psi \quad \frac{d\psi}{dq} = 0 \quad (17.5.5)$$

where ψ is a new intermediate variable. We add these two equations to the set of ODEs being solved.

Completing the prescription, we add a third ODE that is just our desired mesh-density function, namely

$$\phi(x) = \frac{dQ}{dx} = \frac{dQ}{dq} \frac{dq}{dx} \quad (17.5.6)$$

In fact, we can probably make up a formula for what we would like dq/dx to be proportional to. The problem is that we do not know the proportionality constant. That is, the formula that we might invent would not have the correct integral over the whole range of x so as to make q vary from 1 to M , according to its definition. To solve this problem we introduce a second reparametrization $Q(q)$, where Q is a new independent variable. The relation between Q and q is taken to be *linear*, so that a mesh spacing formula for dQ/dx differs only in its unknown proportionality constant. A linear relation implies

$$\frac{d^2Q}{dq^2} = 0 \quad (17.5.4)$$

or, expressed in the usual manner as coupled first-order equations,

$$\frac{dQ(x)}{dq} = \psi \quad \frac{d\psi}{dq} = 0 \quad (17.5.5)$$

where ψ is a new intermediate variable. We add these two equations to the set of ODEs being solved.

Completing the prescription, we add a third ODE that is just our desired mesh-density function, namely

$$\phi(x) = \frac{dQ}{dx} = \frac{dQ}{dq} \frac{dq}{dx} \quad (17.5.6)$$

where $\phi(x)$ is chosen by us. Written in terms of the mesh variable q , this equation is

$$\frac{dx}{dq} = \frac{\psi}{\phi(x)} \quad (17.5.7)$$

Notice that $\phi(x)$ should be chosen to be positive definite, so that the density of mesh points is everywhere positive. Otherwise (17.5.7) can have a zero in its denominator.

To use automated mesh spacing, you add the three ODEs (17.5.5) and (17.5.7) to your set of equations, i.e., to the array $y(j,k)$. Now x becomes a dependent variable! Q and ψ also become new dependent variables. Normally, evaluating ϕ requires little extra work since it will be composed from pieces of the g 's that exist anyway. The automated procedure allows one to investigate quickly how the numerical results might be affected by various strategies for mesh spacing. (A special case occurs if the desired mesh spacing function Q can be found analytically, i.e., dQ/dx is directly integrable. Then, you need to add only two equations, those in 17.5.5, and two new variables x, ψ .)

As an example of a typical strategy for implementing this scheme, consider a system with one dependent variable $y(x)$. We could set

$$dQ = \frac{dx}{\Delta} + \frac{|d \ln y|}{\delta} \quad (17.5.8)$$

or

$$\phi(x) = \frac{dQ}{dx} = \frac{1}{\Delta} + \left| \frac{dy/dx}{y\delta} \right| \quad (17.5.9)$$

where Δ and δ are constants that we choose. The first term would give a uniform spacing in x if it alone were present. The second term forces more grid points to be used where y is changing rapidly. The constants act to make every logarithmic change in y of an amount δ about as “attractive” to a grid point as a change in x of amount Δ . You adjust the constants according to taste. Other strategies are possible, such as a logarithmic spacing in x , replacing dx in the first term with $d \ln x$.

17.6 Handling Internal Boundary Conditions or Singular Points

Singularities can occur in the interiors of two point boundary value problems. Typically, there is a point x_s at which a derivative must be evaluated by an expression of the form

$$S(x_s) = \frac{N(x_s, \mathbf{y})}{D(x_s, \mathbf{y})} \quad (17.6.1)$$

where the denominator $D(x_s, \mathbf{y}) = 0$. In physical problems with finite answers, singular points usually come with their own cure: Where $D \rightarrow 0$, there the physical solution \mathbf{y} must be such as to make $N \rightarrow 0$ simultaneously, in such a way that the ratio takes on a meaningful value. This constraint on the solution \mathbf{y} is often called a *regularity condition*. The condition that $D(x_s, \mathbf{y})$ satisfy some special constraint at x_s is entirely analogous to an extra boundary condition, an algebraic relation among the dependent variables that must hold at a point.

We discussed a related situation earlier, in §17.2, when we described the “fitting point method” to handle the task of integrating equations with singular behavior at the boundaries. In those problems you are unable to integrate from one side of the domain to the other.

17.6 Handling Internal Boundary Conditions or Singular Points

Singularities can occur in the interiors of two point boundary value problems. Typically, there is a point x_s at which a derivative must be evaluated by an expression of the form

$$S(x_s) = \frac{N(x_s, \mathbf{y})}{D(x_s, \mathbf{y})} \quad (17.6.1)$$

where the denominator $D(x_s, \mathbf{y}) = 0$. In physical problems with finite answers, singular points usually come with their own cure: Where $D \rightarrow 0$, there the physical solution \mathbf{y} must be such as to make $N \rightarrow 0$ simultaneously, in such a way that the ratio takes on a meaningful value. This constraint on the solution \mathbf{y} is often called a *regularity condition*. The condition that $D(x_s, \mathbf{y})$ satisfy some special constraint at x_s is entirely analogous to an extra boundary condition, an algebraic relation among the dependent variables that must hold at a point.

We discussed a related situation earlier, in §17.2, when we described the “fitting point method” to handle the task of integrating equations with singular behavior at the boundaries. In those problems you are unable to integrate from one side of the domain to the other.

Figure 17.6.1. FDE matrix structure with an internal boundary condition. The internal condition introduces a special block. (a) Original form, compare with Figure 17.3.1; (b) final form, compare with Figure 17.3.2.

However, the ODEs do have well-behaved derivatives and solutions in the neighborhood of the singularity, so it is readily possible to integrate away from the point. Both the relaxation method and the method of “shooting” to a fitting point handle such problems easily. Also, in those problems the presence of singular behavior served to isolate some special boundary values that had to be satisfied to solve the equations.

The difference here is that we are concerned with singularities arising at intermediate points, where the location of the singular point depends on the solution, so is not known *a priori*. Consequently, we face a circular task: The singularity prevents us from finding a numerical solution, but we need a numerical solution to find its location. Such singularities are also associated with selecting a special value for some variable which allows the solution to satisfy the regularity condition at the singular point. Thus, internal singularities take on aspects of being internal boundary conditions.

One way of handling internal singularities is to treat the problem as a free boundary problem, as discussed at the end of §17.0. Suppose, as a simple example, we consider the equation

$$\frac{dy}{dx} = \frac{N(x, y)}{D(x, y)} \quad (17.6.2)$$

where N and D are required to pass through zero at some unknown point x_s . We add the equation

$$z \equiv x_s - x_1 \quad \frac{dz}{dx} = 0 \quad (17.6.3)$$

where x_s is the unknown location of the singularity, and change the independent variable to t by setting

$$x - x_1 = tz, \quad 0 \leq t \leq 1 \quad (17.6.4)$$

The boundary conditions at $t = 1$ become

$$N(x, y) = 0, \quad D(x, y) = 0 \quad (17.6.5)$$

Use of an adaptive mesh as discussed in the previous section is another way to overcome the difficulties of an internal singularity. For the problem (17.6.2), we add the mesh spacing equations

$$\frac{dQ}{dq} = \psi \quad (17.6.6)$$

$$\frac{d\psi}{dq} = 0 \quad (17.6.7)$$

with a simple mesh spacing function that maps x uniformly into q , where q runs from 1 to M , the number of mesh points:

$$Q(x) = x - x_1, \quad \frac{dQ}{dx} = 1 \quad (17.6.8)$$

Having added three first-order differential equations, we must also add their corresponding boundary conditions. If there were no singularity, these could simply be

$$\text{at } q = 1 : \quad x = x_1, \quad Q = 0 \quad (17.6.9)$$

$$\text{at } q = M : \quad x = x_2 \quad (17.6.10)$$

and a total of N values y_i specified at $q = 1$. In this case the problem is essentially an initial value problem with all boundary conditions specified at x_1 and the mesh spacing function is superfluous.

However, in the actual case at hand we impose the conditions

$$\text{at } q = 1 : \quad x = x_1, \quad Q = 0 \quad (17.6.11)$$

$$\text{at } q = M : \quad N(x, y) = 0, \quad D(x, y) = 0 \quad (17.6.12)$$

and $N - 1$ values y_i at $q = 1$. The “missing” y_i is to be adjusted, in other words, so as to make the solution go through the singular point in a regular (zero-over-zero) rather than irregular (finite-over-zero) manner. Notice also that these boundary conditions do not directly impose a value for x_2 , which becomes an adjustable parameter that the code varies in an attempt to match the regularity condition.

In this example the singularity occurred at a boundary, and the complication arose because the location of the boundary was unknown. In other problems we might wish to continue the integration beyond the internal singularity. For the example given above, we could simply integrate the ODEs to the singular point, then as a separate problem recommence the integration from the singular point on as far we care to go. However, in other cases the singularity occurs internally, but does not completely determine the problem: There are still some more boundary conditions to be satisfied further along in the mesh. Such cases present no difficulty in principle, but do require some adaptation of the relaxation code given in §17.3. In effect all you need to do is to add a “special” block of equations at the mesh point where the internal boundary conditions occur, and do the proper bookkeeping.

Figure 17.6.1 illustrates a concrete example where the overall problem contains 5 equations with 2 boundary conditions at the first point, one “internal” boundary condition, and two final boundary conditions. The figure shows the structure of the overall matrix equations along the diagonal in the vicinity of the special block. In the middle of the domain, blocks typically involve 5 equations (rows) in 10 unknowns (columns). For each block prior to the special block, the initial boundary conditions provided enough information to zero the first two columns of the blocks. The five FDEs eliminate five more columns, and the final three columns need to be stored for the backsubstitution step (as described in §17.3). To handle the extra condition we break the normal cycle and add a special block with only one equation:

the internal boundary condition. This effectively reduces the required storage of unreduced coefficients by one column for the rest of the grid, and allows us to reduce to zero the first three columns of subsequent blocks. The subroutines `red`, `pinvs`, `bksub` can readily handle these cases with minor recoding, but each problem makes for a special case, and you will have to make the modifications as required.

Chapter 18. Integral Equations and Inverse Theory

18.0 Introduction

Many people, otherwise numerically knowledgable, imagine that the numerical solution of integral equations must be an extremely arcane topic, since, until recently, it was almost never treated in numerical analysis textbooks. Actually there is a large and growing literature on the numerical solution of integral equations; several monographs have by now appeared [1-3]. One reason for the sheer volume of this activity is that there are many different kinds of equations, each with many different possible pitfalls; often many different algorithms have been proposed to deal with a single case.

There is a close correspondence between linear integral equations, which specify linear, integral relations among functions in an infinite-dimensional function space, and plain old linear equations, which specify analogous relations among vectors in a finite-dimensional vector space. Because this correspondence lies at the heart of most computational algorithms, it is worth making it explicit as we recall how integral equations are classified.

Fredholm equations involve definite integrals with fixed upper and lower limits. An *inhomogeneous Fredholm equation of the first kind* has the form

$$g(t) = \int_a^b K(t, s)f(s) ds \quad (18.0.1)$$

Here $f(t)$ is the unknown function to be solved for, while $g(t)$ is a known “right-hand side.” (In integral equations, for some odd reason, the familiar “right-hand side” is conventionally written on the left!) The function of two variables, $K(t, s)$ is called the *kernel*. Equation (18.0.1) is analogous to the matrix equation

$$\mathbf{K} \cdot \mathbf{f} = \mathbf{g} \quad (18.0.2)$$

whose solution is $\mathbf{f} = \mathbf{K}^{-1} \cdot \mathbf{g}$, where \mathbf{K}^{-1} is the matrix inverse. Like equation (18.0.2), equation (18.0.1) has a unique solution whenever g is nonzero (the homogeneous case with $g = 0$ is almost never useful) and K is invertible. However, as we shall see, this latter condition is as often the exception as the rule.

The analog of the finite-dimensional eigenvalue problem

$$(\mathbf{K} - \sigma \mathbf{1}) \cdot \mathbf{f} = \mathbf{g} \quad (18.0.3)$$

is called a *Fredholm equation of the second kind*, usually written

$$f(t) = \lambda \int_a^b K(t, s)f(s) ds + g(t) \quad (18.0.4)$$

Again, the notational conventions do not exactly correspond: λ in equation (18.0.4) is $1/\sigma$ in (18.0.3), while \mathbf{g} is $-g/\lambda$. If g (or \mathbf{g}) is zero, then the equation is said to be *homogeneous*. If the kernel $K(t, s)$ is bounded, then, like equation (18.0.3), equation (18.0.4) has the property that its homogeneous form has solutions for at most a denumerably infinite set $\lambda = \lambda_n$, $n = 1, 2, \dots$, the *eigenvalues*. The corresponding solutions $f_n(t)$ are the *eigenfunctions*. The eigenvalues are real if the kernel is symmetric.

In the *inhomogeneous* case of nonzero g (or \mathbf{g}), equations (18.0.3) and (18.0.4) are soluble *except* when λ (or σ) is an eigenvalue — because the integral operator (or matrix) is singular then. In integral equations this dichotomy is called *the Fredholm alternative*.

Fredholm equations of the first kind are often extremely ill-conditioned. Applying the kernel to a function is generally a smoothing operation, so the solution, which requires inverting the operator, will be extremely sensitive to small changes or errors in the input. Smoothing often actually loses information, and there is no way to get it back in an inverse operation. Specialized methods have been developed for such equations, which are often called *inverse problems*. In general, a method must augment the information given with some prior knowledge of the nature of the solution. This prior knowledge is then used, in one way or another, to restore lost information. We will introduce such techniques in §18.4.

Inhomogeneous Fredholm equations of the second kind are much less often ill-conditioned. Equation (18.0.4) can be rewritten as

$$\int_a^b [K(t, s) - \sigma\delta(t - s)]f(s) ds = -\sigma g(t) \quad (18.0.5)$$

where $\delta(t - s)$ is a Dirac delta function (and where we have changed from λ to its reciprocal σ for clarity). If σ is large enough in magnitude, then equation (18.0.5) is, in effect, diagonally dominant and thus well-conditioned. Only if σ is small do we go back to the ill-conditioned case.

Homogeneous Fredholm equations of the second kind are likewise not particularly ill-posed. If K is a smoothing operator, then it will map many f 's to zero, or near-zero; there will thus be a large number of degenerate or nearly degenerate eigenvalues around $\sigma = 0$ ($\lambda \rightarrow \infty$), but this will cause no particular computational difficulties. In fact, we can now see that the magnitude of σ needed to rescue the inhomogeneous equation (18.0.5) from an ill-conditioned fate is generally much *less* than that required for diagonal dominance. Since the σ term shifts all eigenvalues, it is enough that it be large enough to shift a smoothing operator's forest of near-zero eigenvalues away from zero, so that the resulting operator becomes invertible (except, of course, at the discrete eigenvalues).

Volterra equations are a special case of Fredholm equations with $K(t, s) = 0$ for $s > t$. Chopping off the unnecessary part of the integration, Volterra equations are written in a form where the upper limit of integration is the independent variable t .

The Volterra equation of the first kind

$$g(t) = \int_a^t K(t, s)f(s) ds \quad (18.0.6)$$

has as its analog the matrix equation (now written out in components)

$$\sum_{j=1}^k K_{kj}f_j = g_k \quad (18.0.7)$$

Comparing with equation (18.0.2), we see that the Volterra equation corresponds to a matrix \mathbf{K} that is lower (i.e., left) triangular, with zero entries above the diagonal. As we know from Chapter 2, such matrix equations are trivially soluble by forward substitution. Techniques for solving Volterra equations are similarly straightforward. When experimental measurement noise does not dominate, Volterra equations of the first kind tend *not* to be ill-conditioned; the upper limit to the integral introduces a sharp step that conveniently spoils any smoothing properties of the kernel.

The Volterra equation of the second kind is written

$$f(t) = \int_a^t K(t, s)f(s) ds + g(t) \quad (18.0.8)$$

whose matrix analog is the equation

$$(\mathbf{K} - \mathbf{1}) \cdot \mathbf{f} = \mathbf{g} \quad (18.0.9)$$

with \mathbf{K} lower triangular. The reason there is no λ in these equations is that (i) in the inhomogeneous case (nonzero g) it can be absorbed into K , while (ii) in the homogeneous case ($g = 0$), it is a theorem that Volterra equations of the second kind with bounded kernels have no eigenvalues with square-integrable eigenfunctions.

We have specialized our definitions to the case of linear integral equations. The integrand in a nonlinear version of equation (18.0.1) or (18.0.6) would be $K(t, s, f(s))$ instead of $K(t, s)f(s)$; a nonlinear version of equation (18.0.4) or (18.0.8) would have an integrand $K(t, s, f(t), f(s))$. Nonlinear Fredholm equations are considerably more complicated than their linear counterparts. Fortunately, they do not occur as frequently in practice and we shall by and large ignore them in this chapter. By contrast, solving nonlinear Volterra equations usually involves only a slight modification of the algorithm for linear equations, as we shall see.

Almost all methods for solving integral equations numerically make use of *quadrature rules*, frequently Gaussian quadratures. This would be a good time for you to go back and review §4.5, especially the advanced material towards the end of that section.

In the sections that follow, we first discuss Fredholm equations of the second kind with smooth kernels (§18.1). Nontrivial quadrature rules come into the discussion, but we will be dealing with well-conditioned systems of equations. We then return to Volterra equations (§18.2), and find that simple and straightforward methods are generally satisfactory for these equations.

In §18.3 we discuss how to proceed in the case of singular kernels, focusing largely on Fredholm equations (both first and second kinds). Singularities require

special quadrature rules, but they are also sometimes blessings in disguise, since they can spoil a kernel's smoothing and make problems well-conditioned.

In §§18.4–18.7 we face up to the issues of inverse problems. §18.4 is an introduction to this large subject.

We should note here that wavelet transforms, already discussed in §13.10, are applicable not only to data compression and signal processing, but can also be used to transform some classes of integral equations into sparse linear problems that allow fast solution. You may wish to review §13.10 as part of reading this chapter.

Some subjects, such as *integro-differential equations*, we must simply declare to be beyond our scope. For a review of methods for integro-differential equations, see Brunner [4].

It should go without saying that this one short chapter can only barely touch on a few of the most basic methods involved in this complicated subject.

18.1 Fredholm Equations of the Second Kind

We desire a numerical solution for $f(t)$ in the equation

$$f(t) = \lambda \int_a^b K(t, s)f(s) ds + g(t) \quad (18.1.1)$$

The method we describe, a very basic one, is called the *Nystrom method*. It requires the choice of some approximate *quadrature rule*:

$$\int_a^b y(s) ds = \sum_{j=1}^N w_j y(s_j) \quad (18.1.2)$$

Here the set $\{w_j\}$ are the weights of the quadrature rule, while the N points $\{s_j\}$ are the abscissas.

What quadrature rule should we use? It is certainly possible to solve integral equations with low-order quadrature rules like the repeated trapezoidal or Simpson's

special quadrature rules, but they are also sometimes blessings in disguise, since they can spoil a kernel's smoothing and make problems well-conditioned.

In §§18.4–18.7 we face up to the issues of inverse problems. §18.4 is an introduction to this large subject.

We should note here that wavelet transforms, already discussed in §13.10, are applicable not only to data compression and signal processing, but can also be used to transform some classes of integral equations into sparse linear problems that allow fast solution. 18.1 Fredholm Equations of the Second Kind

We desire a numerical solution for $f(t)$ in the equation

$$f(t) = \lambda \int_a^b K(t, s)f(s) ds + g(t) \quad (18.1.1)$$

The method we describe, a very basic one, is called the *Nystrom method*. It requires the choice of some approximate *quadrature rule*:

$$\int_a^b y(s) ds = \sum_{j=1}^N w_j y(s_j) \quad (18.1.2)$$

Here the set $\{w_j\}$ are the weights of the quadrature rule, while the N points $\{s_j\}$ are the abscissas.

What quadrature rule should we use? It is certainly possible to solve integral equations with low-order quadrature rules like the repeated trapezoidal or Simpson's

rules. We will see, however, that the solution method involves $O(N^3)$ operations, and so the most efficient methods tend to use high-order quadrature rules to keep N as small as possible. For smooth, nonsingular problems, nothing beats Gaussian quadrature (e.g., Gauss-Legendre quadrature, §4.5). (For non-smooth or singular kernels, see §18.3.)

Delves and Mohamed [1] investigated methods more complicated than the Nystrom method. For straightforward Fredholm equations of the second kind, they concluded “... the clear winner of this contest has been the Nystrom routine ... with the N -point Gauss-Legendre rule. This routine is extremely simple. . . . Such results are enough to make a numerical analyst weep.”

If we apply the quadrature rule (18.1.2) to equation (18.1.1), we get

$$f(t) = \lambda \sum_{j=1}^N w_j K(t, s_j) f(s_j) + g(t) \quad (18.1.3)$$

Evaluate equation (18.1.3) at the quadrature points:

$$f(t_i) = \lambda \sum_{j=1}^N w_j K(t_i, s_j) f(s_j) + g(t_i) \quad (18.1.4)$$

Let f_i be the vector $f(t_i)$, g_i the vector $g(t_i)$, K_{ij} the matrix $K(t_i, s_j)$, and define

$$\tilde{K}_{ij} = K_{ij} w_j \quad (18.1.5)$$

Then in matrix notation equation (18.1.4) becomes

$$(\mathbf{1} - \lambda \tilde{\mathbf{K}}) \cdot \mathbf{f} = \mathbf{g} \quad (18.1.6)$$

This is a set of N linear algebraic equations in N unknowns that can be solved by standard triangular decomposition techniques (§2.3) — that is where the $O(N^3)$ operations count comes in. The solution is usually well-conditioned, unless λ is very close to an eigenvalue.

Having obtained the solution at the quadrature points $\{t_i\}$, how do you get the solution at some other point t ? You do *not* simply use polynomial interpolation. This destroys all the accuracy you have worked so hard to achieve. Nystrom’s key observation was that you should use equation (18.1.3) as an interpolatory formula, maintaining the accuracy of the solution.

We here give two subroutines for use with linear Fredholm equations of the second kind. The routine `fred2` sets up equation (18.1.6) and then solves it by *LU* decomposition with calls to the routines `ludcmp` and `lubksb`. The Gauss-Legendre quadrature is implemented by first getting the weights and abscissas with a call to `gauleg`. Routine `fred2` requires that you provide an external function that returns $g(t)$ and another that returns λK_{ij} . It then returns the solution f at the quadrature points. It also returns the quadrature points and weights. These are used by the second routine `fredin` to carry out the Nystrom interpolation of equation (18.1.3) and return the value of f at any point in the interval $[a, b]$.

```

SUBROUTINE fred2(n,a,b,t,f,w,g,ak)
INTEGER n,NMAX

```

One disadvantage of a method based on Gaussian quadrature is that there is no simple way to obtain an estimate of the error in the result. The best practical method is to increase N by 50%, say, and treat the difference between the two estimates as a conservative estimate of the error in the result obtained with the larger value of N .

Turn now to solutions of the homogeneous equation. If we set $\lambda = 1/\sigma$ and $\mathbf{g} = 0$, then equation (18.1.6) becomes a standard eigenvalue equation

$$\tilde{\mathbf{K}} \cdot \mathbf{f} = \sigma \mathbf{f} \quad (18.1.7)$$

which we can solve with any convenient matrix eigenvalue routine (see Chapter 11). Note that if our original problem had a symmetric kernel, then the matrix \mathbf{K} is symmetric. However, since the weights w_j are not equal for most quadrature rules, the matrix $\tilde{\mathbf{K}}$ (equation 18.1.5) is not symmetric. The matrix eigenvalue problem is much easier for symmetric matrices, and so we should restore the symmetry if possible. Provided the weights are positive (which they are for Gaussian quadrature), we can define the diagonal matrix $\mathbf{D} = \text{diag}(w_j)$ and its square root, $\mathbf{D}^{1/2} = \text{diag}(\sqrt{w_j})$. Then equation (18.1.7) becomes

$$\mathbf{K} \cdot \mathbf{D} \cdot \mathbf{f} = \sigma \mathbf{f}$$

Multiplying by $\mathbf{D}^{1/2}$, we get

$$(\mathbf{D}^{1/2} \cdot \mathbf{K} \cdot \mathbf{D}^{1/2}) \cdot \mathbf{h} = \sigma \mathbf{h} \quad (18.1.8)$$

where $\mathbf{h} = \mathbf{D}^{1/2} \cdot \mathbf{f}$. Equation (18.1.8) is now in the form of a symmetric eigenvalue problem.

Solution of equations (18.1.7) or (18.1.8) will in general give N eigenvalues, where N is the number of quadrature points used. For square-integrable kernels, these will provide good approximations to the lowest N eigenvalues of the integral equation. Kernels of *finite rank* (also called *degenerate* or *separable* kernels) have only a finite number of nonzero eigenvalues (possibly none). You can diagnose this situation by a cluster of eigenvalues σ that are zero to machine precision. The number of nonzero eigenvalues will stay constant as you increase N to improve their accuracy. Some care is required here: A nondegenerate kernel can have an infinite number of eigenvalues that have an accumulation point at $\sigma = 0$. You distinguish the two cases by the behavior of the solution as you increase N . If you suspect a degenerate kernel, you will usually be able to solve the problem by analytic techniques described in all the textbooks.

18.2 Volterra Equations

Let us now turn to Volterra equations, of which our prototype is the Volterra equation of the second kind,

$$f(t) = \int_a^t K(t, s)f(s) ds + g(t) \quad (18.2.1)$$

Most algorithms for Volterra equations march out from $t = a$, building up the solution as they go. In this sense they resemble not only forward substitution (as discussed in §18.0), but also initial-value problems for ordinary differential equations. In fact, many algorithms for ODEs have counterparts for Volterra equations.

The simplest way to proceed is to solve the equation on a mesh with uniform spacing:

$$t_i = a + ih, \quad i = 0, 1, \dots, N, \quad h \equiv \frac{b - a}{N} \quad (18.2.2)$$

To do so, we must choose a quadrature rule. For a uniform mesh, the simplest scheme is the trapezoidal rule, equation (4.1.11):

$$\int_a^{t_i} K(t_i, s)f(s) ds = h \left(\frac{1}{2}K_{i0}f_0 + \sum_{j=1}^{i-1} K_{ij}f_j + \frac{1}{2}K_{ii}f_i \right) \quad (18.2.3)$$

Thus the trapezoidal method for equation (18.2.1) is:

$$\begin{aligned} f_0 &= g_0 \\ (1 - \frac{1}{2}hK_{ii})f_i &= h \left(\frac{1}{2}K_{i0}f_0 + \sum_{j=1}^{i-1} K_{ij}f_j \right) + g_i, \quad i = 1, \dots, N \end{aligned} \quad (18.2.4)$$

(For a Volterra equation of the first kind, the leading 1 on the left would be absent, and g would have opposite sign, with corresponding straightforward changes in the rest of the discussion.)

Equation (18.2.4) is an explicit prescription that gives the solution in $O(N^2)$ operations. Unlike Fredholm equations, it is not necessary to solve a system of linear equations. Volterra equations thus usually involve less work than the corresponding Fredholm equations which, as we have seen, do involve the inversion of, sometimes large, linear systems.

The efficiency of solving Volterra equations is somewhat counterbalanced by the fact that *systems* of these equations occur more frequently in practice. If we interpret equation (18.2.1) as a *vector* equation for the vector of m functions $f(t)$, then the kernel $K(t, s)$ is an $m \times m$ matrix. Equation (18.2.4) must now also be understood as a vector equation. For each i , we have to solve the $m \times m$ set of linear algebraic equations by Gaussian elimination.

The routine `voltra` below implements this algorithm. You must supply an external function that returns the k th function of the vector $g(t)$ at the point t , and another that returns the (k, l) element of the matrix $K(t, s)$ at (t, s) . The routine `voltra` then returns the vector $f(t)$ at the regularly spaced points t_i .

18.2 Volterra Equations

Let us now turn to Volterra equations, of which our prototype is the Volterra equation of the second kind,

$$f(t) = \int_a^t K(t, s)f(s) ds + g(t) \quad (18.2.1)$$

Most algorithms for Volterra equations march out from $t = a$, building up the solution as they go. In this sense they resemble not only forward substitution (as discussed in §18.0), but also initial-value problems for ordinary differential equations. In fact, many algorithms for ODEs have counterparts for Volterra equations.

The simplest way to proceed is to solve the equation on a mesh with uniform spacing:

$$t_i = a + ih, \quad i = 0, 1, \dots, N, \quad h \equiv \frac{b - a}{N} \quad (18.2.2)$$

To do so, we must choose a quadrature rule. For a uniform mesh, the simplest scheme is the trapezoidal rule, equation (4.1.11):

$$\int_a^{t_i} K(t_i, s)f(s) ds = h \left(\frac{1}{2}K_{i0}f_0 + \sum_{j=1}^{i-1} K_{ij}f_j + \frac{1}{2}K_{ii}f_i \right) \quad (18.2.3)$$

Thus the trapezoidal method for equation (18.2.1) is:

$$\begin{aligned} f_0 &= g_0 \\ (1 - \frac{1}{2}hK_{ii})f_i &= h \left(\frac{1}{2}K_{i0}f_0 + \sum_{j=1}^{i-1} K_{ij}f_j \right) + g_i, \quad i = 1, \dots, N \end{aligned} \quad (18.2.4)$$

(For a Volterra equation of the first kind, the leading 1 on the left would be absent, and g would have opposite sign, with corresponding straightforward changes in the rest of the discussion.)

Equation (18.2.4) is an explicit prescription that gives the solution in $O(N^2)$ operations. Unlike Fredholm equations, it is not necessary to solve a system of linear equations. Volterra equations thus usually involve less work than the corresponding Fredholm equations which, as we have seen, do involve the inversion of, sometimes large, linear systems.

The efficiency of solving Volterra equations is somewhat counterbalanced by the fact that *systems* of these equations occur more frequently in practice. If we interpret equation (18.2.1) as a *vector* equation for the vector of m functions $f(t)$, then the kernel $K(t, s)$ is an $m \times m$ matrix. Equation (18.2.4) must now also be understood as a vector equation. For each i , we have to solve the $m \times m$ set of linear algebraic equations by Gaussian elimination.

The routine `voltra` below implements this algorithm. You must supply an external function that returns the k th function of the vector $g(t)$ at the point t , and another that returns the (k, l) element of the matrix $K(t, s)$ at (t, s) . The routine `voltra` then returns the vector $f(t)$ at the regularly spaced points t_i .

For nonlinear Volterra equations, equation (18.2.4) holds with the product $K_{ii}f_i$ replaced by $K_{ii}(f_i)$, and similarly for the other two products of K 's and f 's. Thus for each i we solve a nonlinear equation for f_i with a known right-hand side. Newton's method (§9.4 or §9.6) with an initial guess of f_{i-1} usually works very well provided the stepsize is not too big.

Higher-order methods for solving Volterra equations are, in our opinion, not as important as for Fredholm equations, since Volterra equations are relatively easy to solve. However, there is an extensive literature on the subject. Several difficulties arise. First, any method that achieves higher order by operating on several quadrature points simultaneously will need a special method to get started, when values at the first few points are not yet known.

Second, stable quadrature rules can give rise to unexpected instabilities in integral equations. For example, suppose we try to replace the trapezoidal rule in

the algorithm above with Simpson's rule. Simpson's rule naturally integrates over an interval $2h$, so we easily get the function values at the even mesh points. For the odd mesh points, we could try appending one panel of trapezoidal rule. But to which end of the integration should we append it? We could do one step of trapezoidal rule followed by all Simpson's rule, or Simpson's rule with one step of trapezoidal rule at the end. Surprisingly, the former scheme is unstable, while the latter is fine!

A simple approach that can be used with the trapezoidal method given above is Richardson extrapolation: Compute the solution with stepsize h and $h/2$. Then, assuming the error scales with h^2 , compute

$$f_E = \frac{4f(h/2) - f(h)}{3} \quad (18.2.5)$$

This procedure can be repeated as with Romberg integration.

The general consensus is that the best of the higher order methods is the *block-by-block method* (see [1]). Another important topic is the use of variable stepsize methods, which are much more efficient if there are sharp features in K or f . Variable stepsize methods are quite a bit more complicated than their counterparts for differential equations; we refer you to the literature [1,2] for a discussion.

You should also be on the lookout for singularities in the integrand. If you find them, then look to §18.3 for additional ideas.

18.3 Integral Equations with Singular Kernels

Many integral equations have singularities in either the kernel or the solution or both. A simple quadrature method will show poor convergence with N if such singularities are ignored. There is sometimes art in how singularities are best handled.

We start with a few straightforward suggestions:

1. Integrable singularities can often be removed by a change of variable. For example, the singular behavior $K(t, s) \sim s^{1/2}$ or $s^{-1/2}$ near $s = 0$ can be removed by the transformation $z = s^{1/2}$. Note that we are assuming that the singular behavior is confined to K , whereas the quadrature actually involves the product $K(t, s)f(s)$, and it is this product that must be "fixed." Ideally, you must deduce the singular nature of the product before you try a numerical solution, and take the appropriate action. Commonly, however, a singular kernel does *not* produce a singular solution $f(t)$. (The highly singular kernel $K(t, s) = \delta(t - s)$ is simply the identity operator, for example.)

2. If $K(t, s)$ can be factored as $w(s)\bar{K}(t, s)$, where $w(s)$ is singular and $\bar{K}(t, s)$ is smooth, then a Gaussian quadrature based on $w(s)$ as a weight function will work well. Even if the factorization is only approximate, the convergence is often improved dramatically. All you have to do is replace `gauleg` in the routine `fred2` by another quadrature routine. Section 4.5 explained how to construct such quadratures; or you can find tabulated abscissas and weights in the standard references [1,2]. You must of course supply \bar{K} instead of K .

18.3 Integral Equations with Singular Kernels

Many integral equations have singularities in either the kernel or the solution or both. A simple quadrature method will show poor convergence with N if such singularities are ignored. There is sometimes art in how singularities are best handled.

We start with a few straightforward suggestions:

1. Integrable singularities can often be removed by a change of variable. For example, the singular behavior $K(t, s) \sim s^{1/2}$ or $s^{-1/2}$ near $s = 0$ can be removed by the transformation $z = s^{1/2}$. Note that we are assuming that the singular behavior is confined to K , whereas the quadrature actually involves the product $K(t, s)f(s)$, and it is this product that must be "fixed." Ideally, you must deduce the singular nature of the product before you try a numerical solution, and take the appropriate action. Commonly, however, a singular kernel does *not* produce a singular solution $f(t)$. (The highly singular kernel $K(t, s) = \delta(t - s)$ is simply the identity operator, for example.)

2. If $K(t, s)$ can be factored as $w(s)\bar{K}(t, s)$, where $w(s)$ is singular and $\bar{K}(t, s)$ is smooth, then a Gaussian quadrature based on $w(s)$ as a weight function will work well. Even if the factorization is only approximate, the convergence is often improved dramatically. All you have to do is replace `gauleg` in the routine `fred2` by another quadrature routine. Section 4.5 explained how to construct such quadratures; or you can find tabulated abscissas and weights in the standard references [1,2]. You must of course supply \bar{K} instead of K .

This method is a special case of the *product Nystrom method* [3,4], where one factors out a singular term $p(t, s)$ depending on both t and s from K and constructs suitable weights for its Gaussian quadrature. The calculations in the general case are quite cumbersome, because the weights depend on the chosen $\{t_i\}$ as well as the form of $p(t, s)$.

We prefer to implement the product Nystrom method on a uniform grid, with a quadrature scheme that generalizes the extended Simpson's 3/8 rule (equation 4.1.5) to arbitrary weight functions. We discuss this in the subsections below.

3. Special quadrature formulas are also useful when the kernel is not strictly singular, but is “almost” so. One example is when the kernel is concentrated near $t = s$ on a scale much smaller than the scale on which the solution $f(t)$ varies. In that case, a quadrature formula can be based on locally approximating $f(s)$ by a polynomial or spline, while calculating the first few *moments* of the kernel $K(t, s)$ at the tabulation points t_i . In such a scheme the narrow width of the kernel becomes an asset, rather than a liability: The quadrature becomes exact as the width of the kernel goes to zero.

4. An infinite range of integration is also a form of singularity. Truncating the range at a large finite value should be used only as a last resort. If the kernel goes rapidly to zero, then a Gauss-Laguerre [$w \sim \exp(-\alpha s)$] or Gauss-Hermite [$w \sim \exp(-s^2)$] quadrature should work well. Long-tailed functions often succumb to the transformation

$$s = \frac{2\alpha}{z+1} - \alpha \quad (18.3.1)$$

which maps $0 < s < \infty$ to $1 > z > -1$ so that Gauss-Legendre integration can be used. Here $\alpha > 0$ is a constant that you adjust to improve the convergence.

5. A common situation in practice is that $K(t, s)$ is singular along the diagonal line $t = s$. Here the Nystrom method fails completely because the kernel gets evaluated at (t_i, s_i) . *Subtraction of the singularity* is one possible cure:

$$\begin{aligned} \int_a^b K(t, s)f(s)ds &= \int_a^b K(t, s)[f(s) - f(t)]ds + \int_a^b K(t, s)f(t)ds \\ &= \int_a^b K(t, s)[f(s) - f(t)]ds + r(t)f(t) \end{aligned} \quad (18.3.2)$$

where $r(t) = \int_a^b K(t, s)ds$ is computed analytically or numerically. If the first term on the right-hand side is now regular, we can use the Nystrom method. Instead of equation (18.1.4), we get

$$f_i = \lambda \sum_{\substack{j=1 \\ j \neq i}}^N w_j K_{ij}[f_j - f_i] + \lambda r_i f_i + g_i \quad (18.3.3)$$

Sometimes the subtraction process must be repeated before the kernel is completely regularized. See [3] for details. (And read on for a different, we think better, way to handle diagonal singularities.)

Quadrature on a Uniform Mesh with Arbitrary Weight

It is possible in general to find n -point linear quadrature rules that approximate the integral of a function $f(x)$, times an arbitrary weight function $w(x)$, over an arbitrary range of integration (a, b) , as the sum of weights times n evenly spaced values of the function $f(x)$, say at $x = kh, (k+1)h, \dots, (k+n-1)h$. The general scheme for deriving such quadrature rules is to write down the n linear equations that must be satisfied if the quadrature rule is to be exact for the n functions $f(x) = \text{const}, x, x^2, \dots, x^{n-1}$, and then solve these for the coefficients. This can be done analytically, once and for all, if the moments of the weight function over the same range of integration,

$$W_n \equiv \frac{1}{h^n} \int_a^b x^n w(x)dx \quad (18.3.4)$$

are assumed to be known. Here the prefactor h^{-n} is chosen to make W_n scale as h if (as in the usual case) $b - a$ is proportional to h .

Carrying out this prescription for the four-point case gives the result

$$\begin{aligned} \int_a^b w(x)f(x)dx = & \frac{1}{6}f(kh)\left[(k+1)(k+2)(k+3)W_0 - (3k^2 + 12k + 11)W_1 + 3(k+2)W_2 - W_3\right] \\ & + \frac{1}{2}f([k+1]h)\left[-k(k+2)(k+3)W_0 + (3k^2 + 10k + 6)W_1 - (3k+5)W_2 + W_3\right] \\ & + \frac{1}{2}f([k+2]h)\left[k(k+1)(k+3)W_0 - (3k^2 + 8k + 3)W_1 + (3k+4)W_2 - W_3\right] \\ & + \frac{1}{6}f([k+3]h)\left[-k(k+1)(k+2)W_0 + (3k^2 + 6k + 2)W_1 - 3(k+1)W_2 + W_3\right] \end{aligned} \quad (18.3.5)$$

While the terms in brackets superficially appear to scale as k^2 , there is typically cancellation at both $O(k^2)$ and $O(k)$.

Equation (18.3.5) can be specialized to various choices of (a, b) . The obvious choice is $a = kh$, $b = (k+3)h$, in which case we get a four-point quadrature rule that generalizes Simpson's 3/8 rule (equation 4.1.5). In fact, we can recover this special case by setting $w(x) = 1$, in which case (18.3.4) becomes

$$W_n = \frac{h}{n+1}[(k+3)^{n+1} - k^{n+1}] \quad (18.3.6)$$

The four terms in square brackets equation (18.3.5) each become independent of k , and (18.3.5) in fact reduces to

$$\int_{kh}^{(k+3)h} f(x)dx = \frac{3h}{8}f(kh) + \frac{9h}{8}f([k+1]h) + \frac{9h}{8}f([k+2]h) + \frac{3h}{8}f([k+3]h) \quad (18.3.7)$$

Back to the case of general $w(x)$, some other choices for a and b are also useful. For example, we may want to choose (a, b) to be $([k+1]h, [k+3]h)$ or $([k+2]h, [k+3]h)$, allowing us to finish off an extended rule whose number of intervals is not a multiple of three, without loss of accuracy: The integral will be estimated using the four values $f(kh), \dots, f([k+3]h)$. Even more useful is to choose (a, b) to be $([k+1]h, [k+2]h)$, thus using four points to integrate a centered single interval. These weights, when sewed together into an extended formula, give quadrature schemes that have smooth coefficients, i.e., without the Simpson-like 2, 4, 2, 4, 2 alternation. (In fact, this was the technique that we used to derive equation 4.1.14, which you may now wish to reexamine.)

All these rules are of the same order as the extended Simpson's rule, that is, exact for $f(x)$ a cubic polynomial. Rules of lower order, if desired, are similarly obtained. The three point formula is

$$\begin{aligned} \int_a^b w(x)f(x)dx = & \frac{1}{2}f(kh)\left[(k+1)(k+2)W_0 - (2k+3)W_1 + W_2\right] \\ & + f([k+1]h)\left[-k(k+2)W_0 + 2(k+1)W_1 - W_2\right] \\ & + \frac{1}{2}f([k+2]h)\left[k(k+1)W_0 - (2k+1)W_1 + W_2\right] \end{aligned} \quad (18.3.8)$$

Here the simple special case is to take, $w(x) = 1$, so that

$$W_n = \frac{h}{n+1}[(k+2)^{n+1} - k^{n+1}] \quad (18.3.9)$$

Then equation (18.3.8) becomes Simpson's rule,

$$\int_{kh}^{(k+2)h} f(x)dx = \frac{h}{3}f(kh) + \frac{4h}{3}f([k+1]h) + \frac{h}{3}f([k+2]h) \quad (18.3.10)$$

For nonconstant weight functions $w(x)$, however, equation (18.3.8) gives rules of one order less than Simpson, since they do not benefit from the extra symmetry of the constant case.

The two point formula is simply

$$\int_{kh}^{(k+1)h} w(x)f(x)dx = f(kh)[(k+1)W_0 - W_1] + f([k+1]h)[-kW_0 + W_1] \quad (18.3.11)$$

Here is a routine `wwgts` that uses the above formulas to return an extended N -point quadrature rule for the interval $(a, b) = (0, [N - 1]h)$. Input to `wwgts` is a user-supplied routine, `kermom`, that is called to get the first four *indefinite-integral* moments of $w(x)$, namely

$$F_m(y) \equiv \int^y s^m w(s)ds \quad m = 0, 1, 2, 3 \quad (18.3.12)$$

(The lower limit is arbitrary and can be chosen for convenience.) Cautionary note: When called with $N < 4$, `wwgts` returns a rule of lower order than Simpson; you should structure your problem to avoid this.

```
SUBROUTINE wwgts(wgts,n,h,kermom)
INTEGER n
REAL wgts(n),h
EXTERNAL kermom
C USES kermom
Constructs in wgts(1:n) weights for the n-point equal-interval quadrature from 0 to
(n-1)h of a function f(x) times an arbitrary (possibly singular) weight function w(x) whose
indefinite-integral moments F_n(y) are provided by the user-supplied subroutine kermom.
INTEGER j,k
DOUBLE PRECISION wold(4),wnew(4),w(4),hh,hi,c,fac,a,b
hh=h
Double precision on internal calculations even though
hi=1.d0/hh
the interface is in single precision.
do 11 j=1,n
  wgts(j)=0.
  enddo 11
call kermom(wold,0.d0,4)
Evaluate indefinite integrals at lower end.
if (n.ge.4) then
  Use highest available order.
  b=0.d0
  For another problem, you might change this lower
  limit.
  do 14 j=1,n-3
    c=j-1
    a=b
    b=a+hh
    if (j.eq.n-3) b=(n-1)*hh
    call kermom(wnew,b,4)
    This is called k in equation (18.3.5).
    Set upper and lower limits for this step.
    fac=1.d0
    do 12 k=1,4
      w(k)=(wnew(k)-wold(k))*fac
      fac=fac*hi
      enddo 12
    wgts(j)=wgts(j)+          Equation (18.3.5).
    ((c+1.d0)*(c+2.d0)*(c+3.d0)*w(1)
    *   -(11.d0+c*(12.d0+c*3.d0))*w(2)
    *   +3.d0*(c+2.d0)*w(3)-w(4))/6.d0
    wgts(j+1)=wgts(j+1)+          Equation (18.3.5).
    *   (-c*(c+2.d0)*(c+3.d0)*w(1)
    *   +(6.d0+c*(10.d0+c*3.d0))*w(2)
    *   -(3.d0*c+5.d0)*w(3)+w(4)).5d0
    wgts(j+2)=wgts(j+2)+          Equation (18.3.5).
    *   (c*(c+1.d0)*(c+3.d0)*w(1)
    *   -(3.d0+c*(8.d0+c*3.d0))*w(2)
    *   +(3.d0*c+4.d0)*w(3)-w(4)).5d0
    wgts(j+3)=wgts(j+3)+          Equation (18.3.5).
    *   (-c*(c+1.d0)*(c+2.d0)*w(1)
    *   +(2.d0+c*(6.d0+c*3.d0))*w(2)
    *   -3.d0*(c+1.d0)*w(3)+w(4))/6.d0
    do 13 k=1,4
      Reset lower limits for moments.
```

```

      wold(k)=wnew(k)
      enddo 13
      enddo 14
      else if (n.eq.3) then           Lower-order cases; not recommended.
        call kermom(wnew, hh+hh, 3)
        w(1)=wnew(1)-wold(1)
        w(2)=hi*(wnew(2)-wold(2))
        w(3)=hi**2*(wnew(3)-wold(3))
        wghts(1)=w(1)-1.5d0*w(2)+0.5d0*w(3)
        wghts(2)=2.d0*w(2)-w(3)
        wghts(3)=0.5d0*(w(3)-w(2))
      else if (n.eq.2) then
        call kermom(wnew, hh, 2)
        wghts(2)=hi*(wnew(2)-wold(2))
        wghts(1)=wnew(1)-wold(1)-wghts(2)
      endif
END

```

We will now give an example of how to apply `wghts` to a singular integral equation.

Worked Example: A Diagonally Singular Kernel

As a particular example, consider the integral equation

$$f(x) + \int_0^\pi K(x, y) f(y) dy = \sin x \quad (18.3.13)$$

with the (arbitrarily chosen) nasty kernel

$$K(x, y) = \cos x \cos y \times \begin{cases} -\ln(x - y) & y < x \\ \sqrt{y - x} & y \geq x \end{cases} \quad (18.3.14)$$

which has a logarithmic singularity on the left of the diagonal, combined with a square-root discontinuity on the right.

The first step is to do (analytically, in this case) the required moment integrals over the singular part of the kernel, equation (18.3.12). Since these integrals are done at a fixed value of x , we can use x as the lower limit. For any specified value of y , the required indefinite integral is then either

$$F_m(y; x) = \int_x^y s^m (s - x)^{1/2} ds = \int_0^{y-x} (x + t)^m t^{1/2} dt \quad \text{if } y > x \quad (18.3.15)$$

$$F_m(y; x) = - \int_x^y s^m \ln(x - s) ds = \int_0^{x-y} (x - t)^m \ln t dt \quad \text{if } y < x \quad (18.3.16)$$

(where a change of variable has been made in the second equality in each case). Doing these integrals analytically (actually, we used a symbolic integration package!), we package the resulting formulas in the following routine. Note that `w(j + 1)` returns $F_j(y; x)$.

```

SUBROUTINE kermom(w,y,m)
  Returns in w(1:m) the first m indefinite-integral moments of one row of the singular part
  of the kernel. (For this example, m is hard-wired to be 4.) The input variable y labels the
  column, while x (in COMMON) is the row.
INTEGER m
DOUBLE PRECISION w(m),y,x,d,df,clog,x2,x3,x4
COMMON /momcom/ x
  We can take x as the lower limit of integration. Thus, we return the moment integrals either
  purely to the left or purely to the right of the diagonal.
if (y.ge.x) then
  d=y-x
  df=2.d0*sqrt(d)*d
  w(1)=df/3.d0

```

```

w(2)=df*(x/3.d0+d/5.d0)
w(3)=df*((x/3.d0 + 0.4d0*d)*x + d**2/7.d0)
w(4)=df*((x/3.d0 + 0.6d0*d)*x + 3.d0*d**2/7.d0)*x
*      + d**3/9.d0)
*
else
  x2=x**2
  x3=x2*x
  x4=x2*x2
  d=x-y
  clog=log(d)
  w(1)=d*(clog-1.d0)
  w(2)=-0.25d0*(3.d0*x+y-2.d0*clog*(x+y))*d
  w(3)=(-11.d0*x3+y*(6.d0*x2+y*(3.d0*x+2.d0*y))
*      +6.d0*clog*(x3-y**3))/18.d0
  w(4)=(-25.d0*x4+y*(12.d0*x3+y*(6.d0*x2+y*
*      (4.d0*x+3.d0*y)))+12.d0*clog*(x4-y**4))/48.d0
endif
return
END

```

Next, we write a routine that constructs the quadrature matrix.

```

SUBROUTINE quadmx(a,n,np)
INTEGER n,np,NMAX
REAL a(np,np),PI
DOUBLE PRECISION xx
PARAMETER (PI=3.14159265,NMAX=257)
COMMON /momcom/ xx
EXTERNAL kermom
C USES wwghts,kermom
Constructs in a(1:n,1:n) the quadrature matrix for an example Fredholm equation of the
second kind. The nonsingular part of the kernel is computed within this routine, while the
quadrature weights which integrate the singular part of the kernel are obtained via calls
to wwghts. An external routine kermom, which supplies indefinite-integral moments of the
singular part of the kernel, is passed to wwghts.
INTEGER j,k
REAL h,wt(NMAX),x,cx,y
h=PI/(n-1)
do 12 j=1,n
  x=(j-1)*h
  xx=x
  call wwghts(wt,n,h,kermom)
  cx=cos(x)
  do 11 k=1,n
    y=(k-1)*h
    a(j,k)=wt(k)*cx*cos(y)
  enddo 11
  a(j,j)=a(j,j)+1.
enddo 12
return
END

```

Put x in COMMON for use by kermom.
Part of nonsingular kernel.
Put together all the pieces of the kernel.
Since equation of the second kind, there is diagonal
piece independent of h.

Finally, we solve the linear system for any particular right-hand side, here $\sin x$.

```

PROGRAM fredex
INTEGER NMAX
REAL PI
PARAMETER (NMAX=100,PI=3.14159265)
INTEGER indx(NMAX),j,n
REAL a(NMAX,NMAX),g(NMAX),x,d
C USES quadmx,ludcmp,lubksb

```

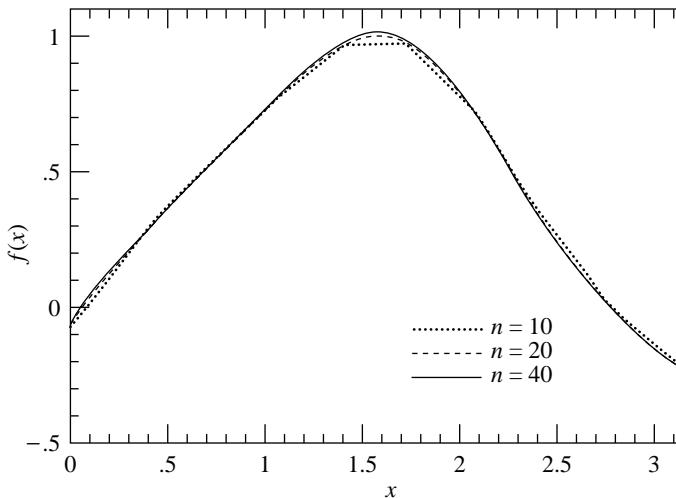

Figure 18.3.1. Solution of the example integral equation (18.3.14) with grid sizes $N = 10, 20$, and 40 . The tabulated solution values have been connected by straight lines; in practice one would interpolate a small N solution more smoothly.

This sample program shows how to solve a Fredholm equation of the second kind using the product Nystrom method and a quadrature rule especially constructed for a particular, singular, kernel.

```

n=40
call quadmx(a,n,NMAX)
call ludcmp(a,n,NMAX,indx,d)
do 11 j=1,n
    x=(j-1)*PI/(n-1)
    g(j)=sin(x)
  enddo 11
call lubksb(a,n,NMAX,indx,g)
do 12 j=1,n
    x=(j-1)*PI/(n-1)
    write (*,*) j,x,g(j)
  enddo 12
write (*,*) 'normal completion'
END

```

Here the size of the grid is specified.
 Make the quadrature matrix; all the action is here.
 Decompose the matrix.
 Construct the right hand side, here $\sin x$.
 Backsubstitute.
 Write out the solution.

With $N = 40$, this program gives accuracy at about the 10^{-5} level. The accuracy increases as N^4 (as it should for our Simpson-order quadrature scheme) *despite* the highly singular kernel. Figure 18.3.1 shows the solution obtained, also plotting the solution for smaller values of N , which are themselves seen to be remarkably faithful. Notice that the solution is smooth, even though the kernel is singular, a common occurrence.

18.4 Inverse Problems and the Use of A Priori Information

Later discussion will be facilitated by some preliminary mention of a couple of mathematical points. Suppose that \mathbf{u} is an “unknown” vector that we plan to determine by some minimization principle. Let $\mathcal{A}[\mathbf{u}] > 0$ and $\mathcal{B}[\mathbf{u}] > 0$ be two positive functionals of \mathbf{u} , so that we can try to determine \mathbf{u} by either

$$\text{minimize: } \mathcal{A}[\mathbf{u}] \quad \text{or} \quad \text{minimize: } \mathcal{B}[\mathbf{u}] \quad (18.4.1)$$

(Of course these will generally give different answers for \mathbf{u} .) As another possibility, now suppose that we want to minimize $\mathcal{A}[\mathbf{u}]$ subject to the *constraint* that $\mathcal{B}[\mathbf{u}]$ have some particular value, say b . The method of Lagrange multipliers gives the variation

$$\frac{\delta}{\delta \mathbf{u}} \{ \mathcal{A}[\mathbf{u}] + \lambda_1 (\mathcal{B}[\mathbf{u}] - b) \} = \frac{\delta}{\delta \mathbf{u}} (\mathcal{A}[\mathbf{u}] + \lambda_1 \mathcal{B}[\mathbf{u}]) = 0 \quad (18.4.2)$$

where λ_1 is a Lagrange multiplier. Notice that b is absent in the second equality, since it doesn’t depend on \mathbf{u} .

Next, suppose that we change our minds and decide to minimize $\mathcal{B}[\mathbf{u}]$ subject to the constraint that $\mathcal{A}[\mathbf{u}]$ have a particular value, a . Instead of equation (18.4.2) we have

$$\frac{\delta}{\delta \mathbf{u}} \{ \mathcal{B}[\mathbf{u}] + \lambda_2 (\mathcal{A}[\mathbf{u}] - a) \} = \frac{\delta}{\delta \mathbf{u}} (\mathcal{B}[\mathbf{u}] + \lambda_2 \mathcal{A}[\mathbf{u}]) = 0 \quad (18.4.3)$$

with, this time, λ_2 the Lagrange multiplier. Multiplying equation (18.4.3) by the constant $1/\lambda_2$, and identifying $1/\lambda_2$ with λ_1 , we see that the actual variations are exactly the same in the two cases. Both cases will yield the same one-parameter family of solutions, say, $\mathbf{u}(\lambda_1)$. As λ_1 varies from 0 to ∞ , the solution $\mathbf{u}(\lambda_1)$ varies along a so-called *trade-off curve* between the problem of minimizing \mathcal{A} and the problem of minimizing \mathcal{B} . Any solution along this curve can equally well be thought of as either (i) a minimization of \mathcal{A} for some constrained value of \mathcal{B} , or (ii) a minimization of \mathcal{B} for some constrained value of \mathcal{A} , or (iii) a weighted minimization of the sum $\mathcal{A} + \lambda_1 \mathcal{B}$.

The second preliminary point has to do with *degenerate* minimization principles. In the example above, now suppose that $\mathcal{A}[\mathbf{u}]$ has the particular form

$$\mathcal{A}[\mathbf{u}] = |\mathbf{A} \cdot \mathbf{u} - \mathbf{c}|^2 \quad (18.4.4)$$

for some matrix \mathbf{A} and vector \mathbf{c} . If \mathbf{A} has fewer rows than columns, or if \mathbf{A} is square but degenerate (has a nontrivial nullspace, see §2.6, especially Figure 2.6.1), then minimizing $\mathcal{A}[\mathbf{u}]$ will *not* give a unique solution for \mathbf{u} . (To see why, review §15.4, and note that for a “design matrix” \mathbf{A} with fewer rows than columns, the matrix $\mathbf{A}^T \cdot \mathbf{A}$ in the normal equations 15.4.10 is degenerate.) However, if we add any multiple λ times a nondegenerate quadratic form $\mathcal{B}[\mathbf{u}]$, for example $\mathbf{u} \cdot \mathbf{H} \cdot \mathbf{u}$ with \mathbf{H} a positive definite matrix, then minimization of $\mathcal{A}[\mathbf{u}] + \lambda \mathcal{B}[\mathbf{u}]$ will lead to a unique solution for \mathbf{u} . (The sum of two quadratic forms is itself a quadratic form, with the second piece guaranteeing nondegeneracy.)

18.4 Inverse Problems and the Use of A Priori Information

Later discussion will be facilitated by some preliminary mention of a couple of mathematical points. Suppose that \mathbf{u} is an “unknown” vector that we plan to determine by some minimization principle. Let $\mathcal{A}[\mathbf{u}] > 0$ and $\mathcal{B}[\mathbf{u}] > 0$ be two positive functionals of \mathbf{u} , so that we can try to determine \mathbf{u} by either

$$\text{minimize: } \mathcal{A}[\mathbf{u}] \quad \text{or} \quad \text{minimize: } \mathcal{B}[\mathbf{u}] \quad (18.4.1)$$

(Of course these will generally give different answers for \mathbf{u} .) As another possibility, now suppose that we want to minimize $\mathcal{A}[\mathbf{u}]$ subject to the *constraint* that $\mathcal{B}[\mathbf{u}]$ have some particular value, say b . The method of Lagrange multipliers gives the variation

$$\frac{\delta}{\delta \mathbf{u}} \{ \mathcal{A}[\mathbf{u}] + \lambda_1 (\mathcal{B}[\mathbf{u}] - b) \} = \frac{\delta}{\delta \mathbf{u}} (\mathcal{A}[\mathbf{u}] + \lambda_1 \mathcal{B}[\mathbf{u}]) = 0 \quad (18.4.2)$$

where λ_1 is a Lagrange multiplier. Notice that b is absent in the second equality, since it doesn’t depend on \mathbf{u} .

Next, suppose that we change our minds and decide to minimize $\mathcal{B}[\mathbf{u}]$ subject to the constraint that $\mathcal{A}[\mathbf{u}]$ have a particular value, a . Instead of equation (18.4.2) we have

$$\frac{\delta}{\delta \mathbf{u}} \{ \mathcal{B}[\mathbf{u}] + \lambda_2 (\mathcal{A}[\mathbf{u}] - a) \} = \frac{\delta}{\delta \mathbf{u}} (\mathcal{B}[\mathbf{u}] + \lambda_2 \mathcal{A}[\mathbf{u}]) = 0 \quad (18.4.3)$$

with, this time, λ_2 the Lagrange multiplier. Multiplying equation (18.4.3) by the constant $1/\lambda_2$, and identifying $1/\lambda_2$ with λ_1 , we see that the actual variations are exactly the same in the two cases. Both cases will yield the same one-parameter family of solutions, say, $\mathbf{u}(\lambda_1)$. As λ_1 varies from 0 to ∞ , the solution $\mathbf{u}(\lambda_1)$ varies along a so-called *trade-off curve* between the problem of minimizing \mathcal{A} and the problem of minimizing \mathcal{B} . Any solution along this curve can equally well be thought of as either (i) a minimization of \mathcal{A} for some constrained value of \mathcal{B} , or (ii) a minimization of \mathcal{B} for some constrained value of \mathcal{A} , or (iii) a weighted minimization of the sum $\mathcal{A} + \lambda_1 \mathcal{B}$.

The second preliminary point has to do with *degenerate* minimization principles. In the example above, now suppose that $\mathcal{A}[\mathbf{u}]$ has the particular form

$$\mathcal{A}[\mathbf{u}] = |\mathbf{A} \cdot \mathbf{u} - \mathbf{c}|^2 \quad (18.4.4)$$

for some matrix \mathbf{A} and vector \mathbf{c} . If \mathbf{A} has fewer rows than columns, or if \mathbf{A} is square but degenerate (has a nontrivial nullspace, see §2.6, especially Figure 2.6.1), then minimizing $\mathcal{A}[\mathbf{u}]$ will *not* give a unique solution for \mathbf{u} . (To see why, review §15.4, and note that for a “design matrix” \mathbf{A} with fewer rows than columns, the matrix $\mathbf{A}^T \cdot \mathbf{A}$ in the normal equations 15.4.10 is degenerate.) However, if we add any multiple λ times a nondegenerate quadratic form $\mathcal{B}[\mathbf{u}]$, for example $\mathbf{u} \cdot \mathbf{H} \cdot \mathbf{u}$ with \mathbf{H} a positive definite matrix, then minimization of $\mathcal{A}[\mathbf{u}] + \lambda \mathcal{B}[\mathbf{u}]$ will lead to a unique solution for \mathbf{u} . (The sum of two quadratic forms is itself a quadratic form, with the second piece guaranteeing nondegeneracy.)

We can combine these two points, for this conclusion: When a quadratic minimization principle is combined with a quadratic constraint, and both are positive, only *one* of the two need be nondegenerate for the overall problem to be well-posed. We are now equipped to face the subject of inverse problems.

The Inverse Problem with Zeroth-Order Regularization

Suppose that $u(x)$ is some unknown or underlying (u stands for both unknown and underlying!) physical process, which we hope to determine by a set of N measurements c_i , $i = 1, 2, \dots, N$. The relation between $u(x)$ and the c_i 's is that each c_i measures a (hopefully distinct) aspect of $u(x)$ through its own linear response kernel r_i , and with its own measurement error n_i . In other words,

$$c_i \equiv s_i + n_i = \int r_i(x)u(x)dx + n_i \quad (18.4.5)$$

(compare this to equations 13.3.1 and 13.3.2). Within the assumption of linearity, this is quite a general formulation. The c_i 's might approximate values of $u(x)$ at certain locations x_i , in which case $r_i(x)$ would have the form of a more or less narrow instrumental response centered around $x = x_i$. Or, the c_i 's might “live” in an entirely different function space from $u(x)$, measuring different Fourier components of $u(x)$ for example.

The *inverse problem* is, given the c_i 's, the $r_i(x)$'s, and perhaps some information about the errors n_i such as their covariance matrix

$$S_{ij} \equiv \text{Covar}[n_i, n_j] \quad (18.4.6)$$

how do we find a good statistical estimator of $u(x)$, call it $\hat{u}(x)$?

It should be obvious that this is an ill-posed problem. After all, how can we reconstruct a whole function $\hat{u}(x)$ from only a finite number of discrete values c_i ? Yet, whether formally or informally, we do this all the time in science. We routinely measure “enough points” and then “draw a curve through them.” In doing so, we are making some assumptions, either about the underlying function $u(x)$, or about the nature of the response functions $r_i(x)$, or both. Our purpose now is to formalize these assumptions, and to extend our abilities to cases where the measurements and underlying function live in quite different function spaces. (How do you “draw a curve” through a scattering of Fourier coefficients?)

We can't really want every point x of the function $\hat{u}(x)$. We do want some large number M of discrete points x_μ , $\mu = 1, 2, \dots, M$, where M is sufficiently large, and the x_μ 's are sufficiently evenly spaced, that neither $u(x)$ nor $r_i(x)$ varies much between any x_μ and $x_{\mu+1}$. (Here and following we will use Greek letters like μ to denote values in the space of the underlying process, and Roman letters like i to denote values of immediate observables.) For such a dense set of x_μ 's, we can replace equation (18.4.5) by a quadrature like

$$c_i = \sum_{\mu} R_{i\mu} u(x_\mu) + n_i \quad (18.4.7)$$

where the $N \times M$ matrix \mathbf{R} has components

$$R_{i\mu} \equiv r_i(x_\mu)(x_{\mu+1} - x_{\mu-1})/2 \quad (18.4.8)$$

(or any other simple quadrature — it rarely matters which). We will view equations (18.4.5) and (18.4.7) as being equivalent for practical purposes.

How do you solve a set of equations like equation (18.4.7) for the unknown $u(x_\mu)$'s? Here is a bad way, but one that contains the germ of some correct ideas: Form a χ^2 measure of how well a model $\hat{u}(x)$ agrees with the measured data,

$$\begin{aligned}\chi^2 &= \sum_{i=1}^N \sum_{j=1}^N \left[c_i - \sum_{\mu=1}^M R_{i\mu} \hat{u}(x_\mu) \right] S_{ij}^{-1} \left[c_j - \sum_{\mu=1}^M R_{j\mu} \hat{u}(x_\mu) \right] \\ &\approx \sum_{i=1}^N \left[\frac{c_i - \sum_{\mu=1}^M R_{i\mu} \hat{u}(x_\mu)}{\sigma_i} \right]^2\end{aligned}\quad (18.4.9)$$

(compare with equation 15.1.5). Here \mathbf{S}^{-1} is the inverse of the covariance matrix, and the approximate equality holds if you can neglect the off-diagonal covariances, with $\sigma_i \equiv (\text{Covar}[i, i])^{1/2}$.

Now you can use the method of singular value decomposition (SVD) in §15.4 to find the vector $\hat{\mathbf{u}}$ that minimizes equation (18.4.9). Don't try to use the method of normal equations; since M is greater than N they will be singular, as we already discussed. The SVD process will thus surely find a large number of zero singular values, indicative of a highly non-unique solution. Among the infinity of degenerate solutions (most of them badly behaved with arbitrarily large $\hat{u}(x_\mu)$'s) SVD will select the one with smallest $|\hat{\mathbf{u}}|$ in the sense of

$$\sum_{\mu} [\hat{u}(x_\mu)]^2 \quad \text{a minimum} \quad (18.4.10)$$

(look at Figure 2.6.1). This solution is often called the *principal solution*. It is a limiting case of what is called *zeroth-order regularization*, corresponding to minimizing the sum of the two positive functionals

$$\text{minimize: } \chi^2[\hat{\mathbf{u}}] + \lambda(\hat{\mathbf{u}} \cdot \hat{\mathbf{u}}) \quad (18.4.11)$$

in the limit of small λ . Below, we will learn how to do such minimizations, as well as more general ones, without the *ad hoc* use of SVD.

What happens if we determine $\hat{\mathbf{u}}$ by equation (18.4.11) with a non-infinitesimal value of λ ? First, note that if $M \gg N$ (many more unknowns than equations), then \mathbf{u} will often have enough freedom to be able to make χ^2 (equation 18.4.9) quite unrealistically small, if not zero. In the language of §15.1, the number of degrees of freedom $\nu = N - M$, which is approximately the expected value of χ^2 when ν is large, is being driven down to zero (and, not meaningfully, beyond). Yet, we know that for the *true* underlying function $u(x)$, which has no adjustable parameters, the number of degrees of freedom and the expected value of χ^2 should be about $\nu \approx N$.

Increasing λ pulls the solution away from minimizing χ^2 in favor of minimizing $\hat{\mathbf{u}} \cdot \hat{\mathbf{u}}$. From the preliminary discussion above, we can view this as minimizing $\hat{\mathbf{u}} \cdot \hat{\mathbf{u}}$ subject to the *constraint* that χ^2 have some constant nonzero value. A popular choice, in fact, is to find that value of λ which yields $\chi^2 = N$, that is, to get about as much extra regularization as a plausible value of χ^2 dictates. The resulting $\hat{u}(x)$ is called the *solution of the inverse problem with zeroth-order regularization*.

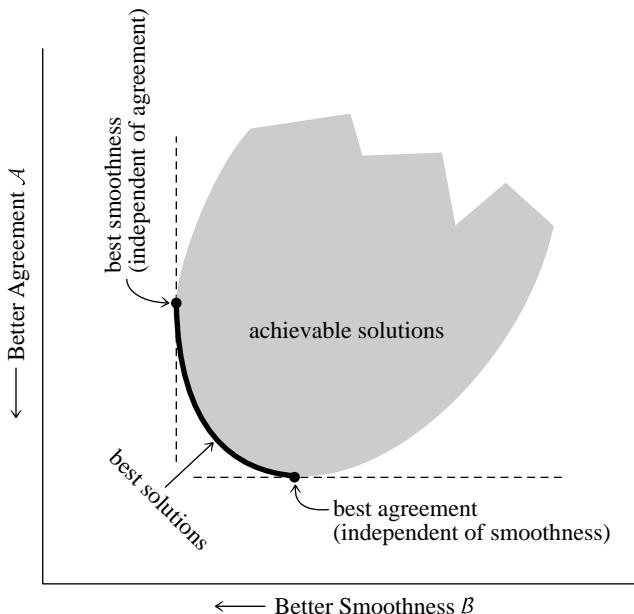

Figure 18.4.1. Almost all inverse problem methods involve a trade-off between two optimizations: agreement between data and solution, or “sharpness” of mapping between true and estimated solution (here denoted \mathcal{A}), and smoothness or stability of the solution (here denoted \mathcal{B}). Among all possible solutions, shown here schematically as the shaded region, those on the boundary connecting the unconstrained minimum of \mathcal{A} and the unconstrained minimum of \mathcal{B} are the “best” solutions, in the sense that every other solution is dominated by at least one solution on the curve.

The value N is actually a surrogate for any value drawn from a Gaussian distribution with mean N and standard deviation $(2N)^{1/2}$ (the asymptotic χ^2 distribution). One might equally plausibly try two values of λ , one giving $\chi^2 = N + (2N)^{1/2}$, the other $N - (2N)^{1/2}$.

Zeroth-order regularization, though dominated by better methods, demonstrates most of the basic ideas that are used in inverse problem theory. In general, there are two positive functionals, call them \mathcal{A} and \mathcal{B} . The first, \mathcal{A} , measures something like the agreement of a model to the data (e.g., χ^2), or sometimes a related quantity like the “sharpness” of the mapping between the solution and the underlying function. When \mathcal{A} by itself is minimized, the agreement or sharpness becomes very good (often impossibly good), but the solution becomes unstable, wildly oscillating, or in other ways unrealistic, reflecting that \mathcal{A} alone typically defines a highly degenerate minimization problem.

That is where \mathcal{B} comes in. It measures something like the “smoothness” of the desired solution, or sometimes a related quantity that parametrizes the stability of the solution with respect to variations in the data, or sometimes a quantity reflecting *a priori* judgments about the likelihood of a solution. \mathcal{B} is called the *stabilizing functional* or *regularizing operator*. In any case, minimizing \mathcal{B} by itself is supposed to give a solution that is “smooth” or “stable” or “likely” — and that has nothing at all to do with the measured data.

The single central idea in inverse theory is the prescription

$$\text{minimize: } \mathcal{A} + \lambda \mathcal{B} \quad (18.4.12)$$

for various values of $0 < \lambda < \infty$ along the so-called trade-off curve (see Figure 18.4.1), and then to settle on a “best” value of λ by one or another criterion, ranging from fairly objective (e.g., making $\chi^2 = N$) to entirely subjective. Successful methods, several of which we will now describe, differ as to their choices of \mathcal{A} and \mathcal{B} , as to whether the prescription (18.4.12) yields linear or nonlinear equations, as to their recommended method for selecting a final λ , and as to their practicality for computer-intensive two-dimensional problems like image processing.

They also differ as to the philosophical baggage that they (or rather, their proponents) carry. We have thus far avoided the word “Bayesian.” (Courts have consistently held that academic license does not extend to shouting “Bayesian” in a crowded lecture hall.) But it is hard, nor have we any wish, to disguise the fact that \mathcal{B} has something to do with *a priori* expectation, or knowledge, of a solution, while \mathcal{A} has something to do with *a posteriori* knowledge. The constant λ adjudicates a delicate compromise between the two. Some inverse methods have acquired a more Bayesian stamp than others, but we think that this is purely an accident of history. An outsider looking only at the equations that are actually solved, and not at the accompanying philosophical justifications, would have a difficult time separating the so-called Bayesian methods from the so-called empirical ones, we think.

The next three sections discuss three different approaches to the problem of inversion, which have had considerable success in different fields. All three fit within the general framework that we have outlined, but they are quite different in detail and in implementation.

18.5 Linear Regularization Methods

What we will call *linear regularization* is also called the *Phillips-Twomey method* [1,2], the *constrained linear inversion method* [3], the *method of regularization* [4], and *Tikhonov-Miller regularization* [5-7]. (It probably has other names also,

since it is so obviously a good idea.) In its simplest form, the method is an immediate generalization of zeroth-order regularization (equation 18.4.11, above). As before, the functional \mathcal{A} is taken to be the χ^2 deviation, equation (18.4.9), but the functional \mathcal{B} is replaced by more sophisticated measures of smoothness that derive from first or higher derivatives.

For example, suppose that your *a priori* belief is that a credible $u(x)$ is not too different from a constant. Then a reasonable functional to minimize is

$$\mathcal{B} \propto \int [\hat{u}'(x)]^2 dx \propto \sum_{\mu=1}^{M-1} [\hat{u}_\mu - \hat{u}_{\mu+1}]^2 \quad (18.5.1)$$

since it is nonnegative and equal to zero only when $\hat{u}(x)$ is constant. Here $\hat{u}_\mu \equiv \hat{u}(x_\mu)$, and the second equality (proportionality) assumes that the x_μ 's are uniformly spaced. We can write the second form of \mathcal{B} as

$$\mathcal{B} = |\mathbf{B} \cdot \hat{\mathbf{u}}|^2 = \hat{\mathbf{u}} \cdot (\mathbf{B}^T \cdot \mathbf{B}) \cdot \hat{\mathbf{u}} \equiv \hat{\mathbf{u}} \cdot \mathbf{H} \cdot \hat{\mathbf{u}} \quad (18.5.2)$$

where $\hat{\mathbf{u}}$ is the vector of components \hat{u}_μ , $\mu = 1, \dots, M$, \mathbf{B} is the $(M-1) \times M$ first difference matrix

$$\mathbf{B} = \begin{pmatrix} -1 & 1 & 0 & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & & & \vdots \\ 0 & \cdots & 0 & 0 & 0 & 0 & -1 & 1 & 0 \\ 0 & \cdots & 0 & 0 & 0 & 0 & 0 & -1 & 1 \end{pmatrix} \quad (18.5.3)$$

and \mathbf{H} is the $M \times M$ matrix

$$\mathbf{H} = \mathbf{B}^T \cdot \mathbf{B} = \begin{pmatrix} 1 & -1 & 0 & 0 & 0 & 0 & 0 & \cdots & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & & & \vdots \\ 0 & \cdots & 0 & 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & \cdots & 0 & 0 & 0 & 0 & -1 & 2 & -1 \\ 0 & \cdots & 0 & 0 & 0 & 0 & 0 & -1 & 1 \end{pmatrix} \quad (18.5.4)$$

Note that \mathbf{B} has one fewer row than column. It follows that the symmetric \mathbf{H} is degenerate; it has exactly one zero eigenvalue corresponding to the *value* of a constant function, any one of which makes \mathcal{B} exactly zero.

If, just as in §15.4, we write

$$A_{i\mu} \equiv R_{i\mu}/\sigma_i \quad b_i \equiv c_i/\sigma_i \quad (18.5.5)$$

then, using equation (18.4.9), the minimization principle (18.4.12) is

$$\text{minimize: } \mathcal{A} + \lambda \mathcal{B} = |\mathbf{A} \cdot \hat{\mathbf{u}} - \mathbf{b}|^2 + \lambda \hat{\mathbf{u}} \cdot \mathbf{H} \cdot \hat{\mathbf{u}} \quad (18.5.6)$$

This can readily be reduced to a linear set of *normal equations*, just as in §15.4: The components \hat{u}_μ of the solution satisfy the set of M equations in M unknowns,

$$\sum_{\rho} \left[\left(\sum_i A_{i\mu} A_{i\rho} \right) + \lambda H_{\mu\rho} \right] \hat{u}_{\rho} = \sum_i A_{i\mu} b_i \quad \mu = 1, 2, \dots, M \quad (18.5.7)$$

or, in vector notation,

$$(\mathbf{A}^T \cdot \mathbf{A} + \lambda \mathbf{H}) \cdot \hat{\mathbf{u}} = \mathbf{A}^T \cdot \mathbf{b} \quad (18.5.8)$$

Equations (18.5.7) or (18.5.8) can be solved by the standard techniques of Chapter 2, e.g., *LU* decomposition. The usual warnings about normal equations being ill-conditioned do not apply, since the whole purpose of the λ term is to cure that same ill-conditioning. Note, however, that the λ term *by itself* is ill-conditioned, since it does not select a preferred constant value. You hope your data can at least do *that!*

Although inversion of the matrix $(\mathbf{A}^T \cdot \mathbf{A} + \lambda \mathbf{H})$ is not generally the best way to solve for $\hat{\mathbf{u}}$, let us digress to write the solution to equation (18.5.8) schematically as

$$\hat{\mathbf{u}} = \left(\frac{1}{\mathbf{A}^T \cdot \mathbf{A} + \lambda \mathbf{H}} \cdot \mathbf{A}^T \cdot \mathbf{A} \right) \mathbf{A}^{-1} \cdot \mathbf{b} \quad (\text{schematic only!}) \quad (18.5.9)$$

where the identity matrix in the form $\mathbf{A} \cdot \mathbf{A}^{-1}$ has been inserted. This is schematic not only because the matrix inverse is fancifully written as a denominator, but also because, in general, the inverse matrix \mathbf{A}^{-1} does not exist. However, it is illuminating to compare equation (18.5.9) with equation (13.3.6) for optimal or Wiener filtering, or with equation (13.6.6) for general linear prediction. One sees that $\mathbf{A}^T \cdot \mathbf{A}$ plays the role of S^2 , the signal power or autocorrelation, while $\lambda \mathbf{H}$ plays the role of N^2 , the noise power or autocorrelation. The term in parentheses in equation (18.5.9) is something like an optimal filter, whose effect is to pass the ill-posed inverse $\mathbf{A}^{-1} \cdot \mathbf{b}$ through unmodified when $\mathbf{A}^T \cdot \mathbf{A}$ is sufficiently large, but to suppress it when $\mathbf{A}^T \cdot \mathbf{A}$ is small.

The above choices of \mathbf{B} and \mathbf{H} are only the simplest in an obvious sequence of derivatives. If your *a priori* belief is that a *linear* function is a good approximation to $u(x)$, then minimize

$$\mathcal{B} \propto \int [\hat{u}''(x)]^2 dx \propto \sum_{\mu=1}^{M-2} [-\hat{u}_\mu + 2\hat{u}_{\mu+1} - \hat{u}_{\mu+2}]^2 \quad (18.5.10)$$

implying

$$\mathbf{B} = \begin{pmatrix} -1 & 2 & -1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 2 & -1 & 0 & 0 & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & & & \vdots \\ 0 & \cdots & 0 & 0 & 0 & -1 & 2 & -1 & 0 \\ 0 & \cdots & 0 & 0 & 0 & 0 & -1 & 2 & -1 \end{pmatrix} \quad (18.5.11)$$

and

$$\mathbf{H} = \mathbf{B}^T \cdot \mathbf{B} = \begin{pmatrix} 1 & -2 & 1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ -2 & 5 & -4 & 1 & 0 & 0 & 0 & \cdots & 0 \\ 1 & -4 & 6 & -4 & 1 & 0 & 0 & \cdots & 0 \\ 0 & 1 & -4 & 6 & -4 & 1 & 0 & \cdots & 0 \\ \vdots & & & \ddots & & & & & \vdots \\ 0 & \cdots & 0 & 1 & -4 & 6 & -4 & 1 & 0 \\ 0 & \cdots & 0 & 0 & 1 & -4 & 6 & -4 & 1 \\ 0 & \cdots & 0 & 0 & 0 & 1 & -4 & 5 & -2 \\ 0 & \cdots & 0 & 0 & 0 & 0 & 1 & -2 & 1 \end{pmatrix} \quad (18.5.12)$$

This \mathbf{H} has two zero eigenvalues, corresponding to the two undetermined parameters of a linear function.

If your *a priori* belief is that a *quadratic* function is preferable, then minimize

$$\mathcal{B} \propto \int [\hat{u}'''(x)]^2 dx \propto \sum_{\mu=1}^{M-3} [-\hat{u}_\mu + 3\hat{u}_{\mu+1} - 3\hat{u}_{\mu+2} + \hat{u}_{\mu+3}]^2 \quad (18.5.13)$$

with

$$\mathbf{B} = \begin{pmatrix} -1 & 3 & -3 & 1 & 0 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 3 & -3 & 1 & 0 & 0 & \cdots & 0 \\ \vdots & & & & \ddots & & & & \vdots \\ 0 & \cdots & 0 & 0 & -1 & 3 & -3 & 1 & 0 \\ 0 & \cdots & 0 & 0 & 0 & -1 & 3 & -3 & 1 \end{pmatrix} \quad (18.5.14)$$

and now

$$\mathbf{H} = \begin{pmatrix} 1 & -3 & 3 & -1 & 0 & 0 & 0 & 0 & 0 & \cdots & 0 \\ -3 & 10 & -12 & 6 & -1 & 0 & 0 & 0 & 0 & \cdots & 0 \\ 3 & -12 & 19 & -15 & 6 & -1 & 0 & 0 & 0 & \cdots & 0 \\ -1 & 6 & -15 & 20 & -15 & 6 & -1 & 0 & 0 & \cdots & 0 \\ 0 & -1 & 6 & -15 & 20 & -15 & 6 & -1 & 0 & \cdots & 0 \\ \vdots & & & & \ddots & & & & & & \vdots \\ 0 & \cdots & 0 & -1 & 6 & -15 & 20 & -15 & 6 & -1 & 0 \\ 0 & \cdots & 0 & 0 & -1 & 6 & -15 & 20 & -15 & 6 & -1 \\ 0 & \cdots & 0 & 0 & 0 & -1 & 6 & -15 & 19 & -12 & 3 \\ 0 & \cdots & 0 & 0 & 0 & 0 & -1 & 6 & -12 & 10 & -3 \\ 0 & \cdots & 0 & 0 & 0 & 0 & 0 & -1 & 3 & -3 & 1 \end{pmatrix} \quad (18.5.15)$$

(We'll leave the calculation of cubics and above to the compulsive reader.)

Notice that you can regularize with "closeness to a differential equation," if you want. Just pick \mathbf{B} to be the appropriate sum of finite-difference operators (the coefficients can depend on x), and calculate $\mathbf{H} = \mathbf{B}^T \cdot \mathbf{B}$. You don't need to know the values of your boundary conditions, since \mathbf{B} can have fewer rows than columns, as above; hopefully, your data will determine them. Of course, if you do know some boundary conditions, you can build these into \mathbf{B} too.

With all the proportionality signs above, you may have lost track of what actual value of λ to try first. A simple trick for at least getting "on the map" is to first try

$$\lambda = \text{Tr}(\mathbf{A}^T \cdot \mathbf{A}) / \text{Tr}(\mathbf{H}) \quad (18.5.16)$$

where Tr is the trace of the matrix (sum of diagonal components). This choice will tend to make the two parts of the minimization have comparable weights, and you can adjust from there.

As for what is the "correct" value of λ , an objective criterion, if you know your errors σ_i with reasonable accuracy, is to make χ^2 (that is, $|\mathbf{A} \cdot \hat{\mathbf{u}} - \mathbf{b}|^2$) equal to N , the number of measurements. We remarked above on the twin acceptable choices $N \pm (2N)^{1/2}$. A subjective criterion is to pick any value that you like in the

range $0 < \lambda < \infty$, depending on your relative degree of belief in the *a priori* and *a posteriori* evidence. (Yes, people actually do that. Don't blame us.)

Two-Dimensional Problems and Iterative Methods

Up to now our notation has been indicative of a one-dimensional problem, finding $\hat{u}(x)$ or $\hat{u}_\mu = \hat{u}(x_\mu)$. However, all of the discussion easily generalizes to the problem of estimating a two-dimensional set of unknowns $\hat{u}_{\mu\kappa}$, $\mu = 1, \dots, M$, $\kappa = 1, \dots, K$, corresponding, say, to the pixel intensities of a measured image. In this case, equation (18.5.8) is still the one we want to solve.

In image processing, it is usual to have the same number of input pixels in a measured “raw” or “dirty” image as desired “clean” pixels in the processed output image, so the matrices \mathbf{R} and \mathbf{A} (equation 18.5.5) are square and of size $MK \times MK$. \mathbf{A} is typically much too large to represent as a full matrix, but often it is either (i) sparse, with coefficients blurring an underlying pixel (i, j) only into measurements $(i \pm \text{few}, j \pm \text{few})$, or (ii) translationally invariant, so that $A_{(i,j)(\mu,\nu)} = A(i-\mu, j-\nu)$. Both of these situations lead to tractable problems.

In the case of translational invariance, fast Fourier transforms (FFTs) are the obvious method of choice. The general linear relation between underlying function and measured values (18.4.7) now becomes a discrete convolution like equation (13.1.1). If \mathbf{k} denotes a two-dimensional wave-vector, then the two-dimensional FFT takes us back and forth between the transform pairs

$$A(i - \mu, j - \nu) \iff \tilde{\mathbf{A}}(\mathbf{k}) \quad b_{(i,j)} \iff \tilde{b}(\mathbf{k}) \quad \hat{u}_{(i,j)} \iff \tilde{u}(\mathbf{k}) \quad (18.5.17)$$

We also need a regularization or smoothing operator \mathbf{B} and the derived $\mathbf{H} = \mathbf{B}^T \cdot \mathbf{B}$. One popular choice for \mathbf{B} is the five-point finite-difference approximation of the Laplacian operator, that is, the difference between the value of each point and the average of its four Cartesian neighbors. In Fourier space, this choice implies,

$$\begin{aligned} \tilde{B}(\mathbf{k}) &\propto \sin^2(\pi k_1/M) \sin^2(\pi k_2/K) \\ \tilde{H}(\mathbf{k}) &\propto \sin^4(\pi k_1/M) \sin^4(\pi k_2/K) \end{aligned} \quad (18.5.18)$$

In Fourier space, equation (18.5.7) is merely algebraic, with solution

$$\tilde{u}(\mathbf{k}) = \frac{\tilde{A}^*(\mathbf{k})\tilde{b}(\mathbf{k})}{|\tilde{A}(\mathbf{k})|^2 + \lambda\tilde{H}(\mathbf{k})} \quad (18.5.19)$$

where asterisk denotes complex conjugation. You can make use of the FFT routines for real data in §12.5.

Turn now to the case where \mathbf{A} is not translationally invariant. Direct solution of (18.5.8) is now hopeless, since the matrix \mathbf{A} is just too large. We need some kind of iterative scheme.

One way to proceed is to use the full machinery of the conjugate gradient method in §10.6 to find the minimum of $\mathcal{A} + \lambda\mathcal{B}$, equation (18.5.6). Of the various methods in Chapter 10, conjugate gradient is the unique best choice because (i) it does not require storage of a Hessian matrix, which would be infeasible here,

and (ii) it does exploit gradient information, which we can readily compute: The gradient of equation (18.5.6) is

$$\nabla(\mathcal{A} + \lambda\mathcal{B}) = 2[(\mathbf{A}^T \cdot \mathbf{A} + \lambda\mathbf{H}) \cdot \hat{\mathbf{u}} - \mathbf{A}^T \cdot \mathbf{b}] \quad (18.5.20)$$

(cf. 18.5.8). Evaluation of both the function and the gradient should of course take advantage of the sparsity of \mathbf{A} , for example via the routines `sprax` and `sprstx` in §2.7. We will discuss the conjugate gradient technique further in §18.7, in the context of the (nonlinear) maximum entropy method. Some of that discussion can apply here as well.

The conjugate gradient method notwithstanding, application of the unsophisticated steepest descent method (see §10.6) can sometimes produce useful results, particularly when combined with projections onto convex sets (see below). If the solution after k iterations is denoted $\hat{\mathbf{u}}^{(k)}$, then after $k + 1$ iterations we have

$$\hat{\mathbf{u}}^{(k+1)} = [\mathbf{1} - \epsilon(\mathbf{A}^T \cdot \mathbf{A} + \lambda\mathbf{H})] \cdot \hat{\mathbf{u}}^{(k)} + \epsilon\mathbf{A}^T \cdot \mathbf{b} \quad (18.5.21)$$

Here ϵ is a parameter that dictates how far to move in the downhill gradient direction. The method converges when ϵ is small enough, in particular satisfying

$$0 < \epsilon < \frac{2}{\text{max eigenvalue } (\mathbf{A}^T \cdot \mathbf{A} + \lambda\mathbf{H})} \quad (18.5.22)$$

There exist complicated schemes for finding optimal values or sequences for ϵ , see [7]; or, one can adopt an experimental approach, evaluating (18.5.6) to be sure that downhill steps are in fact being taken.

In those image processing problems where the final measure of success is somewhat subjective (e.g., “how good does the picture look?”), iteration (18.5.21) sometimes produces significantly improved images long before convergence is achieved. This probably accounts for much of its use, since its mathematical convergence is extremely slow. In fact, (18.5.21) can be used with $\mathbf{H} = 0$, in which case the solution is not regularized at all, and full convergence would be disastrous! This is called *Van Cittert’s method* and goes back to the 1930s. A number of iterations the order of 1000 is not uncommon [7].

Deterministic Constraints: Projections onto Convex Sets

A set of possible underlying functions (or images) $\{\hat{\mathbf{u}}\}$ is said to be *convex* if, for any two elements $\hat{\mathbf{u}}_a$ and $\hat{\mathbf{u}}_b$ in the set, all the linearly interpolated combinations

$$(1 - \eta)\hat{\mathbf{u}}_a + \eta\hat{\mathbf{u}}_b \quad 0 \leq \eta \leq 1 \quad (18.5.23)$$

are also in the set. Many *deterministic constraints* that one might want to impose on the solution $\hat{\mathbf{u}}$ to an inverse problem in fact define convex sets, for example:

- positivity
- compact support (i.e., zero value outside of a certain region)

- known bounds (i.e., $u_L(x) \leq \hat{u}(x) \leq u_U(x)$ for specified functions u_L and u_U).

(In this last case, the bounds might be related to an initial estimate and its error bars, e.g., $\hat{u}_0(x) \pm \gamma\sigma(x)$, where γ is of order 1 or 2.) Notice that these, and similar, constraints can be either in the image space, or in the Fourier transform space, or (in fact) in the space of any linear transformation of $\hat{\mathbf{u}}$.

If C_i is a convex set, then \mathcal{P}_i is called a *nonexpansive projection operator* onto that set if (i) \mathcal{P}_i leaves unchanged any $\hat{\mathbf{u}}$ already in C_i , and (ii) \mathcal{P}_i maps any $\hat{\mathbf{u}}$ outside C_i to the *closest* element of C_i , in the sense that

$$|\mathcal{P}_i \hat{\mathbf{u}} - \hat{\mathbf{u}}| \leq |\hat{\mathbf{u}}_a - \hat{\mathbf{u}}| \quad \text{for all } \hat{\mathbf{u}}_a \text{ in } C_i \quad (18.5.24)$$

While this definition sounds complicated, examples are very simple: A nonexpansive projection onto the set of positive $\hat{\mathbf{u}}$'s is “set all negative components of $\hat{\mathbf{u}}$ equal to zero.” A nonexpansive projection onto the set of $\hat{u}(x)$'s bounded by $u_L(x) \leq \hat{u}(x) \leq u_U(x)$ is “set all values less than the lower bound equal to that bound, and set all values greater than the upper bound equal to *that* bound.” A nonexpansive projection onto functions with compact support is “zero the values outside of the region of support.”

The usefulness of these definitions is the following remarkable theorem: Let C be the intersection of m convex sets C_1, C_2, \dots, C_m . Then the iteration

$$\hat{\mathbf{u}}^{(k+1)} = (\mathcal{P}_1 \mathcal{P}_2 \cdots \mathcal{P}_m) \hat{\mathbf{u}}^{(k)} \quad (18.5.25)$$

will converge to C from all starting points, as $k \rightarrow \infty$. Also, if C is empty (there is no intersection), then the iteration will have no limit point. Application of this theorem is called the *method of projections onto convex sets* or sometimes *POCS* [7].

A generalization of the POCS theorem is that the \mathcal{P}_i 's can be replaced by a set of \mathcal{T}_i 's,

$$\mathcal{T}_i \equiv \mathbf{1} + \beta_i (\mathcal{P}_i - \mathbf{1}) \quad 0 < \beta_i < 2 \quad (18.5.26)$$

A well-chosen set of β_i 's can accelerate the convergence to the intersection set C .

Some inverse problems can be completely solved by iteration (18.5.25) alone! For example, a problem that occurs in both astronomical imaging and X-ray diffraction work is to recover an image given only the *modulus* of its Fourier transform (equivalent to its power spectrum or autocorrelation) and not the *phase*. Here three convex sets can be utilized: the set of all images whose Fourier transform has the specified modulus to within specified error bounds; the set of all positive images; and the set of all images with zero intensity outside of some specified region. In this case the POCS iteration (18.5.25) cycles among these three, imposing each constraint in turn; FFTs are used to get in and out of Fourier space each time the Fourier constraint is imposed.

The specific application of POCS to constraints alternately in the spatial and Fourier domains is also known as the *Gerchberg-Saxton* algorithm [8]. While this algorithm is non-expansive, and is frequently convergent in practice, it has not been proved to converge in all cases [9]. In the phase-retrieval problem mentioned above, the algorithm often “gets stuck” on a plateau for many iterations before making sudden, dramatic improvements. As many as 10^4 to 10^5 iterations are sometimes

necessary. (For “unsticking” procedures, see [10].) The uniqueness of the solution is also not well understood, although for two-dimensional images of reasonable complexity it is believed to be unique.

Deterministic constraints can be incorporated, via projection operators, into iterative methods of linear regularization. In particular, rearranging terms somewhat, we can write the iteration (18.5.21) as

$$\hat{\mathbf{u}}^{(k+1)} = (\mathbf{1} - \epsilon\lambda\mathbf{H}) \cdot \hat{\mathbf{u}}^{(k)} + \epsilon\mathbf{A}^T \cdot (\mathbf{b} - \mathbf{A} \cdot \hat{\mathbf{u}}^{(k)}) \quad (18.5.27)$$

If the iteration is modified by the insertion of projection operators at each step

$$\hat{\mathbf{u}}^{(k+1)} = (\mathcal{P}_1\mathcal{P}_2 \cdots \mathcal{P}_m)[(\mathbf{1} - \epsilon\lambda\mathbf{H}) \cdot \hat{\mathbf{u}}^{(k)} + \epsilon\mathbf{A}^T \cdot (\mathbf{b} - \mathbf{A} \cdot \hat{\mathbf{u}}^{(k)})] \quad (18.5.28)$$

(or, instead of \mathcal{P}_i ’s, the T_i operators of equation 18.5.26), then it can be shown that the convergence condition (18.5.22) is unmodified, and the iteration will converge to minimize the quadratic functional (18.5.6) subject to the desired nonlinear deterministic constraints. See [7] for references to more sophisticated, and faster converging, iterations along these lines.

18.6 Backus-Gilbert Method

The *Backus-Gilbert method* [1,2] (see, e.g., [3] or [4] for summaries) differs from other regularization methods in the nature of its functionals \mathcal{A} and \mathcal{B} . For \mathcal{B} , the method seeks to maximize the *stability* of the solution $\hat{u}(x)$ rather than, in the first instance, its smoothness. That is,

$$\mathcal{B} \equiv \text{Var}[\hat{u}(x)] \quad (18.6.1)$$

necessary. (For “unsticking” procedures, see [10].) The uniqueness of the solution is also not well understood, although for two-dimensional images of reasonable complexity it is believed to be unique.

Deterministic constraints can be incorporated, via projection operators, into iterative methods of linear regularization. In particular, rearranging terms somewhat, we can write the iteration (18.5.21) as

$$\hat{\mathbf{u}}^{(k+1)} = (\mathbf{1} - \epsilon\lambda\mathbf{H}) \cdot \hat{\mathbf{u}}^{(k)} + \epsilon\mathbf{A}^T \cdot (\mathbf{b} - \mathbf{A} \cdot \hat{\mathbf{u}}^{(k)}) \quad (18.5.27)$$

If the iteration is modified by the insertion of projection operators at each step

$$\hat{\mathbf{u}}^{(k+1)} = (\mathcal{P}_1\mathcal{P}_2 \cdots \mathcal{P}_m)[(\mathbf{1} - \epsilon\lambda\mathbf{H}) \cdot \hat{\mathbf{u}}^{(k)} + \epsilon\mathbf{A}^T \cdot (\mathbf{b} - \mathbf{A} \cdot \hat{\mathbf{u}}^{(k)})] \quad (18.5.28)$$

(or, instead of \mathcal{P}_i ’s, the T_i operators of equation 18.5.26), then it can be shown that the convergence condition (18.5.22) is unmodified, and the iteration will converge to minimize the quadratic functional (18.5.6) subject to the desired nonlinear deterministic constraints. See [7] for references to more sophisticated, and faster converging, iterations along these lines.

18.6 Backus-Gilbert Method

The *Backus-Gilbert method* [1,2] (see, e.g., [3] or [4] for summaries) differs from other regularization methods in the nature of its functionals \mathcal{A} and \mathcal{B} . For \mathcal{B} , the method seeks to maximize the *stability* of the solution $\hat{u}(x)$ rather than, in the first instance, its smoothness. That is,

$$\mathcal{B} \equiv \text{Var}[\hat{u}(x)] \quad (18.6.1)$$

is used as a measure of how much the solution $\hat{u}(x)$ varies as the data vary within their measurement errors. Note that this variance is not the expected deviation of $\hat{u}(x)$ from the true $u(x)$ — that will be constrained by \mathcal{A} — but rather measures the expected experiment-to-experiment scatter among estimates $\hat{u}(x)$ if the whole experiment were to be repeated many times.

For \mathcal{A} the Backus-Gilbert method looks at the relationship between the solution $\hat{u}(x)$ and the true function $u(x)$, and seeks to make the mapping between these as close to the identity map as possible in the limit of error-free data. The method is linear, so the relationship between $\hat{u}(x)$ and $u(x)$ can be written as

$$\hat{u}(x) = \int \hat{\delta}(x, x') u(x') dx' \quad (18.6.2)$$

for some so-called *resolution function* or *averaging kernel* $\hat{\delta}(x, x')$. The Backus-Gilbert method seeks to minimize the width or *spread* of $\hat{\delta}$ (that is, maximize the resolving power). \mathcal{A} is chosen to be some positive measure of the spread.

While Backus-Gilbert's philosophy is thus rather different from that of Phillips-Twomey and related methods, in practice the differences between the methods are less than one might think. A *stable* solution is almost inevitably bound to be *smooth*: The wild, unstable oscillations that result from an unregularized solution are always exquisitely sensitive to small changes in the data. Likewise, making $\hat{u}(x)$ close to $u(x)$ inevitably will bring error-free data into agreement with the model. Thus \mathcal{A} and \mathcal{B} play roles closely analogous to their corresponding roles in the previous two sections.

The principal advantage of the Backus-Gilbert formulation is that it gives good control over just those properties that it seeks to measure, namely stability and resolving power. Moreover, in the Backus-Gilbert method, the choice of λ (playing its usual role of compromise between \mathcal{A} and \mathcal{B}) is conventionally made, or at least can easily be made, *before* any actual data are processed. One's uneasiness at making a *post hoc*, and therefore potentially subjectively biased, choice of λ is thus removed. Backus-Gilbert is often recommended as the method of choice for designing, and predicting the performance of, experiments that require data inversion.

Let's see how this all works. Starting with equation (18.4.5),

$$c_i \equiv s_i + n_i = \int r_i(x) u(x) dx + n_i \quad (18.6.3)$$

and building in linearity from the start, we seek a set of *inverse response kernels* $q_i(x)$ such that

$$\hat{u}(x) = \sum_i q_i(x) c_i \quad (18.6.4)$$

is the desired estimator of $u(x)$. It is useful to define the integrals of the response kernels for each data point,

$$R_i \equiv \int r_i(x) dx \quad (18.6.5)$$

Substituting equation (18.6.4) into equation (18.6.3), and comparing with equation (18.6.2), we see that

$$\hat{\delta}(x, x') = \sum_i q_i(x) r_i(x') \quad (18.6.6)$$

We can require this averaging kernel to have unit area at every x , giving

$$1 = \int \hat{\delta}(x, x') dx' = \sum_i q_i(x) \int r_i(x') dx' = \sum_i q_i(x) R_i \equiv \mathbf{q}(x) \cdot \mathbf{R} \quad (18.6.7)$$

where $\mathbf{q}(x)$ and \mathbf{R} are each vectors of length N , the number of measurements.

Standard propagation of errors, and equation (18.6.1), give

$$\mathcal{B} = \text{Var}[\hat{u}(x)] = \sum_i \sum_j q_i(x) S_{ij} q_j(x) = \mathbf{q}(x) \cdot \mathbf{S} \cdot \mathbf{q}(x) \quad (18.6.8)$$

where S_{ij} is the covariance matrix (equation 18.4.6). If one can neglect off-diagonal covariances (as when the errors on the c_i 's are independent), then $S_{ij} = \delta_{ij} \sigma_i^2$ is diagonal.

We now need to define a measure of the width or spread of $\hat{\delta}(x, x')$ at each value of x . While many choices are possible, Backus and Gilbert choose the second moment of its square. This measure becomes the functional \mathcal{A} ,

$$\begin{aligned} \mathcal{A} \equiv w(x) &= \int (x' - x)^2 [\hat{\delta}(x, x')]^2 dx' \\ &= \sum_i \sum_j q_i(x) W_{ij}(x) q_j(x) \equiv \mathbf{q}(x) \cdot \mathbf{W}(x) \cdot \mathbf{q}(x) \end{aligned} \quad (18.6.9)$$

where we have here used equation (18.6.6) and defined the *spread matrix* $\mathbf{W}(x)$ by

$$W_{ij}(x) \equiv \int (x' - x)^2 r_i(x') r_j(x') dx' \quad (18.6.10)$$

The functions $q_i(x)$ are now determined by the minimization principle

$$\text{minimize: } \mathcal{A} + \lambda \mathcal{B} = \mathbf{q}(x) \cdot [\mathbf{W}(x) + \lambda \mathbf{S}] \cdot \mathbf{q}(x) \quad (18.6.11)$$

subject to the constraint (18.6.7) that $\mathbf{q}(x) \cdot \mathbf{R} = 1$.

The solution of equation (18.6.11) is

$$\mathbf{q}(x) = \frac{[\mathbf{W}(x) + \lambda \mathbf{S}]^{-1} \cdot \mathbf{R}}{\mathbf{R} \cdot [\mathbf{W}(x) + \lambda \mathbf{S}]^{-1} \cdot \mathbf{R}} \quad (18.6.12)$$

(Reference [4] gives an accessible proof.) For any particular data set \mathbf{c} (set of measurements c_i), the solution $\hat{u}(x)$ is thus

$$\hat{u}(x) = \frac{\mathbf{c} \cdot [\mathbf{W}(x) + \lambda \mathbf{S}]^{-1} \cdot \mathbf{R}}{\mathbf{R} \cdot [\mathbf{W}(x) + \lambda \mathbf{S}]^{-1} \cdot \mathbf{R}} \quad (18.6.13)$$

(Don't let this notation mislead you into inverting the full matrix $\mathbf{W}(x) + \lambda\mathbf{S}$. You only need to solve for some \mathbf{y} the linear system $(\mathbf{W}(x) + \lambda\mathbf{S}) \cdot \mathbf{y} = \mathbf{R}$, and then substitute \mathbf{y} into both the numerators and denominators of 18.6.12 or 18.6.13.)

Equations (18.6.12) and (18.6.13) have a completely different character from the linearly regularized solutions to (18.5.7) and (18.5.8). The vectors and matrices in (18.6.12) all have size N , the number of measurements. There is no discretization of the underlying variable x , so M does not come into play at all. One solves a different $N \times N$ set of linear equations for each desired value of x . By contrast, in (18.5.8), one solves an $M \times M$ linear set, but only once. In general, the computational burden of repeatedly solving linear systems makes the Backus-Gilbert method unsuitable for other than one-dimensional problems.

How does one choose λ within the Backus-Gilbert scheme? As already mentioned, you can (in some cases *should*) make the choice *before* you see any actual data. For a given trial value of λ , and for a sequence of x 's, use equation (18.6.12) to calculate $\mathbf{q}(x)$; then use equation (18.6.6) to plot the resolution functions $\hat{\delta}(x, x')$ as a function of x' . These plots will exhibit the amplitude with which different underlying values x' contribute to the point $\hat{u}(x)$ of your estimate. For the same value of λ , also plot the function $\sqrt{\text{Var}[\hat{u}(x)]}$ using equation (18.6.8). (You need an estimate of your measurement covariance matrix for this.)

As you change λ you will see very explicitly the trade-off between resolution and stability. Pick the value that meets your needs. You can even choose λ to be a function of x , $\lambda = \lambda(x)$, in equations (18.6.12) and (18.6.13), should you desire to do so. (This is one benefit of solving a separate set of equations for each x .) For the chosen value or values of λ , you now have a quantitative understanding of your inverse solution procedure. This can prove invaluable if — once you are processing real data — you need to judge whether a particular feature, a spike or jump for example, is genuine, and/or is actually resolved. The Backus-Gilbert method has found particular success among geophysicists, who use it to obtain information about the structure of the Earth (e.g., density run with depth) from seismic travel time data.

18.7 Maximum Entropy Image Restoration

Above, we commented that the association of certain inversion methods with Bayesian arguments is more historical accident than intellectual imperative. *Maximum entropy methods*, so-called, are notorious in this regard; to summarize these methods without some, at least introductory, Bayesian invocations would be to serve a steak without the sizzle, or a sundae without the cherry. We should

also comment in passing that the connection between maximum entropy inversion methods, considered here, and maximum entropy spectral estimation, discussed in §13.7, is rather abstract. For practical purposes the two techniques, though both named *maximum entropy method* or *MEM*, are unrelated.

Bayes' Theorem, which follows from the standard axioms of probability, relates the conditional probabilities of two events, say A and B :

$$\text{Prob}(A|B) = \text{Prob}(A) \frac{\text{Prob}(B|A)}{\text{Prob}(B)} \quad (18.7.1)$$

Here $\text{Prob}(A|B)$ is the probability of A given that B has occurred, and similarly for $\text{Prob}(B|A)$, while $\text{Prob}(A)$ and $\text{Prob}(B)$ are unconditional probabilities.

“Bayesians” (so-called) adopt a broader interpretation of probabilities than do so-called “frequentists.” To a Bayesian, $P(A|B)$ is a measure of the degree of plausibility of A (given B) on a scale ranging from zero to one. In this broader view, A and B need not be repeatable events; they can be propositions or hypotheses. The equations of probability theory then become a set of consistent rules for conducting inference [1,2]. Since plausibility is itself always conditioned on some, perhaps unarticulated, set of assumptions, all Bayesian probabilities are viewed as conditional on some collective background information I .

Suppose H is some hypothesis. Even before there exist any explicit data, a Bayesian can assign to H some degree of plausibility $\text{Prob}(H|I)$, called the “Bayesian prior.” Now, when some data D_1 comes along, Bayes theorem tells how to reassess the plausibility of H ,

$$\text{Prob}(H|D_1I) = \text{Prob}(H|I) \frac{\text{Prob}(D_1|HI)}{\text{Prob}(D_1|I)} \quad (18.7.2)$$

The factor in the numerator on the right of equation (18.7.2) is calculable as the probability of a data set given the hypothesis (compare with “likelihood” in §15.1). The denominator, called the “prior predictive probability” of the data, is in this case merely a normalization constant which can be calculated by the requirement that the probability of all hypotheses should sum to unity. (In other Bayesian contexts, the prior predictive probabilities of two qualitatively different models can be used to assess their relative plausibility.)

If some additional data D_2 comes along tomorrow, we can further refine our estimate of H 's probability, as

$$\text{Prob}(H|D_2D_1I) = \text{Prob}(H|D_1I) \frac{\text{Prob}(D_2|HD_1I)}{\text{Prob}(D_2|D_1I)} \quad (18.7.3)$$

Using the product rule for probabilities, $\text{Prob}(AB|C) = \text{Prob}(A|C)\text{Prob}(B|AC)$, we find that equations (18.7.2) and (18.7.3) imply

$$\text{Prob}(H|D_2D_1I) = \text{Prob}(H|I) \frac{\text{Prob}(D_2D_1|HI)}{\text{Prob}(D_2D_1|I)} \quad (18.7.4)$$

which shows that we would have gotten the same answer if all the data D_1D_2 had been taken together.

From a Bayesian perspective, inverse problems are inference problems [3,4]. The underlying parameter set \mathbf{u} is a hypothesis whose probability, given the measured data values \mathbf{c} , and the Bayesian prior $\text{Prob}(\mathbf{u}|I)$ can be calculated. We might want to report a single “best” inverse \mathbf{u} , the one that maximizes

$$\text{Prob}(\mathbf{u}|\mathbf{c}I) = \text{Prob}(\mathbf{c}|\mathbf{u}I) \frac{\text{Prob}(\mathbf{u}|I)}{\text{Prob}(\mathbf{c}|I)} \quad (18.7.5)$$

over all possible choices of \mathbf{u} . Bayesian analysis also admits the possibility of reporting additional information that characterizes the region of possible \mathbf{u} 's with high relative probability, the so-called “posterior bubble” in \mathbf{u} .

The calculation of the probability of the data \mathbf{c} , given the hypothesis \mathbf{u} proceeds exactly as in the maximum likelihood method. For Gaussian errors, e.g., it is given by

$$\text{Prob}(\mathbf{c}|\mathbf{u}I) = \exp\left(-\frac{1}{2}\chi^2\right) \Delta u_1 \Delta u_2 \cdots \Delta u_M \quad (18.7.6)$$

where χ^2 is calculated from \mathbf{u} and \mathbf{c} using equation (18.4.9), and the Δu_μ 's are constant, small ranges of the components of \mathbf{u} whose actual magnitude is irrelevant, because they do not depend on \mathbf{u} (compare equations 15.1.3 and 15.1.4).

In maximum likelihood estimation we, in effect, chose the prior $\text{Prob}(\mathbf{u}|I)$ to be constant. That was a luxury that we could afford when estimating a small number of parameters from a large amount of data. Here, the number of “parameters” (components of \mathbf{u}) is comparable to or larger than the number of measured values (components of \mathbf{c}); we *need* to have a nontrivial prior, $\text{Prob}(\mathbf{u}|I)$, to resolve the degeneracy of the solution.

In maximum entropy image restoration, that is where *entropy* comes in. The entropy of a physical system in some macroscopic state, usually denoted S , is the logarithm of the number of microscopically distinct configurations that all have the same macroscopic observables (i.e., consistent with the observed macroscopic state). Actually, we will find it useful to denote the *negative* of the entropy, also called the *negentropy*, by $H \equiv -S$ (a notation that goes back to Boltzmann). In situations where there is reason to believe that the *a priori* probabilities of the *microscopic* configurations are all the same (these situations are called *ergodic*), then the Bayesian prior $\text{Prob}(\mathbf{u}|I)$ for a *macroscopic* state with entropy S is proportional to $\exp(S)$ or $\exp(-H)$.

MEM uses this concept to assign a prior probability to any given underlying function \mathbf{u} . For example [5-7], suppose that the measurement of luminance in each pixel is quantized to (in some units) an integer value. Let

$$U = \sum_{\mu=1}^M u_\mu \quad (18.7.7)$$

be the total number of luminance quanta in the whole image. Then we can base our “prior” on the notion that each luminance quantum has an equal *a priori* chance of being in any pixel. (See [8] for a more abstract justification of this idea.) The number of ways of getting a particular configuration \mathbf{u} is

$$\frac{U!}{u_1!u_2!\cdots u_M!} \propto \exp \left[- \sum_{\mu} u_\mu \ln(u_\mu/U) + \frac{1}{2} \left(\ln U - \sum_{\mu} \ln u_\mu \right) \right] \quad (18.7.8)$$

Here the left side can be understood as the number of distinct orderings of all the luminance quanta, divided by the numbers of equivalent reorderings within each pixel, while the right side follows by Stirling's approximation to the factorial function. Taking the negative of the logarithm, and neglecting terms of order $\log U$ in the presence of terms of order U , we get the negentropy

$$H(\mathbf{u}) = \sum_{\mu=1}^M u_\mu \ln(u_\mu/U) \quad (18.7.9)$$

From equations (18.7.5), (18.7.6), and (18.7.9) we now seek to maximize

$$\text{Prob}(\mathbf{u}|\mathbf{c}) \propto \exp\left[-\frac{1}{2}\chi^2\right] \exp[-H(\mathbf{u})] \quad (18.7.10)$$

or, equivalently,

$$\text{minimize: } -\ln[\text{Prob}(\mathbf{u}|\mathbf{c})] = \frac{1}{2}\chi^2[\mathbf{u}] + H(\mathbf{u}) = \frac{1}{2}\chi^2[\mathbf{u}] + \sum_{\mu=1}^M u_\mu \ln(u_\mu/U) \quad (18.7.11)$$

This ought to remind you of equation (18.4.11), or equation (18.5.6), or in fact any of our previous minimization principles along the lines of $\mathcal{A} + \lambda\mathcal{B}$, where $\lambda\mathcal{B} = H(\mathbf{u})$ is a regularizing operator. Where is λ ? We need to put it in for exactly the reason discussed following equation (18.4.11): Degenerate inversions are likely to be able to achieve unrealistically small values of χ^2 . We need an adjustable parameter to bring χ^2 into its expected narrow statistical range of $N \pm (2N)^{1/2}$. The discussion at the beginning of §18.4 showed that it makes no difference which term we attach the λ to. For consistency in notation, we absorb a factor 2 into λ and put it on the entropy term. (Another way to see the necessity of an undetermined λ factor is to note that it is necessary if our minimization principle is to be invariant under changing the units in which \mathbf{u} is quantized, e.g., if an 8-bit analog-to-digital converter is replaced by a 12-bit one.) We can now also put "hats" back to indicate that this is the procedure for obtaining our chosen statistical estimator:

$$\text{minimize: } \mathcal{A} + \lambda\mathcal{B} = \chi^2[\widehat{\mathbf{u}}] + \lambda H(\widehat{\mathbf{u}}) = \chi^2[\widehat{\mathbf{u}}] + \lambda \sum_{\mu=1}^M \widehat{u}_\mu \ln(\widehat{u}_\mu) \quad (18.7.12)$$

(Formally, we might also add a second Lagrange multiplier $\lambda'U$, to constrain the total intensity U to be constant.)

It is not hard to see that the negentropy, $H(\widehat{\mathbf{u}})$, is in fact a regularizing operator, similar to $\widehat{\mathbf{u}} \cdot \widehat{\mathbf{u}}$ (equation 18.4.11) or $\widehat{\mathbf{u}} \cdot \mathbf{H} \cdot \widehat{\mathbf{u}}$ (equation 18.5.6). The following of its properties are noteworthy:

1. When U is held constant, $H(\widehat{\mathbf{u}})$ is minimized for $\widehat{u}_\mu = U/M = \text{constant}$, so it smooths in the sense of trying to achieve a constant solution, similar to equation (18.5.4). The fact that the constant solution is a minimum follows from the fact that the second derivative of $u \ln u$ is positive.

2. Unlike equation (18.5.4), however, $H(\hat{\mathbf{u}})$ is *local*, in the sense that it does not difference neighboring pixels. It simply sums some function f , here

$$f(u) = u \ln u \quad (18.7.13)$$

over all pixels; it is invariant, in fact, under a complete scrambling of the pixels in an image. This form implies that $H(\hat{\mathbf{u}})$ is not seriously increased by the occurrence of a small number of very bright pixels (point sources) embedded in a low-intensity smooth background.

3. $H(\hat{\mathbf{u}})$ goes to infinite slope as any one pixel goes to zero. This causes it to enforce positivity of the image, without the necessity of additional deterministic constraints.
4. The biggest difference between $H(\hat{\mathbf{u}})$ and the other regularizing operators that we have met is that $H(\hat{\mathbf{u}})$ is not a quadratic functional of $\hat{\mathbf{u}}$, so the equations obtained by varying equation (18.7.12) are *nonlinear*. This fact is itself worthy of some additional discussion.

Nonlinear equations are harder to solve than linear equations. For image processing, however, the large number of equations usually dictates an iterative solution procedure, even for linear equations, so the practical effect of the nonlinearity is somewhat mitigated. Below, we will summarize some of the methods that are successfully used for MEM inverse problems.

For some problems, notably the problem in radio-astronomy of image recovery from an incomplete set of Fourier coefficients, the superior performance of MEM inversion can be, in part, traced to the nonlinearity of $H(\hat{\mathbf{u}})$. One way to see this [5] is to consider the limit of perfect measurements $\sigma_i \rightarrow 0$. In this case the χ^2 term in the minimization principle (18.7.12) gets replaced by a set of constraints, each with its own Lagrange multiplier, requiring agreement between model and data; that is,

$$\text{minimize: } \sum_j \lambda_j \left[c_j - \sum_\mu R_{j\mu} \hat{u}_\mu \right] + H(\hat{\mathbf{u}}) \quad (18.7.14)$$

(cf. equation 18.4.7). Setting the formal derivative with respect to \hat{u}_μ to zero gives

$$\frac{\partial H}{\partial \hat{u}_\mu} = f'(\hat{u}_\mu) = \sum_j \lambda_j R_{j\mu} \quad (18.7.15)$$

or defining a function G as the inverse function of f' ,

$$\hat{u}_\mu = G \left(\sum_j \lambda_j R_{j\mu} \right) \quad (18.7.16)$$

This solution is only formal, since the λ_j 's must be found by requiring that equation (18.7.16) satisfy all the constraints built into equation (18.7.14). However, equation (18.7.16) does show the crucial fact that if G is *linear*, then the solution $\hat{\mathbf{u}}$ contains *only* a linear combination of basis functions $R_{j\mu}$ corresponding to actual measurements j . This is equivalent to setting unmeasured c_j 's to zero. Notice that the principal solution obtained from equation (18.4.11) in fact has a linear G .

In the problem of incomplete Fourier image reconstruction, the typical $R_{j\mu}$ has the form $\exp(-2\pi i \mathbf{k}_j \cdot \mathbf{x}_\mu)$, where \mathbf{x}_μ is a two-dimensional vector in the image space and \mathbf{k}_μ is a two-dimensional wave-vector. If an image contains strong point sources, then the effect of setting unmeasured c_j 's to zero is to produce sidelobe ripples throughout the image plane. These ripples can mask any actual extended, low-intensity image features lying between the point sources. If, however, the slope of G is smaller for small values of its argument, larger for large values, then ripples in low-intensity portions of the image are relatively suppressed, while strong point sources will be relatively sharpened (“superresolution”). This behavior on the slope of G is equivalent to requiring $f'''(u) < 0$. For $f(u) = u \ln u$, we in fact have $f'''(u) = -1/u^2 < 0$.

In more picturesque language, the nonlinearity acts to “create” nonzero values for the unmeasured c_i 's, so as to suppress the low-intensity ripple and sharpen the point sources.

Is MEM Really Magical?

How unique is the negentropy functional (18.7.9)? Recall that that equation is based on the assumption that luminance elements are *a priori* distributed over the pixels uniformly. If we instead had some other preferred *a priori* image in mind, one with pixel intensities m_μ , then it is easy to show that the negentropy becomes

$$H(\mathbf{u}) = \sum_{\mu=1}^M u_\mu \ln(u_\mu/m_\mu) + \text{constant} \quad (18.7.17)$$

(the constant can then be ignored). All the rest of the discussion then goes through.

More fundamentally, and despite statements by zealots to the contrary [7], there is actually nothing universal about the functional form $f(u) = u \ln u$. In some other physical situations (for example, the entropy of an electromagnetic field in the limit of many photons per mode, as in radio-astronomy) the physical negentropy functional is actually $f(u) = -\ln u$ (see [5] for other examples). In general, the question, “Entropy of what?” is not uniquely answerable in any particular situation. (See reference [9] for an attempt at articulating a more general principle that reduces to one or another entropy functional under appropriate circumstances.)

The four numbered properties summarized above, plus the desirable sign for nonlinearity, $f'''(u) < 0$, are all as true for $f(u) = -\ln u$ as for $f(u) = u \ln u$. In fact these properties are shared by a nonlinear function as simple as $f(u) = -\sqrt{u}$, which has no information theoretic justification at all (no logarithms!). MEM reconstructions of test images using any of these entropy forms are virtually indistinguishable [5].

By all available evidence, MEM seems to be neither more nor less than one usefully nonlinear version of the general regularization scheme $\mathcal{A} + \lambda \mathcal{B}$ that we have by now considered in many forms. Its peculiarities become strengths when applied to the reconstruction from incomplete Fourier data of images that are expected to be dominated by very bright point sources, but which also contain interesting low-intensity, extended sources. For images of some other character, there is no reason to suppose that MEM methods will generally dominate other regularization schemes, either ones already known or yet to be invented.

Algorithms for MEM

The goal is to find the vector $\hat{\mathbf{u}}$ that minimizes $\mathcal{A} + \lambda\mathcal{B}$ where in the notation of equations (18.5.5), (18.5.6), and (18.7.13),

$$\mathcal{A} = |\mathbf{b} - \mathbf{A} \cdot \hat{\mathbf{u}}|^2 \quad \mathcal{B} = \sum_{\mu} f(\hat{u}_{\mu}) \quad (18.7.18)$$

Compared with a “general” minimization problem, we have the advantage that we can compute the gradients and the second partial derivative matrices (Hessian matrices) explicitly,

$$\begin{aligned} \nabla \mathcal{A} &= 2(\mathbf{A}^T \cdot \mathbf{A} \cdot \hat{\mathbf{u}} - \mathbf{A}^T \cdot \mathbf{b}) & \frac{\partial^2 \mathcal{A}}{\partial \hat{u}_{\mu} \partial \hat{u}_{\rho}} &= [2\mathbf{A}^T \cdot \mathbf{A}]_{\mu\rho} \\ [\nabla \mathcal{B}]_{\mu} &= f'(\hat{u}_{\mu}) & \frac{\partial^2 \mathcal{B}}{\partial \hat{u}_{\mu} \partial \hat{u}_{\rho}} &= \delta_{\mu\rho} f''(\hat{u}_{\mu}) \end{aligned} \quad (18.7.19)$$

It is important to note that while \mathcal{A} ’s second partial derivative matrix cannot be stored (its size is the square of the number of pixels), it can be applied to any vector by first applying \mathbf{A} , then \mathbf{A}^T . In the case of reconstruction from incomplete Fourier data, or in the case of convolution with a translation invariant point spread function, these applications will typically involve several FFTs. Likewise, the calculation of the gradient $\nabla \mathcal{A}$ will involve FFTs in the application of \mathbf{A} and \mathbf{A}^T .

While some success has been achieved with the classical conjugate gradient method (§10.6), it is often found that the nonlinearity in $f(u) = u \ln u$ causes problems. Attempted steps that give $\hat{\mathbf{u}}$ with even one negative value must be cut in magnitude, sometimes so severely as to slow the solution to a crawl. The underlying problem is that the conjugate gradient method develops its information about the inverse of the Hessian matrix a bit at a time, while changing its location in the search space. When a nonlinear function is quite different from a pure quadratic form, the old information becomes obsolete before it gets usefully exploited.

Skilling and collaborators [6,7,10,11] developed a complicated but highly successful scheme, wherein a minimum is repeatedly sought not along a single search direction, but in a small- (typically three-) dimensional subspace, spanned by vectors that are calculated anew at each landing point. The subspace basis vectors are chosen in such a way as to avoid directions leading to negative values. One of the most successful choices is the three-dimensional subspace spanned by the vectors with components given by

$$\begin{aligned} e_{\mu}^{(1)} &= \hat{u}_{\mu} [\nabla \mathcal{A}]_{\mu} \\ e_{\mu}^{(2)} &= \hat{u}_{\mu} [\nabla \mathcal{B}]_{\mu} \\ e_{\mu}^{(3)} &= \frac{\hat{u}_{\mu} \sum_{\rho} (\partial^2 \mathcal{A} / \partial \hat{u}_{\mu} \partial \hat{u}_{\rho}) \hat{u}_{\rho} [\nabla \mathcal{B}]_{\rho}}{\sqrt{\sum_{\rho} \hat{u}_{\rho} ([\nabla \mathcal{B}]_{\rho})^2}} - \frac{\hat{u}_{\mu} \sum_{\rho} (\partial^2 \mathcal{A} / \partial \hat{u}_{\mu} \partial \hat{u}_{\rho}) \hat{u}_{\rho} [\nabla \mathcal{A}]_{\rho}}{\sqrt{\sum_{\rho} \hat{u}_{\rho} ([\nabla \mathcal{A}]_{\rho})^2}} \end{aligned} \quad (18.7.20)$$

(In these equations there is no sum over μ .) The form of the $e^{(3)}$ has some justification if one views dot products as occurring in a space with the metric $g_{\mu\nu} = \delta_{\mu\nu} / u_{\mu}$, chosen to make zero values “far away”; see [6].

Within the three-dimensional subspace, the three-component gradient and nine-component Hessian matrix are computed by projection from the large space, and the minimum in the subspace is estimated by (trivially) solving three simultaneous linear equations, as in §10.7, equation (10.7.4). The size of a step $\Delta \hat{\mathbf{u}}$ is required to be limited by the inequality

$$\sum_{\mu} (\Delta \hat{u}_{\mu})^2 / \hat{u}_{\mu} < (0.1 \text{ to } 0.5)U \quad (18.7.21)$$

Because the gradient directions $\nabla \mathcal{A}$ and $\nabla \mathcal{B}$ are separately available, it is possible to combine the minimum search with a simultaneous adjustment of λ so as finally to satisfy the desired constraint. There are various further tricks employed.

A less general, but in practice often equally satisfactory, approach is due to Cornwell and Evans [12]. Here, noting that \mathcal{B} 's Hessian (second partial derivative) matrix is diagonal, one asks whether there is a useful diagonal approximation to \mathcal{A} 's Hessian, namely $2\mathbf{A}^T \cdot \mathbf{A}$. If Λ_{μ} denotes the diagonal components of such an approximation, then a useful step in $\hat{\mathbf{u}}$ would be

$$\Delta \hat{u}_{\mu} = -\frac{1}{\Lambda_{\mu} + \lambda f''(\hat{u}_{\mu})} (\nabla \mathcal{A} + \lambda \nabla \mathcal{B}) \quad (18.7.22)$$

(again compare equation 10.7.4). Even more extreme, one might seek an approximation with constant diagonal elements, $\Lambda_{\mu} = \Lambda$, so that

$$\Delta \hat{u}_{\mu} = -\frac{1}{\Lambda + \lambda f''(\hat{u}_{\mu})} (\nabla \mathcal{A} + \lambda \nabla \mathcal{B}) \quad (18.7.23)$$

Since $\mathbf{A}^T \cdot \mathbf{A}$ has something of the nature of a doubly convolved point spread function, and since in real cases one often has a point spread function with a sharp central peak, even the more extreme of these approximations is often fruitful. One starts with a rough estimate of Λ obtained from the $A_{i\mu}$'s, e.g.,

$$\Lambda \sim \left\langle \sum_i [A_{i\mu}]^2 \right\rangle \quad (18.7.24)$$

An accurate value is not important, since in practice Λ is adjusted adaptively: If Λ is too large, then equation (18.7.23)'s steps will be too small (that is, larger steps in the same direction will produce even greater decrease in $\mathcal{A} + \lambda \mathcal{B}$). If Λ is too small, then attempted steps will land in an unfeasible region (negative values of \hat{u}_{μ}), or will result in an increased $\mathcal{A} + \lambda \mathcal{B}$. There is an obvious similarity between the adjustment of Λ here and the Levenberg-Marquardt method of §15.5; this should not be too surprising, since MEM is closely akin to the problem of nonlinear least-squares fitting. Reference [12] also discusses how the value of $\Lambda + \lambda f''(\hat{u}_{\mu})$ can be used to adjust the Lagrange multiplier λ so as to converge to the desired value of χ^2 .

All practical MEM algorithms are found to require on the order of 30 to 50 iterations to converge. This convergence behavior is not now understood in any fundamental way.

"Bayesian" versus "Historic" Maximum Entropy

Several more recent developments in maximum entropy image restoration go under the rubric "Bayesian" to distinguish them from the previous "historic" methods. See [13] for details and references.

- Better priors: We already noted that the entropy functional (equation 18.7.13) is invariant under scrambling all pixels and has no notion of smoothness. The so-called “intrinsic correlation function” (ICF) model (Ref. [13], where it is called “New MaxEnt”) is similar enough to the entropy functional to allow similar algorithms, but it makes the values of neighboring pixels correlated, enforcing smoothness.
- Better estimation of λ : Above we chose λ to bring χ^2 into its expected narrow statistical range of $N \pm (2N)^{1/2}$. This in effect overestimates χ^2 , however, since some effective number γ of parameters are being “fitted” in doing the reconstruction. A Bayesian approach leads to a self-consistent estimate of this γ and an objectively better choice for λ .

Chapter 19. Partial Differential Equations

19.0 Introduction

The numerical treatment of partial differential equations is, by itself, a vast subject. Partial differential equations are at the heart of many, if not most, computer analyses or simulations of continuous physical systems, such as fluids, electromagnetic fields, the human body, and so on. The intent of this chapter is to give the briefest possible useful introduction. Ideally, there would be an entire second volume of *Numerical Recipes* dealing with partial differential equations alone. (The references [1-4] provide, of course, available alternatives.)

In most mathematics books, partial differential equations (PDEs) are classified into the three categories, *hyperbolic*, *parabolic*, and *elliptic*, on the basis of their *characteristics*, or curves of information propagation. The prototypical example of a hyperbolic equation is the one-dimensional *wave* equation

$$\frac{\partial^2 u}{\partial t^2} = v^2 \frac{\partial^2 u}{\partial x^2} \quad (19.0.1)$$

where $v = \text{constant}$ is the velocity of wave propagation. The prototypical parabolic equation is the *diffusion* equation

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial u}{\partial x} \right) \quad (19.0.2)$$

where D is the diffusion coefficient. The prototypical elliptic equation is the *Poisson* equation

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = \rho(x, y) \quad (19.0.3)$$

where the source term ρ is given. If the source term is equal to zero, the equation is *Laplace's equation*.

From a computational point of view, the classification into these three canonical types is not very meaningful — or at least not as important as some other essential distinctions. Equations (19.0.1) and (19.0.2) both define *initial value* or *Cauchy* problems: If information on u (perhaps including time derivative information) is

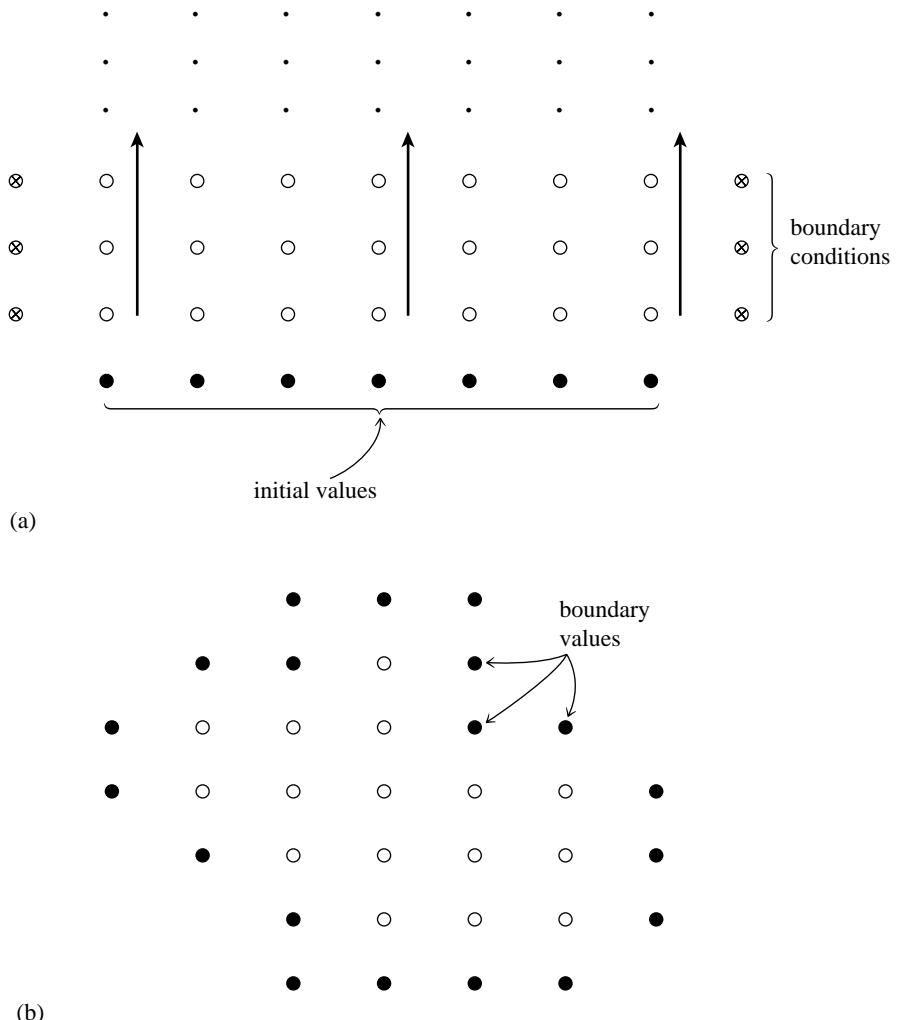

Figure 19.0.1. Initial value problem (a) and boundary value problem (b) are contrasted. In (a) initial values are given on one “time slice,” and it is desired to advance the solution in time, computing successive rows of open dots in the direction shown by the arrows. Boundary conditions at the left and right edges of each row (\otimes) must also be supplied, but only one row at a time. Only one, or a few, previous rows need be maintained in memory. In (b), boundary values are specified around the edge of a grid, and an iterative process is employed to find the values of all the internal points (open circles). All grid points must be maintained in memory.

given at some initial time t_0 for all x , then the equations describe how $u(x, t)$ propagates itself forward in time. In other words, equations (19.0.1) and (19.0.2) describe time evolution. The goal of a numerical code should be to track that time evolution with some desired accuracy.

By contrast, equation (19.0.3) directs us to find a single “static” function $u(x, y)$ which satisfies the equation within some (x, y) region of interest, and which — one must also specify — has some desired behavior on the boundary of the region of interest. These problems are called *boundary value problems*. In general it is not

possible stably to just “integrate in from the boundary” in the same sense that an initial value problem can be “integrated forward in time.” Therefore, the goal of a numerical code is somehow to converge on the correct solution everywhere at once.

This, then, is the most important classification from a computational point of view: Is the problem at hand an *initial value* (time evolution) problem? or is it a *boundary value* (static solution) problem? Figure 19.0.1 emphasizes the distinction. Notice that while the italicized terminology is standard, the terminology in parentheses is a much better description of the dichotomy from a computational perspective. The subclassification of initial value problems into parabolic and hyperbolic is much less important because (i) many actual problems are of a mixed type, and (ii) as we will see, most hyperbolic problems get parabolic pieces mixed into them by the time one is discussing practical computational schemes.

Initial Value Problems

An initial value problem is defined by answers to the following questions:

- What are the dependent variables to be propagated forward in time?
- What is the evolution equation for each variable? Usually the evolution equations will all be coupled, with more than one dependent variable appearing on the right-hand side of each equation.
- What is the highest time derivative that occurs in each variable’s evolution equation? If possible, this time derivative should be put alone on the equation’s left-hand side. Not only the value of a variable, but also the value of all its time derivatives — up to the highest one — must be specified to define the evolution.
- What special equations (boundary conditions) govern the evolution in time of points on the boundary of the spatial region of interest? Examples: *Dirichlet conditions* specify the values of the boundary points as a function of time; *Neumann conditions* specify the values of the normal gradients on the boundary; *outgoing-wave boundary conditions* are just what they say.

Sections 19.1–19.3 of this chapter deal with initial value problems of several different forms. We make no pretence of completeness, but rather hope to convey a certain amount of generalizable information through a few carefully chosen model examples. These examples will illustrate an important point: One’s principal *computational* concern must be the *stability* of the algorithm. Many reasonable-looking algorithms for initial value problems just don’t work — they are numerically unstable.

Boundary Value Problems

The questions that define a boundary value problem are:

- What are the variables?
- What equations are satisfied in the interior of the region of interest?
- What equations are satisfied by points on the boundary of the region of interest? (Here Dirichlet and Neumann conditions are possible choices for elliptic second-order equations, but more complicated boundary conditions can also be encountered.)

In contrast to initial value problems, stability is relatively easy to achieve for boundary value problems. Thus, the *efficiency* of the algorithms, both in computational load and storage requirements, becomes the principal concern.

Because all the conditions on a boundary value problem must be satisfied “simultaneously,” these problems usually boil down, at least conceptually, to the solution of large numbers of simultaneous algebraic equations. When such equations are nonlinear, they are usually solved by linearization and iteration; so without much loss of generality we can view the problem as being the solution of special, large linear sets of equations.

As an example, one which we will refer to in §§19.4–19.6 as our “model problem,” let us consider the solution of equation (19.0.3) by the *finite-difference method*. We represent the function $u(x, y)$ by its values at the discrete set of points

$$\begin{aligned} x_j &= x_0 + j\Delta, & j &= 0, 1, \dots, J \\ y_l &= y_0 + l\Delta, & l &= 0, 1, \dots, L \end{aligned} \quad (19.0.4)$$

where Δ is the *grid spacing*. From now on, we will write $u_{j,l}$ for $u(x_j, y_l)$, and $\rho_{j,l}$ for $\rho(x_j, y_l)$. For (19.0.3) we substitute a finite-difference representation (see Figure 19.0.2),

$$\frac{u_{j+1,l} - 2u_{j,l} + u_{j-1,l}}{\Delta^2} + \frac{u_{j,l+1} - 2u_{j,l} + u_{j,l-1}}{\Delta^2} = \rho_{j,l} \quad (19.0.5)$$

or equivalently

$$u_{j+1,l} + u_{j-1,l} + u_{j,l+1} + u_{j,l-1} - 4u_{j,l} = \Delta^2 \rho_{j,l} \quad (19.0.6)$$

To write this system of linear equations in matrix form we need to make a vector out of u . Let us number the two dimensions of grid points in a single one-dimensional sequence by defining

$$i \equiv j(L+1) + l \quad \text{for } j = 0, 1, \dots, J, \quad l = 0, 1, \dots, L \quad (19.0.7)$$

In other words, i increases most rapidly along the columns representing y values. Equation (19.0.6) now becomes

$$u_{i+L+1} + u_{i-(L+1)} + u_{i+1} + u_{i-1} - 4u_i = \Delta^2 \rho_i \quad (19.0.8)$$

This equation holds only at the interior points $j = 1, 2, \dots, J-1; l = 1, 2, \dots, L-1$.

The points where

$$\begin{aligned} j = 0 &\quad [\text{i.e., } i = 0, \dots, L] \\ j = J &\quad [\text{i.e., } i = J(L+1), \dots, J(L+1)+L] \\ l = 0 &\quad [\text{i.e., } i = 0, L+1, \dots, J(L+1)] \\ l = L &\quad [\text{i.e., } i = L, L+1+\dots, J(L+1)+L] \end{aligned} \quad (19.0.9)$$

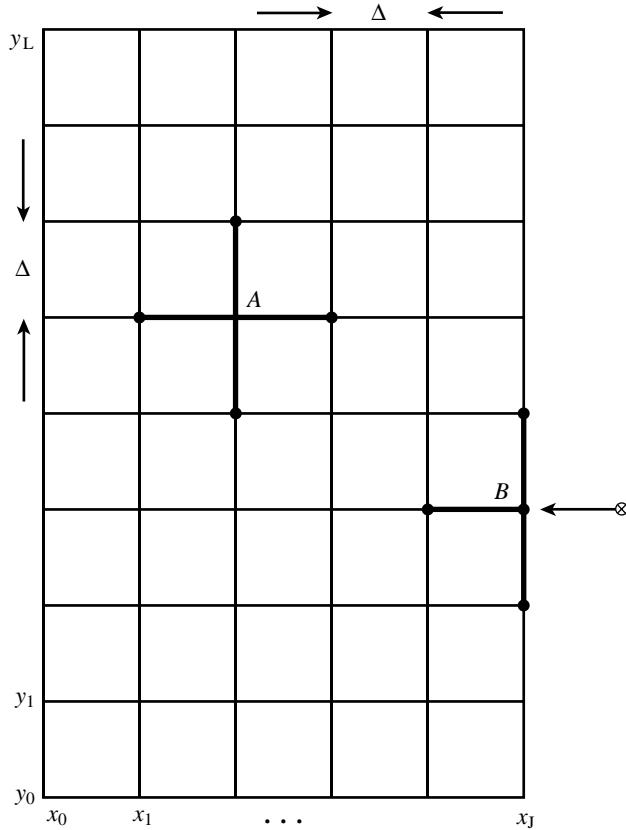

Figure 19.0.2. Finite-difference representation of a second-order elliptic equation on a two-dimensional grid. The second derivatives at the point A are evaluated using the points to which A is shown connected. The second derivatives at point B are evaluated using the connected points and also using “right-hand side” boundary information, shown schematically as \otimes .

are boundary points where either u or its derivative has been specified. If we pull all this “known” information over to the right-hand side of equation (19.0.8), then the equation takes the form

$$\mathbf{A} \cdot \mathbf{u} = \mathbf{b} \quad (19.0.10)$$

where \mathbf{A} has the form shown in Figure 19.0.3. The matrix \mathbf{A} is called “tridiagonal with fringes.” A general linear second-order elliptic equation

$$\begin{aligned} a(x, y) \frac{\partial^2 u}{\partial x^2} + b(x, y) \frac{\partial u}{\partial x} + c(x, y) \frac{\partial^2 u}{\partial y^2} + d(x, y) \frac{\partial u}{\partial y} \\ + e(x, y) \frac{\partial^2 u}{\partial x \partial y} + f(x, y)u = g(x, y) \end{aligned} \quad (19.0.11)$$

will lead to a matrix of similar structure except that the nonzero entries will not be constants.

As a rough classification, there are three different approaches to the solution of equation (19.0.10), not all applicable in all cases: relaxation methods, “rapid” methods (e.g., Fourier methods), and direct matrix methods.

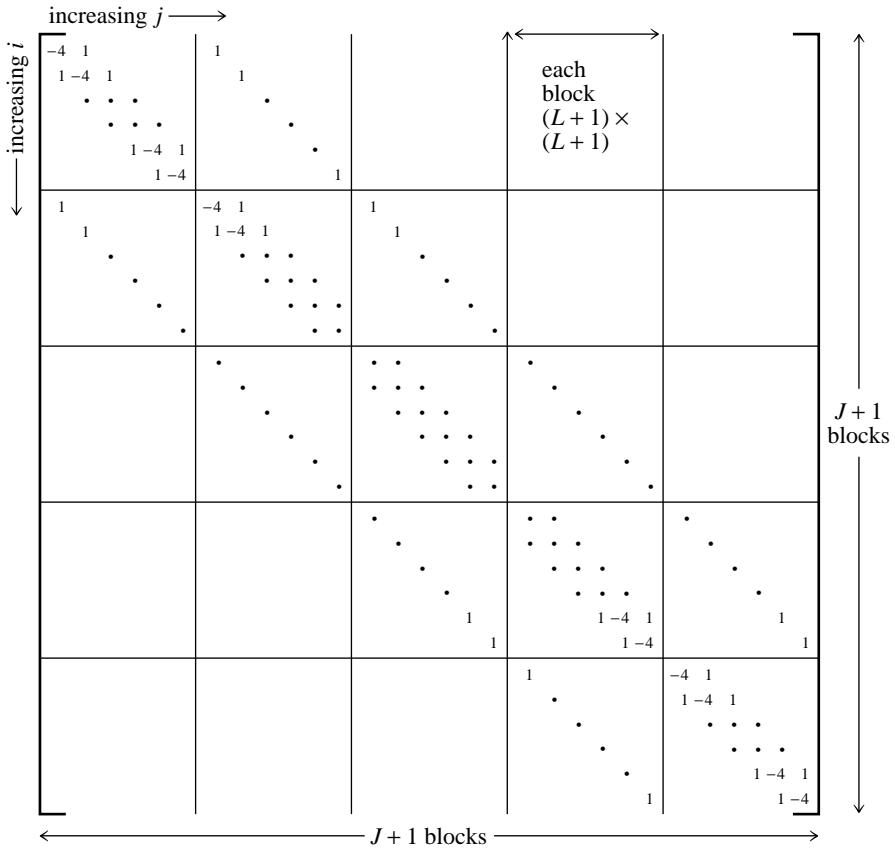

Figure 19.0.3. Matrix structure derived from a second-order elliptic equation (here equation 19.0.6). All elements not shown are zero. The matrix has diagonal blocks that are themselves tridiagonal, and sub- and super-diagonal blocks that are diagonal. This form is called “tridiagonal with fringes.” A matrix this sparse would never be stored in its full form as shown here.

Relaxation methods make immediate use of the structure of the sparse matrix
A. The matrix is split into two parts

$$\mathbf{A} = \mathbf{E} - \mathbf{F} \quad (19.0.12)$$

where **E** is easily invertible and **F** is the remainder. Then (19.0.10) becomes

$$\mathbf{E} \cdot \mathbf{u} = \mathbf{F} \cdot \mathbf{u} + \mathbf{b} \quad (19.0.13)$$

The relaxation method involves choosing an initial guess $\mathbf{u}^{(0)}$ and then solving successively for iterates $\mathbf{u}^{(r)}$ from

$$\mathbf{E} \cdot \mathbf{u}^{(r)} = \mathbf{F} \cdot \mathbf{u}^{(r-1)} + \mathbf{b} \quad (19.0.14)$$

Since **E** is chosen to be easily invertible, each iteration is fast. We will discuss relaxation methods in some detail in §19.5 and §19.6.

So-called rapid methods [5] apply for only a rather special class of equations: those with constant coefficients, or, more generally, those that are separable in the chosen coordinates. In addition, the boundaries must coincide with coordinate lines. This special class of equations is met quite often in practice. We defer detailed discussion to §19.4. Note, however, that the multigrid relaxation methods discussed in §19.6 can be faster than “rapid” methods.

Matrix methods attempt to solve the equation

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (19.0.15)$$

directly. The degree to which this is practical depends very strongly on the exact structure of the matrix \mathbf{A} for the problem at hand, so our discussion can go no farther than a few remarks and references at this point.

Spareness of the matrix *must* be the guiding force. Otherwise the matrix problem is prohibitively large. For example, the simplest problem on a 100×100 spatial grid would involve 10000 unknown $u_{j,l}$ ’s, implying a 10000×10000 matrix \mathbf{A} , containing 10^8 elements!

As we discussed at the end of §2.7, if \mathbf{A} is symmetric and positive definite (as it usually is in elliptic problems), the conjugate-gradient algorithm can be used. In practice, rounding error often spoils the effectiveness of the conjugate gradient algorithm for solving finite-difference equations. However, it is useful when incorporated in methods that first rewrite the equations so that \mathbf{A} is transformed to a matrix \mathbf{A}' that is close to the identity matrix. The quadratic surface defined by the equations then has almost spherical contours, and the conjugate gradient algorithm works very well. In §2.7, in the routine `linbcg`, an analogous *preconditioner* was exploited for non-positive definite problems with the more general biconjugate gradient method. For the positive definite case that arises in PDEs, an example of a successful implementation is the *incomplete Cholesky conjugate gradient method (ICCG)* (see [6-8]).

Another method that relies on a transformation approach is the *strongly implicit procedure* of Stone [9]. A program called `SIPSOL` that implements this routine has been published [10].

A third class of matrix methods is the Analyze-Factorize-Operate approach as described in §2.7.

Generally speaking, when you have the storage available to implement these methods — not nearly as much as the 10^8 above, but usually much more than is required by relaxation methods — then you should consider doing so. Only multigrid relaxation methods (§19.6) are competitive with the best matrix methods. For grids larger than, say, 300×300 , however, it is generally found that only relaxation methods, or “rapid” methods when they are applicable, are possible.

There Is More to Life than Finite Differencing

Besides finite differencing, there are other methods for solving PDEs. Most important are finite element, Monte Carlo, spectral, and variational methods. Unfortunately, we shall barely be able to do justice to finite differencing in this chapter, and so shall not be able to discuss these other methods in this book. Finite element methods [11-12] are often preferred by practitioners in solid mechanics and structural

engineering; these methods allow considerable freedom in putting computational elements where you want them, important when dealing with highly irregular geometries. Spectral methods [13-15] are preferred for very regular geometries and smooth functions; they converge more rapidly than finite-difference methods (cf. §19.4), but they do not work well for problems with discontinuities.

19.1 Flux-Conservative Initial Value Problems

A large class of initial value (time-evolution) PDEs in one space dimension can be cast into the form of a *flux-conservative equation*,

$$\frac{\partial \mathbf{u}}{\partial t} = -\frac{\partial \mathbf{F}(\mathbf{u})}{\partial x} \quad (19.1.1)$$

where \mathbf{u} and \mathbf{F} are vectors, and where (in some cases) \mathbf{F} may depend not only on \mathbf{u} but also on spatial derivatives of \mathbf{u} . The vector \mathbf{F} is called the *conserved flux*.

For example, the prototypical hyperbolic equation, the one-dimensional wave equation with constant velocity of propagation v

$$\frac{\partial^2 u}{\partial t^2} = v^2 \frac{\partial^2 u}{\partial x^2} \quad (19.1.2)$$

engineering; these methods allow considerable freedom in putting computational elements where you want them, important when dealing with highly irregular geometries. Spectral methods [13-15] are preferred for very regular geometries and smooth functions; they converge more rapidly than finite-difference methods (cf. §19.4), but they do not work well for problems with discontinuities.

19.1 Flux-Conservative Initial Value Problems

A large class of initial value (time-evolution) PDEs in one space dimension can be cast into the form of a *flux-conservative equation*,

$$\frac{\partial \mathbf{u}}{\partial t} = -\frac{\partial \mathbf{F}(\mathbf{u})}{\partial x} \quad (19.1.1)$$

where \mathbf{u} and \mathbf{F} are vectors, and where (in some cases) \mathbf{F} may depend not only on \mathbf{u} but also on spatial derivatives of \mathbf{u} . The vector \mathbf{F} is called the *conserved flux*.

For example, the prototypical hyperbolic equation, the one-dimensional wave equation with constant velocity of propagation v

$$\frac{\partial^2 u}{\partial t^2} = v^2 \frac{\partial^2 u}{\partial x^2} \quad (19.1.2)$$

can be rewritten as a set of two first-order equations

$$\begin{aligned}\frac{\partial r}{\partial t} &= v \frac{\partial s}{\partial x} \\ \frac{\partial s}{\partial t} &= v \frac{\partial r}{\partial x}\end{aligned}\tag{19.1.3}$$

where

$$\begin{aligned}r &\equiv v \frac{\partial u}{\partial x} \\ s &\equiv \frac{\partial u}{\partial t}\end{aligned}\tag{19.1.4}$$

In this case r and s become the two components of \mathbf{u} , and the flux is given by the linear matrix relation

$$\mathbf{F}(\mathbf{u}) = \begin{pmatrix} 0 & -v \\ -v & 0 \end{pmatrix} \cdot \mathbf{u}\tag{19.1.5}$$

(The physicist-reader may recognize equations (19.1.3) as analogous to Maxwell's equations for one-dimensional propagation of electromagnetic waves.)

We will consider, in this section, a prototypical example of the general flux-conservative equation (19.1.1), namely the equation for a scalar u ,

$$\frac{\partial u}{\partial t} = -v \frac{\partial u}{\partial x}\tag{19.1.6}$$

with v a constant. As it happens, we already know analytically that the general solution of this equation is a wave propagating in the positive x -direction,

$$u = f(x - vt)\tag{19.1.7}$$

where f is an arbitrary function. However, the numerical strategies that we develop will be equally applicable to the more general equations represented by (19.1.1). In some contexts, equation (19.1.6) is called an *advective* equation, because the quantity u is transported by a "fluid flow" with a velocity v .

How do we go about finite differencing equation (19.1.6) (or, analogously, 19.1.1)? The straightforward approach is to choose equally spaced points along both the t - and x -axes. Thus denote

$$\begin{aligned}x_j &= x_0 + j\Delta x, & j &= 0, 1, \dots, J \\ t_n &= t_0 + n\Delta t, & n &= 0, 1, \dots, N\end{aligned}\tag{19.1.8}$$

Let u_j^n denote $u(t_n, x_j)$. We have several choices for representing the time derivative term. The obvious way is to set

$$\left. \frac{\partial u}{\partial t} \right|_{j,n} = \frac{u_j^{n+1} - u_j^n}{\Delta t} + O(\Delta t)\tag{19.1.9}$$

This is called *forward Euler* differencing (cf. equation 16.1.1). While forward Euler is only first-order accurate in Δt , it has the advantage that one is able to calculate

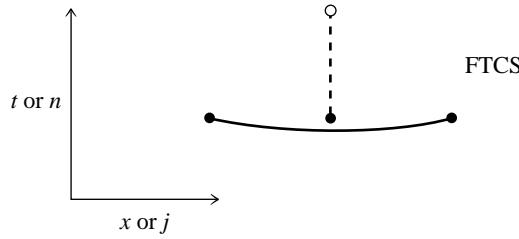

Figure 19.1.1. Representation of the Forward Time Centered Space (FTCS) differencing scheme. In this and subsequent figures, the open circle is the new point at which the solution is desired; filled circles are known points whose function values are used in calculating the new point; the solid lines connect points that are used to calculate spatial derivatives; the dashed lines connect points that are used to calculate time derivatives. The FTCS scheme is generally unstable for hyperbolic problems and cannot usually be used.

quantities at timestep $n + 1$ in terms of only quantities known at timestep n . For the space derivative, we can use a second-order representation still using only quantities known at timestep n :

$$\frac{\partial u}{\partial x} \Big|_{j,n} = \frac{u_{j+1}^n - u_{j-1}^n}{2\Delta x} + O(\Delta x^2) \quad (19.1.10)$$

The resulting finite-difference approximation to equation (19.1.6) is called the FTCS representation (Forward Time Centered Space),

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = -v \left(\frac{u_{j+1}^n - u_{j-1}^n}{2\Delta x} \right) \quad (19.1.11)$$

which can easily be rearranged to be a formula for u_j^{n+1} in terms of the other quantities. The FTCS scheme is illustrated in Figure 19.1.1. It's a fine example of an algorithm that is easy to derive, takes little storage, and executes quickly. Too bad it doesn't work! (See below.)

The FTCS representation is an *explicit* scheme. This means that u_j^{n+1} for each j can be calculated explicitly from the quantities that are already known. Later we shall meet *implicit* schemes, which require us to solve implicit equations coupling the u_j^{n+1} for various j . (Explicit and implicit methods for ordinary differential equations were discussed in §16.6.) The FTCS algorithm is also an example of a *single-level* scheme, since only values at time level n have to be stored to find values at time level $n + 1$.

von Neumann Stability Analysis

Unfortunately, equation (19.1.11) is of very limited usefulness. It is an *unstable* method, which can be used only (if at all) to study waves for a short fraction of one oscillation period. To find alternative methods with more general applicability, we must introduce the *von Neumann stability analysis*.

The von Neumann analysis is local: We imagine that the coefficients of the difference equations are so slowly varying as to be considered constant in space and time. In that case, the independent solutions, or *eigenmodes*, of the difference equations are all of the form

$$u_j^n = \xi^n e^{ikj\Delta x} \quad (19.1.12)$$

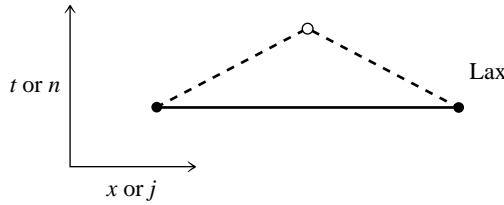

Figure 19.1.2. Representation of the Lax differencing scheme, as in the previous figure. The stability criterion for this scheme is the Courant condition.

where k is a real spatial wave number (which can have any value) and $\xi = \xi(k)$ is a complex number that depends on k . The key fact is that the time dependence of a single eigenmode is nothing more than successive integer powers of the complex number ξ . Therefore, the difference equations are unstable (have exponentially growing modes) if $|\xi(k)| > 1$ for *some* k . The number ξ is called the *amplification factor* at a given wave number k .

To find $\xi(k)$, we simply substitute (19.1.12) back into (19.1.11). Dividing by ξ^n , we get

$$\xi(k) = 1 - i \frac{v\Delta t}{\Delta x} \sin k\Delta x \quad (19.1.13)$$

whose modulus is > 1 for *all* k ; so the FTCS scheme is unconditionally unstable.

If the velocity v were a function of t and x , then we would write v_j^n in equation (19.1.11). In the von Neumann stability analysis we would still treat v as a constant, the idea being that for v slowly varying the analysis is local. In fact, even in the case of strictly constant v , the von Neumann analysis does not rigorously treat the end effects at $j = 0$ and $j = N$.

More generally, if the equation's right-hand side were nonlinear in u , then a von Neumann analysis would linearize by writing $u = u_0 + \delta u$, expanding to linear order in δu . Assuming that the u_0 quantities already satisfy the difference equation exactly, the analysis would look for an unstable eigenmode of δu .

Despite its lack of rigor, the von Neumann method generally gives valid answers and is much easier to apply than more careful methods. We accordingly adopt it exclusively. (See, for example, [1] for a discussion of other methods of stability analysis.)

Lax Method

The instability in the FTCS method can be cured by a simple change due to Lax. One replaces the term u_j^n in the time derivative term by its average (Figure 19.1.2):

$$u_j^n \rightarrow \frac{1}{2} (u_{j+1}^n + u_{j-1}^n) \quad (19.1.14)$$

This turns (19.1.11) into

$$u_j^{n+1} = \frac{1}{2} (u_{j+1}^n + u_{j-1}^n) - \frac{v\Delta t}{2\Delta x} (u_{j+1}^n - u_{j-1}^n) \quad (19.1.15)$$

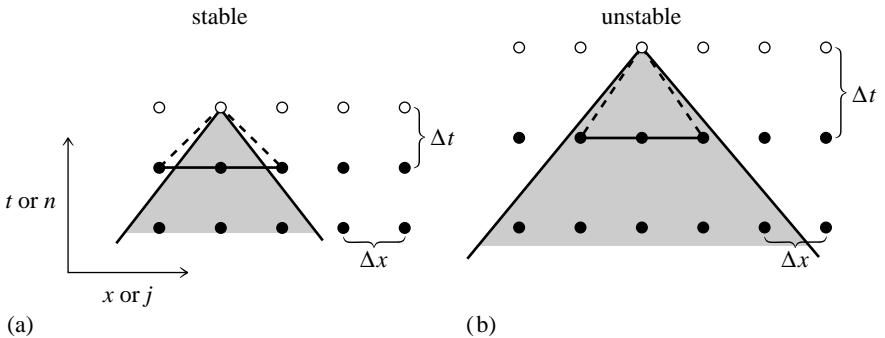

Figure 19.1.3. Courant condition for stability of a differencing scheme. The solution of a hyperbolic problem at a point depends on information within some domain of dependency to the past, shown here shaded. The differencing scheme (19.1.15) has its own domain of dependency determined by the choice of points on one time slice (shown as connected solid dots) whose values are used in determining a new point (shown connected by dashed lines). A differencing scheme is Courant stable if the differencing domain of dependency is larger than that of the PDEs, as in (a), and unstable if the relationship is the reverse, as in (b). For more complicated differencing schemes, the domain of dependency might not be determined simply by the outermost points.

Substituting equation (19.1.12), we find for the amplification factor

$$\xi = \cos k\Delta x - i \frac{v\Delta t}{\Delta x} \sin k\Delta x \quad (19.1.16)$$

The stability condition $|\xi|^2 \leq 1$ leads to the requirement

$$\frac{|v|\Delta t}{\Delta x} \leq 1 \quad (19.1.17)$$

This is the famous Courant-Friedrichs-Lowy stability criterion, often called simply the *Courant condition*. Intuitively, the stability condition can be understood as follows (Figure 19.1.3): The quantity u_j^{n+1} in equation (19.1.15) is computed from information at points $j-1$ and $j+1$ at time n . In other words, x_{j-1} and x_{j+1} are the boundaries of the spatial region that is allowed to communicate information to u_j^{n+1} . Now recall that in the continuum wave equation, information actually propagates with a maximum velocity v . If the point u_j^{n+1} is outside of the shaded region in Figure 19.1.3, then it requires information from points more distant than the differencing scheme allows. Lack of that information gives rise to an instability. Therefore, Δt cannot be made too large.

The surprising result, that the simple replacement (19.1.14) stabilizes the FTCS scheme, is our first encounter with the fact that differencing PDEs is an art as much as a science. To see if we can demystify the art somewhat, let us compare the FTCS and Lax schemes by rewriting equation (19.1.15) so that it is in the form of equation (19.1.11) with a remainder term:

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = -v \left(\frac{u_{j+1}^n - u_{j-1}^n}{2\Delta x} \right) + \frac{1}{2} \left(\frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{\Delta t} \right) \quad (19.1.18)$$

But this is exactly the FTCS representation of the equation

$$\frac{\partial u}{\partial t} = -v \frac{\partial u}{\partial x} + \frac{(\Delta x)^2}{2\Delta t} \nabla^2 u \quad (19.1.19)$$

where $\nabla^2 = \partial^2/\partial x^2$ in one dimension. We have, in effect, added a diffusion term to the equation, or, if you recall the form of the Navier-Stokes equation for viscous fluid flow, a dissipative term. The Lax scheme is thus said to have *numerical dissipation*, or *numerical viscosity*. We can see this also in the amplification factor. Unless $|v|\Delta t$ is exactly equal to Δx , $|\xi| < 1$ and the amplitude of the wave decreases spuriously.

Isn't a spurious decrease as bad as a spurious increase? No. The scales that we hope to study accurately are those that encompass many grid points, so that they have $k\Delta x \ll 1$. (The spatial wave number k is defined by equation 19.1.12.) For these scales, the amplification factor can be seen to be very close to one, in both the stable and unstable schemes. The stable and unstable schemes are therefore about equally accurate. For the unstable scheme, however, short scales with $k\Delta x \sim 1$, which we are not interested in, will blow up and swamp the interesting part of the solution. Much better to have a stable scheme in which these short wavelengths die away innocuously. Both the stable and the unstable schemes are *inaccurate* for these short wavelengths, but the inaccuracy is of a tolerable character when the scheme is stable.

When the independent variable \mathbf{u} is a vector, then the von Neumann analysis is slightly more complicated. For example, we can consider equation (19.1.3), rewritten as

$$\frac{\partial}{\partial t} \begin{bmatrix} r \\ s \end{bmatrix} = \frac{\partial}{\partial x} \begin{bmatrix} vs \\ vr \end{bmatrix} \quad (19.1.20)$$

The Lax method for this equation is

$$\begin{aligned} r_j^{n+1} &= \frac{1}{2}(r_{j+1}^n + r_{j-1}^n) + \frac{v\Delta t}{2\Delta x}(s_{j+1}^n - s_{j-1}^n) \\ s_j^{n+1} &= \frac{1}{2}(s_{j+1}^n + s_{j-1}^n) + \frac{v\Delta t}{2\Delta x}(r_{j+1}^n - r_{j-1}^n) \end{aligned} \quad (19.1.21)$$

The von Neumann stability analysis now proceeds by assuming that the eigenmode is of the following (vector) form,

$$\begin{bmatrix} r_j^n \\ s_j^n \end{bmatrix} = \xi^n e^{ikj\Delta x} \begin{bmatrix} r^0 \\ s^0 \end{bmatrix} \quad (19.1.22)$$

Here the vector on the right-hand side is a constant (both in space and in time) eigenvector, and ξ is a complex number, as before. Substituting (19.1.22) into (19.1.21), and dividing by the power ξ^n , gives the homogeneous vector equation

$$\begin{bmatrix} (\cos k\Delta x) - \xi & i\frac{v\Delta t}{\Delta x} \sin k\Delta x \\ i\frac{v\Delta t}{\Delta x} \sin k\Delta x & (\cos k\Delta x) - \xi \end{bmatrix} \cdot \begin{bmatrix} r^0 \\ s^0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix} \quad (19.1.23)$$

This admits a solution only if the determinant of the matrix on the left vanishes, a condition easily shown to yield the two roots ξ

$$\xi = \cos k\Delta x \pm i\frac{v\Delta t}{\Delta x} \sin k\Delta x \quad (19.1.24)$$

The stability condition is that both roots satisfy $|\xi| \leq 1$. This again turns out to be simply the Courant condition (19.1.17).

Other Varieties of Error

Thus far we have been concerned with *amplitude error*, because of its intimate connection with the stability or instability of a differencing scheme. Other varieties of error are relevant when we shift our concern to accuracy, rather than stability.

Finite-difference schemes for hyperbolic equations can exhibit dispersion, or *phase errors*. For example, equation (19.1.16) can be rewritten as

$$\xi = e^{-ik\Delta x} + i \left(1 - \frac{v\Delta t}{\Delta x}\right) \sin k\Delta x \quad (19.1.25)$$

An arbitrary initial wave packet is a superposition of modes with different k 's. At each timestep the modes get multiplied by different phase factors (19.1.25), depending on their value of k . If $\Delta t = \Delta x/v$, then the exact solution for each mode of a wave packet $f(x-vt)$ is obtained if each mode gets multiplied by $\exp(-ik\Delta x)$. For this value of Δt , equation (19.1.25) shows that the finite-difference solution gives the exact analytic result. However, if $v\Delta t/\Delta x$ is not exactly 1, the phase relations of the modes can become hopelessly garbled and the wave packet disperses. Note from (19.1.25) that the dispersion becomes large as soon as the wavelength becomes comparable to the grid spacing Δx .

A third type of error is one associated with nonlinear hyperbolic equations and is therefore sometimes called *nonlinear instability*. For example, a piece of the Euler or Navier-Stokes equations for fluid flow looks like

$$\frac{\partial v}{\partial t} = -v \frac{\partial v}{\partial x} + \dots \quad (19.1.26)$$

The nonlinear term in v can cause a transfer of energy in Fourier space from long wavelengths to short wavelengths. This results in a wave profile steepening until a vertical profile or “shock” develops. Since the von Neumann analysis suggests that the stability can depend on $k\Delta x$, a scheme that was stable for shallow profiles can become unstable for steep profiles. This kind of difficulty arises in a differencing scheme where the cascade in Fourier space is halted at the shortest wavelength representable on the grid, that is, at $k \sim 1/\Delta x$. If energy simply accumulates in these modes, it eventually swamps the energy in the long wavelength modes of interest.

Nonlinear instability and shock formation is thus somewhat controlled by numerical viscosity such as that discussed in connection with equation (19.1.18) above. In some fluid problems, however, shock formation is not merely an annoyance, but an actual physical behavior of the fluid whose detailed study is a goal. Then, numerical viscosity alone may not be adequate or sufficiently controllable. This is a complicated subject which we discuss further in the subsection on fluid dynamics, below.

For wave equations, propagation errors (amplitude or phase) are usually most worrisome. For advective equations, on the other hand, *transport errors* are usually of greater concern. In the Lax scheme, equation (19.1.15), a disturbance in the advected quantity u at mesh point j propagates to mesh points $j+1$ and $j-1$ at the next timestep. In reality, however, if the velocity v is positive then only mesh point $j+1$ should be affected.

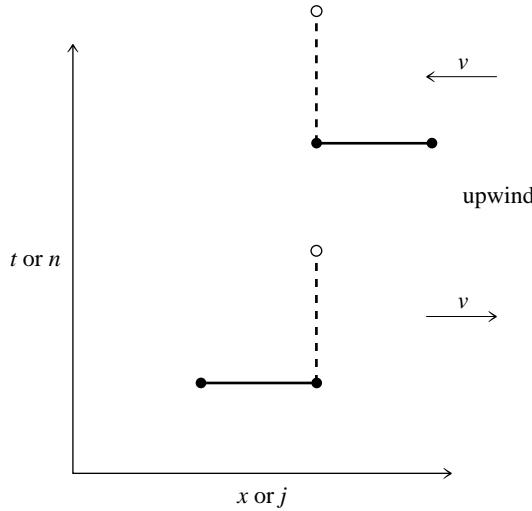

Figure 19.1.4. Representation of upwind differencing schemes. The upper scheme is stable when the advection constant v is negative, as shown; the lower scheme is stable when the advection constant v is positive, also as shown. The Courant condition must, of course, also be satisfied.

The simplest way to model the transport properties “better” is to use *upwind differencing* (see Figure 19.1.4):

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = -v_j^n \begin{cases} \frac{u_j^n - u_{j-1}^n}{\Delta x}, & v_j^n > 0 \\ \frac{u_{j+1}^n - u_j^n}{\Delta x}, & v_j^n < 0 \end{cases} \quad (19.1.27)$$

Note that this scheme is only first-order, not second-order, accurate in the calculation of the spatial derivatives. How can it be “better”? The answer is one that annoys the mathematicians: The goal of numerical simulations is not always “accuracy” in a strictly mathematical sense, but sometimes “fidelity” to the underlying physics in a sense that is looser and more pragmatic. In such contexts, some kinds of error are much more tolerable than others. Upwind differencing generally adds fidelity to problems where the advected variables are liable to undergo sudden changes of state, e.g., as they pass through shocks or other discontinuities. You will have to be guided by the specific nature of your own problem.

For the differencing scheme (19.1.27), the amplification factor (for constant v) is

$$\xi = 1 - \left| \frac{v\Delta t}{\Delta x} \right| (1 - \cos k\Delta x) - i \frac{v\Delta t}{\Delta x} \sin k\Delta x \quad (19.1.28)$$

$$|\xi|^2 = 1 - 2 \left| \frac{v\Delta t}{\Delta x} \right| \left(1 - \left| \frac{v\Delta t}{\Delta x} \right| \right) (1 - \cos k\Delta x) \quad (19.1.29)$$

So the stability criterion $|\xi|^2 \leq 1$ is (again) simply the Courant condition (19.1.17).

There are various ways of improving the accuracy of first-order upwind differencing. In the continuum equation, material originally a distance $v\Delta t$ away

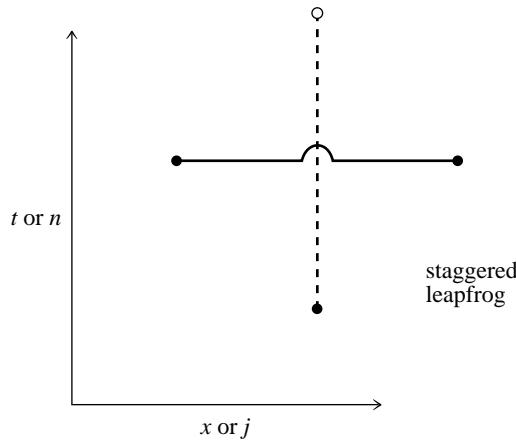

Figure 19.1.5. Representation of the staggered leapfrog differencing scheme. Note that information from two previous time slices is used in obtaining the desired point. This scheme is second-order accurate in both space and time.

arrives at a given point after a time interval Δt . In the first-order method, the material always arrives from Δx away. If $v\Delta t \ll \Delta x$ (to insure accuracy), this can cause a large error. One way of reducing this error is to interpolate u between $j - 1$ and j before transporting it. This gives effectively a second-order method. Various schemes for second-order upwind differencing are discussed and compared in [2-3].

Second-Order Accuracy in Time

When using a method that is first-order accurate in time but second-order accurate in space, one generally has to take $v\Delta t$ significantly smaller than Δx to achieve desired accuracy, say, by at least a factor of 5. Thus the Courant condition is not actually the limiting factor with such schemes in practice. However, there are schemes that are second-order accurate in both space and time, and these can often be pushed right to their stability limit, with correspondingly smaller computation times.

For example, the *staggered leapfrog* method for the conservation equation (19.1.1) is defined as follows (Figure 19.1.5): Using the values of u^n at time t^n , compute the fluxes F_j^n . Then compute new values u^{n+1} using the time-centered values of the fluxes:

$$u_j^{n+1} - u_j^{n-1} = -\frac{\Delta t}{\Delta x} (F_{j+1}^n - F_{j-1}^n) \quad (19.1.30)$$

The name comes from the fact that the time levels in the time derivative term “leapfrog” over the time levels in the space derivative term. The method requires that u^{n-1} and u^n be stored to compute u^{n+1} .

For our simple model equation (19.1.6), staggered leapfrog takes the form

$$u_j^{n+1} - u_j^{n-1} = -\frac{v\Delta t}{\Delta x} (u_{j+1}^n - u_{j-1}^n) \quad (19.1.31)$$

The von Neumann stability analysis now gives a quadratic equation for ξ , rather than a linear one, because of the occurrence of three consecutive powers of ξ when the

form (19.1.12) for an eigenmode is substituted into equation (19.1.31),

$$\xi^2 - 1 = -2i\xi \frac{v\Delta t}{\Delta x} \sin k\Delta x \quad (19.1.32)$$

whose solution is

$$\xi = -i \frac{v\Delta t}{\Delta x} \sin k\Delta x \pm \sqrt{1 - \left(\frac{v\Delta t}{\Delta x} \sin k\Delta x \right)^2} \quad (19.1.33)$$

Thus the Courant condition is again required for stability. In fact, in equation (19.1.33), $|\xi|^2 = 1$ for any $v\Delta t \leq \Delta x$. This is the great advantage of the staggered leapfrog method: There is no amplitude dissipation.

Staggered leapfrog differencing of equations like (19.1.20) is most transparent if the variables are centered on appropriate half-mesh points:

$$\begin{aligned} r_{j+1/2}^n &\equiv v \frac{\partial u}{\partial x} \Big|_{j+1/2}^n = v \frac{u_{j+1}^n - u_j^n}{\Delta x} \\ s_j^{n+1/2} &\equiv \frac{\partial u}{\partial t} \Big|_j^{n+1/2} = \frac{u_j^{n+1} - u_j^n}{\Delta t} \end{aligned} \quad (19.1.34)$$

This is purely a notational convenience: we can think of the mesh on which r and s are defined as being twice as fine as the mesh on which the original variable u is defined. The leapfrog differencing of equation (19.1.20) is

$$\begin{aligned} \frac{r_{j+1/2}^{n+1} - r_{j+1/2}^n}{\Delta t} &= \frac{s_{j+1}^{n+1/2} - s_j^{n+1/2}}{\Delta x} \\ \frac{s_j^{n+1/2} - s_j^{n-1/2}}{\Delta t} &= v \frac{r_{j+1/2}^n - r_{j-1/2}^n}{\Delta x} \end{aligned} \quad (19.1.35)$$

If you substitute equation (19.1.22) in equation (19.1.35), you will find that once again the Courant condition is required for stability, and that there is no amplitude dissipation when it is satisfied.

If we substitute equation (19.1.34) in equation (19.1.35), we find that equation (19.1.35) is equivalent to

$$\frac{u_j^{n+1} - 2u_j^n + u_j^{n-1}}{(\Delta t)^2} = v^2 \frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{(\Delta x)^2} \quad (19.1.36)$$

This is just the “usual” second-order differencing of the wave equation (19.1.2). We see that it is a two-level scheme, requiring both u^n and u^{n-1} to obtain u^{n+1} . In equation (19.1.35) this shows up as both $s^{n-1/2}$ and r^n being needed to advance the solution.

For equations more complicated than our simple model equation, especially nonlinear equations, the leapfrog method usually becomes unstable when the gradients get large. The instability is related to the fact that odd and even mesh points are completely decoupled, like the black and white squares of a chess board, as shown

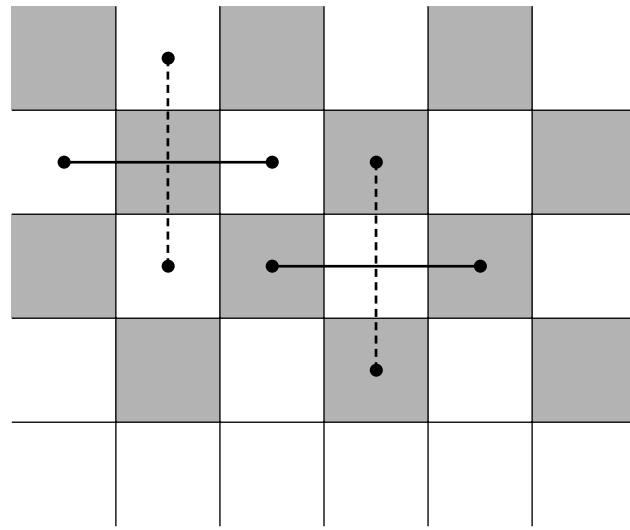

Figure 19.1.6. Origin of mesh-drift instabilities in a staggered leapfrog scheme. If the mesh points are imagined to lie in the squares of a chess board, then white squares couple to themselves, black to themselves, but there is no coupling between white and black. The fix is to introduce a small diffusive mesh-coupling piece.

in Figure 19.1.6. This mesh drifting instability is cured by coupling the two meshes through a numerical viscosity term, e.g., adding to the right side of (19.1.31) a small coefficient ($\ll 1$) times $u_{j+1}^n - 2u_j^n + u_{j-1}^n$. For more on stabilizing difference schemes by adding numerical dissipation, see, e.g., [4].

The *Two-Step Lax-Wendroff* scheme is a second-order in time method that avoids large numerical dissipation and mesh drifting. One defines intermediate values $u_{j+1/2}$ at the half timesteps $t_{n+1/2}$ and the half mesh points $x_{j+1/2}$. These are calculated by the Lax scheme:

$$u_{j+1/2}^{n+1/2} = \frac{1}{2}(u_{j+1}^n + u_j^n) - \frac{\Delta t}{2\Delta x}(F_{j+1}^n - F_j^n) \quad (19.1.37)$$

Using these variables, one calculates the fluxes $F_{j+1/2}^{n+1/2}$. Then the updated values u_j^{n+1} are calculated by the properly centered expression

$$u_j^{n+1} = u_j^n - \frac{\Delta t}{\Delta x} \left(F_{j+1/2}^{n+1/2} - F_{j-1/2}^{n+1/2} \right) \quad (19.1.38)$$

The provisional values $u_{j+1/2}^{n+1/2}$ are now discarded. (See Figure 19.1.7.)

Let us investigate the stability of this method for our model advective equation, where $F = vu$. Substitute (19.1.37) in (19.1.38) to get

$$\begin{aligned} u_j^{n+1} = u_j^n & - \alpha \left[\frac{1}{2}(u_{j+1}^n + u_j^n) - \frac{1}{2}\alpha(u_{j+1}^n - u_j^n) \right. \\ & \left. - \frac{1}{2}(u_j^n + u_{j-1}^n) + \frac{1}{2}\alpha(u_j^n - u_{j-1}^n) \right] \end{aligned} \quad (19.1.39)$$

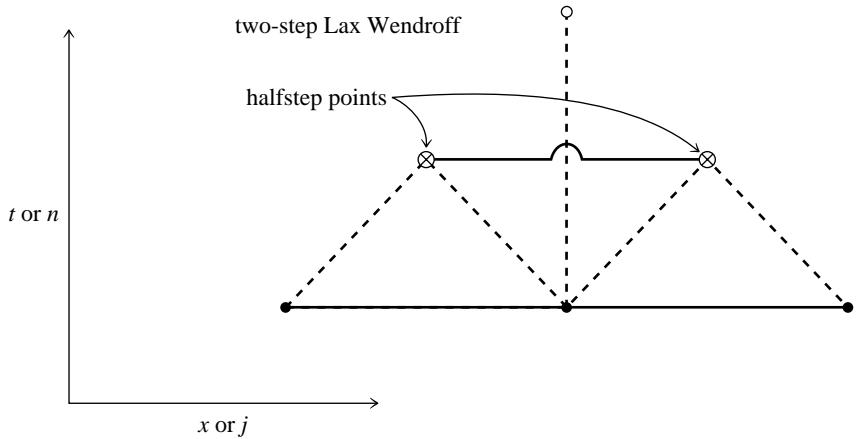

Figure 19.1.7. Representation of the two-step Lax-Wendroff differencing scheme. Two halfstep points (\otimes) are calculated by the Lax method. These, plus one of the original points, produce the new point via staggered leapfrog. Halfstep points are used only temporarily and do not require storage allocation on the grid. This scheme is second-order accurate in both space and time.

where

$$\alpha \equiv \frac{v\Delta t}{\Delta x} \quad (19.1.40)$$

Then

$$\xi = 1 - i\alpha \sin k\Delta x - \alpha^2(1 - \cos k\Delta x) \quad (19.1.41)$$

so

$$|\xi|^2 = 1 - \alpha^2(1 - \alpha^2)(1 - \cos k\Delta x)^2 \quad (19.1.42)$$

The stability criterion $|\xi|^2 \leq 1$ is therefore $\alpha^2 \leq 1$, or $v\Delta t \leq \Delta x$ as usual. Incidentally, you should not think that the Courant condition is the only stability requirement that ever turns up in PDEs. It keeps doing so in our model examples just because those examples are so simple in form. The method of analysis is, however, general.

Except when $\alpha = 1$, $|\xi|^2 < 1$ in (19.1.42), so some amplitude damping does occur. The effect is relatively small, however, for wavelengths large compared with the mesh size Δx . If we expand (19.1.42) for small $k\Delta x$, we find

$$|\xi|^2 = 1 - \alpha^2(1 - \alpha^2)\frac{(k\Delta x)^4}{4} + \dots \quad (19.1.43)$$

The departure from unity occurs only at fourth order in k . This should be contrasted with equation (19.1.16) for the Lax method, which shows that

$$|\xi|^2 = 1 - (1 - \alpha^2)(k\Delta x)^2 + \dots \quad (19.1.44)$$

for small $k\Delta x$.

In summary, our recommendation for initial value problems that can be cast in flux-conservative form, and especially problems related to the wave equation, is to use the staggered leapfrog method when possible. We have personally had better success with it than with the Two-Step Lax-Wendroff method. For problems sensitive to transport errors, upwind differencing or one of its refinements should be considered.

Fluid Dynamics with Shocks

As we alluded to earlier, the treatment of fluid dynamics problems with shocks has become a very complicated and very sophisticated subject. All we can attempt to do here is to guide you to some starting points in the literature.

There are basically three important general methods for handling shocks. The oldest and simplest method, invented by von Neumann and Richtmyer, is to add *artificial viscosity* to the equations, modeling the way Nature uses real viscosity to smooth discontinuities. A good starting point for trying out this method is the differencing scheme in §12.11 of [1]. This scheme is excellent for nearly all problems in one spatial dimension.

The second method combines a high-order differencing scheme that is accurate for smooth flows with a low order scheme that is very dissipative and can smooth the shocks. Typically, various upwind differencing schemes are combined using weights chosen to zero the low order scheme unless steep gradients are present, and also chosen to enforce various “monotonicity” constraints that prevent nonphysical oscillations from appearing in the numerical solution. References [2-3.5] are a good place to start with these methods.

The third, and potentially most powerful method, is Godunov’s approach. Here one gives up the simple linearization inherent in finite differencing based on Taylor series and includes the nonlinearity of the equations explicitly. There is an analytic solution for the evolution of two uniform states of a fluid separated by a discontinuity, the Riemann shock problem. Godunov’s idea was to approximate the fluid by a large number of cells of uniform states, and piece them together using the Riemann solution. There have been many generalizations of Godunov’s approach, of which the most powerful is probably the PPM method [6].

Readable reviews of all these methods, discussing the difficulties arising when one-dimensional methods are generalized to multidimensions, are given in [7-9].

19.2 Diffusive Initial Value Problems

Recall the model parabolic equation, the diffusion equation in one space dimension,

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial u}{\partial x} \right) \quad (19.2.1)$$

where D is the diffusion coefficient. Actually, this equation is a flux-conservative equation of the form considered in the previous section, with

$$F = -D \frac{\partial u}{\partial x} \quad (19.2.2)$$

the flux in the x -direction. We will assume $D \geq 0$, otherwise equation (19.2.1) has physically unstable solutions: A small disturbance evolves to become more and more concentrated instead of dispersing. (Don't make the mistake of trying to find a stable differencing scheme for a problem whose underlying PDEs are themselves unstable!)

Even though (19.2.1) is of the form already considered, it is useful to consider it as a model in its own right. The particular form of flux (19.2.2), and its direct generalizations, occur quite frequently in practice. Moreover, we have already seen that numerical viscosity and artificial viscosity can introduce diffusive pieces like the right-hand side of (19.2.1) in many other situations.

Consider first the case when D is a constant. Then the equation

$$\frac{\partial u}{\partial t} = D \frac{\partial^2 u}{\partial x^2} \quad (19.2.3)$$

can be differenced in the obvious way:

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = D \left[\frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{(\Delta x)^2} \right] \quad (19.2.4)$$

This is the FTCS scheme again, except that it is a second derivative that has been differenced on the right-hand side. But this makes a world of difference! The FTCS scheme was unstable for the hyperbolic equation; however, a quick calculation shows that the amplification factor for equation (19.2.4) is

$$\xi = 1 - \frac{4D\Delta t}{(\Delta x)^2} \sin^2 \left(\frac{k\Delta x}{2} \right) \quad (19.2.5)$$

The requirement $|\xi| \leq 1$ leads to the stability criterion

$$\frac{2D\Delta t}{(\Delta x)^2} \leq 1 \quad (19.2.6)$$

19.2 Diffusive Initial Value Problems

Recall the model parabolic equation, the diffusion equation in one space dimension,

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x} \left(D \frac{\partial u}{\partial x} \right) \quad (19.2.1)$$

where D is the diffusion coefficient. Actually, this equation is a flux-conservative equation of the form considered in the previous section, with

$$F = -D \frac{\partial u}{\partial x} \quad (19.2.2)$$

the flux in the x -direction. We will assume $D \geq 0$, otherwise equation (19.2.1) has physically unstable solutions: A small disturbance evolves to become more and more concentrated instead of dispersing. (Don't make the mistake of trying to find a stable differencing scheme for a problem whose underlying PDEs are themselves unstable!)

Even though (19.2.1) is of the form already considered, it is useful to consider it as a model in its own right. The particular form of flux (19.2.2), and its direct generalizations, occur quite frequently in practice. Moreover, we have already seen that numerical viscosity and artificial viscosity can introduce diffusive pieces like the right-hand side of (19.2.1) in many other situations.

Consider first the case when D is a constant. Then the equation

$$\frac{\partial u}{\partial t} = D \frac{\partial^2 u}{\partial x^2} \quad (19.2.3)$$

can be differenced in the obvious way:

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = D \left[\frac{u_{j+1}^n - 2u_j^n + u_{j-1}^n}{(\Delta x)^2} \right] \quad (19.2.4)$$

This is the FTCS scheme again, except that it is a second derivative that has been differenced on the right-hand side. But this makes a world of difference! The FTCS scheme was unstable for the hyperbolic equation; however, a quick calculation shows that the amplification factor for equation (19.2.4) is

$$\xi = 1 - \frac{4D\Delta t}{(\Delta x)^2} \sin^2 \left(\frac{k\Delta x}{2} \right) \quad (19.2.5)$$

The requirement $|\xi| \leq 1$ leads to the stability criterion

$$\frac{2D\Delta t}{(\Delta x)^2} \leq 1 \quad (19.2.6)$$

The physical interpretation of the restriction (19.2.6) is that the maximum allowed timestep is, up to a numerical factor, the diffusion time across a cell of width Δx .

More generally, the diffusion time τ across a spatial scale of size λ is of order

$$\tau \sim \frac{\lambda^2}{D} \quad (19.2.7)$$

Usually we are interested in modeling accurately the evolution of features with spatial scales $\lambda \gg \Delta x$. If we are limited to timesteps satisfying (19.2.6), we will need to evolve through of order $\lambda^2/(\Delta x)^2$ steps before things start to happen on the scale of interest. This number of steps is usually prohibitive. We must therefore find a stable way of taking timesteps comparable to, or perhaps — for accuracy — somewhat smaller than, the time scale of (19.2.7).

This goal poses an immediate “philosophical” question. Obviously the large timesteps that we propose to take are going to be woefully inaccurate for the small scales that we have decided not to be interested in. We want those scales to do something stable, “innocuous,” and perhaps not too physically unreasonable. We want to build this innocuous behavior into our differencing scheme. What should it be?

There are two different answers, each of which has its pros and cons. The first answer is to seek a differencing scheme that drives small-scale features to their *equilibrium* forms, e.g., satisfying equation (19.2.3) with the left-hand side set to zero. This answer generally makes the best physical sense; but, as we will see, it leads to a differencing scheme (“fully implicit”) that is only *first-order* accurate in time for the scales that we are interested in. The second answer is to let small-scale features *Maintain* their initial amplitudes, so that the evolution of the larger-scale features of interest takes place superposed with a kind of “frozen in” (though fluctuating) background of small-scale stuff. This answer gives a differencing scheme (“Crank-Nicolson”) that is *second-order* accurate in time. Toward the end of an evolution calculation, however, one might want to switch over to some steps of the other kind, to drive the small-scale stuff into equilibrium. Let us now see where these distinct differencing schemes come from:

Consider the following differencing of (19.2.3),

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = D \left[\frac{u_{j+1}^{n+1} - 2u_j^{n+1} + u_{j-1}^{n+1}}{(\Delta x)^2} \right] \quad (19.2.8)$$

This is exactly like the FTCS scheme (19.2.4), except that the spatial derivatives on the right-hand side are evaluated at timestep $n + 1$. Schemes with this character are called *fully implicit* or *backward time*, by contrast with FTCS (which is called *fully explicit*). To solve equation (19.2.8) one has to solve a set of simultaneous linear equations at each timestep for the u_j^{n+1} . Fortunately, this is a simple problem because the system is tridiagonal: Just group the terms in equation (19.2.8) appropriately:

$$-\alpha u_{j-1}^{n+1} + (1 + 2\alpha)u_j^{n+1} - \alpha u_{j+1}^{n+1} = u_j^n, \quad j = 1, 2, \dots, J-1 \quad (19.2.9)$$

where

$$\alpha \equiv \frac{D \Delta t}{(\Delta x)^2} \quad (19.2.10)$$

Supplemented by Dirichlet or Neumann boundary conditions at $j = 0$ and $j = J$, equation (19.2.9) is clearly a tridiagonal system, which can easily be solved at each timestep by the method of §2.4.

What is the behavior of (19.2.8) for very large timesteps? The answer is seen most clearly in (19.2.9), in the limit $\alpha \rightarrow \infty$ ($\Delta t \rightarrow \infty$). Dividing by α , we see that the difference equations are just the finite-difference form of the equilibrium equation

$$\frac{\partial^2 u}{\partial x^2} = 0 \quad (19.2.11)$$

What about stability? The amplification factor for equation (19.2.8) is

$$\xi = \frac{1}{1 + 4\alpha \sin^2\left(\frac{k\Delta x}{2}\right)} \quad (19.2.12)$$

Clearly $|\xi| < 1$ for any stepsize Δt . The scheme is unconditionally stable. The details of the small-scale evolution from the initial conditions are obviously inaccurate for large Δt . But, as advertised, the correct equilibrium solution is obtained. This is the characteristic feature of implicit methods.

Here, on the other hand, is how one gets to the second of our above philosophical answers, combining the stability of an implicit method with the accuracy of a method that is second-order in both space and time. Simply form the average of the explicit and implicit FTCS schemes:

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = \frac{D}{2} \left[\frac{(u_{j+1}^{n+1} - 2u_j^{n+1} + u_{j-1}^{n+1}) + (u_{j+1}^n - 2u_j^n + u_{j-1}^n)}{(\Delta x)^2} \right] \quad (19.2.13)$$

Here both the left- and right-hand sides are centered at timestep $n + \frac{1}{2}$, so the method is second-order accurate in time as claimed. The amplification factor is

$$\xi = \frac{1 - 2\alpha \sin^2\left(\frac{k\Delta x}{2}\right)}{1 + 2\alpha \sin^2\left(\frac{k\Delta x}{2}\right)} \quad (19.2.14)$$

so the method is stable for any size Δt . This scheme is called the *Crank-Nicolson* scheme, and is our recommended method for any simple diffusion problem (perhaps supplemented by a few fully implicit steps at the end). (See Figure 19.2.1.)

Now turn to some generalizations of the simple diffusion equation (19.2.3). Suppose first that the diffusion coefficient D is not constant, say $D = D(x)$. We can adopt either of two strategies. First, we can make an analytic change of variable

$$y = \int \frac{dx}{D(x)} \quad (19.2.15)$$

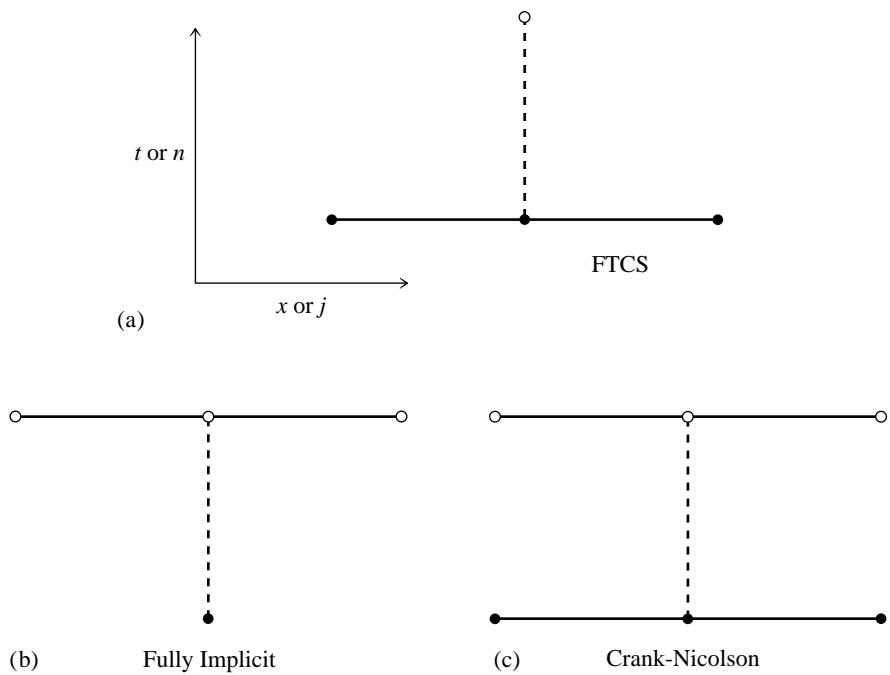

Figure 19.2.1. Three differencing schemes for diffusive problems (shown as in Figure 19.1.2). (a) Forward Time Center Space is first-order accurate, but stable only for sufficiently small timesteps. (b) Fully Implicit is stable for arbitrarily large timesteps, but is still only first-order accurate. (c) Crank-Nicolson is second-order accurate, and is usually stable for large timesteps.

Then

$$\frac{\partial u}{\partial t} = \frac{\partial}{\partial x} D(x) \frac{\partial u}{\partial x} \quad (19.2.16)$$

becomes

$$\frac{\partial u}{\partial t} = \frac{1}{D(y)} \frac{\partial^2 u}{\partial y^2} \quad (19.2.17)$$

and we evaluate D at the appropriate y_j . Heuristically, the stability criterion (19.2.6) in an explicit scheme becomes

$$\Delta t \leq \min_j \left[\frac{(\Delta y)^2}{2D_j^{-1}} \right] \quad (19.2.18)$$

Note that constant spacing Δy in y does not imply constant spacing in x .

An alternative method that does not require analytically tractable forms for D is simply to difference equation (19.2.16) as it stands, centering everything appropriately. Thus the FTCS method becomes

$$\frac{u_j^{n+1} - u_j^n}{\Delta t} = \frac{D_{j+1/2}(u_{j+1}^n - u_j^n) - D_{j-1/2}(u_j^n - u_{j-1}^n)}{(\Delta x)^2} \quad (19.2.19)$$

where

$$D_{j+1/2} \equiv D(x_{j+1/2}) \quad (19.2.20)$$

and the heuristic stability criterion is

$$\Delta t \leq \min_j \left[\frac{(\Delta x)^2}{2D_{j+1/2}} \right] \quad (19.2.21)$$

The Crank-Nicolson method can be generalized similarly.

The second complication one can consider is a nonlinear diffusion problem, for example where $D = D(u)$. Explicit schemes can be generalized in the obvious way. For example, in equation (19.2.19) write

$$D_{j+1/2} = \frac{1}{2} [D(u_{j+1}^n) + D(u_j^n)] \quad (19.2.22)$$

Implicit schemes are not as easy. The replacement (19.2.22) with $n \rightarrow n + 1$ leaves us with a nasty set of coupled nonlinear equations to solve at each timestep. Often there is an easier way: If the form of $D(u)$ allows us to integrate

$$dz = D(u)du \quad (19.2.23)$$

analytically for $z(u)$, then the right-hand side of (19.2.1) becomes $\partial^2 z / \partial x^2$, which we difference implicitly as

$$\frac{z_{j+1}^{n+1} - 2z_j^{n+1} + z_{j-1}^{n+1}}{(\Delta x)^2} \quad (19.2.24)$$

Now linearize each term on the right-hand side of equation (19.2.24), for example

$$\begin{aligned} z_j^{n+1} &\equiv z(u_j^{n+1}) = z(u_j^n) + (u_j^{n+1} - u_j^n) \frac{\partial z}{\partial u} \Big|_{j,n} \\ &= z(u_j^n) + (u_j^{n+1} - u_j^n) D(u_j^n) \end{aligned} \quad (19.2.25)$$

This reduces the problem to tridiagonal form again and in practice usually retains the stability advantages of fully implicit differencing.

Schrödinger Equation

Sometimes the physical problem being solved imposes constraints on the differencing scheme that we have not yet taken into account. For example, consider the time-dependent Schrödinger equation of quantum mechanics. This is basically a parabolic equation for the evolution of a complex quantity ψ . For the scattering of a wavepacket by a one-dimensional potential $V(x)$, the equation has the form

$$i \frac{\partial \psi}{\partial t} = -\frac{\partial^2 \psi}{\partial x^2} + V(x)\psi \quad (19.2.26)$$

(Here we have chosen units so that Planck's constant $\hbar = 1$ and the particle mass $m = 1/2$.) One is given the initial wavepacket, $\psi(x, t = 0)$, together with boundary

conditions that $\psi \rightarrow 0$ at $x \rightarrow \pm\infty$. Suppose we content ourselves with first-order accuracy in time, but want to use an implicit scheme, for stability. A slight generalization of (19.2.8) leads to

$$i \left[\frac{\psi_j^{n+1} - \psi_j^n}{\Delta t} \right] = - \left[\frac{\psi_{j+1}^{n+1} - 2\psi_j^{n+1} + \psi_{j-1}^{n+1}}{(\Delta x)^2} \right] + V_j \psi_j^{n+1} \quad (19.2.27)$$

for which

$$\xi = \frac{1}{1 + i \left[\frac{4\Delta t}{(\Delta x)^2} \sin^2 \left(\frac{k\Delta x}{2} \right) + V_j \Delta t \right]} \quad (19.2.28)$$

This is unconditionally stable, but unfortunately is not *unitary*. The underlying physical problem requires that the total probability of finding the particle somewhere remains unity. This is represented formally by the modulus-square norm of ψ remaining unity:

$$\int_{-\infty}^{\infty} |\psi|^2 dx = 1 \quad (19.2.29)$$

The initial wave function $\psi(x, 0)$ is normalized to satisfy (19.2.29). The Schrödinger equation (19.2.26) then guarantees that this condition is satisfied at all later times.

Let us write equation (19.2.26) in the form

$$i \frac{\partial \psi}{\partial t} = H\psi \quad (19.2.30)$$

where the operator H is

$$H = -\frac{\partial^2}{\partial x^2} + V(x) \quad (19.2.31)$$

The formal solution of equation (19.2.30) is

$$\psi(x, t) = e^{-iHt} \psi(x, 0) \quad (19.2.32)$$

where the exponential of the operator is defined by its power series expansion.

The unstable explicit FTCS scheme approximates (19.2.32) as

$$\psi_j^{n+1} = (1 - iH\Delta t)\psi_j^n \quad (19.2.33)$$

where H is represented by a centered finite-difference approximation in x . The stable implicit scheme (19.2.27) is, by contrast,

$$\psi_j^{n+1} = (1 + iH\Delta t)^{-1}\psi_j^n \quad (19.2.34)$$

These are both first-order accurate in time, as can be seen by expanding equation (19.2.32). However, neither operator in (19.2.33) or (19.2.34) is unitary.

The correct way to difference Schrödinger's equation [1,2] is to use *Cayley's form* for the finite-difference representation of e^{-iHt} , which is second-order accurate and unitary:

$$e^{-iHt} \simeq \frac{1 - \frac{1}{2}iH\Delta t}{1 + \frac{1}{2}iH\Delta t} \quad (19.2.35)$$

In other words,

$$(1 + \frac{1}{2}iH\Delta t)\psi_j^{n+1} = (1 - \frac{1}{2}iH\Delta t)\psi_j^n \quad (19.2.36)$$

On replacing H by its finite-difference approximation in x , we have a complex tridiagonal system to solve. The method is stable, unitary, and second-order accurate in space and time. In fact, it is simply the Crank-Nicolson method once again!

19.3 Initial Value Problems in Multidimensions

The methods described in §19.1 and §19.2 for problems in $1 + 1$ dimension (one space and one time dimension) can easily be generalized to $N + 1$ dimensions. However, the computing power necessary to solve the resulting equations is enormous. If you have solved a one-dimensional problem with 100 spatial grid points, solving the two-dimensional version with 100×100 mesh points requires *at least* 100 times as much computing. You generally have to be content with very modest spatial resolution in multidimensional problems.

Indulge us in offering a bit of advice about the development and testing of multidimensional PDE codes: You should always first run your programs on *very small* grids, e.g., 8×8 , even though the resulting accuracy is so poor as to be useless. When your program is all debugged and demonstrably stable, *then* you can increase the grid size to a reasonable one and start looking at the results. We have actually heard someone protest, “my program would be unstable for a crude grid, but I am sure the instability will go away on a larger grid.” That is nonsense of a most pernicious sort, evidencing total confusion between accuracy and stability. In fact, new instabilities sometimes do show up on *larger* grids; but old instabilities never (in our experience) just go away.

Forced to live with modest grid sizes, some people recommend going to higher-order methods in an attempt to improve accuracy. This is very dangerous. Unless the solution you are looking for is known to be smooth, and the high-order method you

19.3 Initial Value Problems in Multidimensions

The methods described in §19.1 and §19.2 for problems in $1 + 1$ dimension (one space and one time dimension) can easily be generalized to $N + 1$ dimensions. However, the computing power necessary to solve the resulting equations is enormous. If you have solved a one-dimensional problem with 100 spatial grid points, solving the two-dimensional version with 100×100 mesh points requires *at least* 100 times as much computing. You generally have to be content with very modest spatial resolution in multidimensional problems.

Indulge us in offering a bit of advice about the development and testing of multidimensional PDE codes: You should always first run your programs on *very small* grids, e.g., 8×8 , even though the resulting accuracy is so poor as to be useless. When your program is all debugged and demonstrably stable, *then* you can increase the grid size to a reasonable one and start looking at the results. We have actually heard someone protest, “my program would be unstable for a crude grid, but I am sure the instability will go away on a larger grid.” That is nonsense of a most pernicious sort, evidencing total confusion between accuracy and stability. In fact, new instabilities sometimes do show up on *larger* grids; but old instabilities never (in our experience) just go away.

Forced to live with modest grid sizes, some people recommend going to higher-order methods in an attempt to improve accuracy. This is very dangerous. Unless the solution you are looking for is known to be smooth, and the high-order method you

are using is known to be extremely stable, we do not recommend anything higher than second-order in time (for sets of first-order equations). For spatial differencing, we recommend the order of the underlying PDEs, perhaps allowing second-order spatial differencing for first-order-in-space PDEs. When you increase the order of a differencing method to greater than the order of the original PDEs, you introduce spurious solutions to the difference equations. This does not create a problem if they all happen to decay exponentially; otherwise you are going to see all hell break loose!

Lax Method for a Flux-Conservative Equation

As an example, we show how to generalize the Lax method (19.1.15) to two dimensions for the conservation equation

$$\frac{\partial u}{\partial t} = -\nabla \cdot \mathbf{F} = -\left(\frac{\partial F_x}{\partial x} + \frac{\partial F_y}{\partial y}\right) \quad (19.3.1)$$

Use a spatial grid with

$$\begin{aligned} x_j &= x_0 + j\Delta \\ y_l &= y_0 + l\Delta \end{aligned} \quad (19.3.2)$$

We have chosen $\Delta x = \Delta y \equiv \Delta$ for simplicity. Then the Lax scheme is

$$\begin{aligned} u_{j,l}^{n+1} &= \frac{1}{4}(u_{j+1,l}^n + u_{j-1,l}^n + u_{j,l+1}^n + u_{j,l-1}^n) \\ &\quad - \frac{\Delta t}{2\Delta}(F_{j+1,l}^n - F_{j-1,l}^n + F_{j,l+1}^n - F_{j,l-1}^n) \end{aligned} \quad (19.3.3)$$

Note that as an abbreviated notation F_{j+1} and F_{j-1} refer to F_x , while F_{l+1} and F_{l-1} refer to F_y .

Let us carry out a stability analysis for the model advective equation (analog of 19.1.6) with

$$F_x = v_x u, \quad F_y = v_y u \quad (19.3.4)$$

This requires an eigenmode with two dimensions in space, though still only a simple dependence on powers of ξ in time,

$$u_{j,l}^n = \xi^n e^{ik_x j\Delta} e^{ik_y l\Delta} \quad (19.3.5)$$

Substituting in equation (19.3.3), we find

$$\xi = \frac{1}{2}(\cos k_x \Delta + \cos k_y \Delta) - i\alpha_x \sin k_x \Delta - i\alpha_y \sin k_y \Delta \quad (19.3.6)$$

where

$$\alpha_x = \frac{v_x \Delta t}{\Delta}, \quad \alpha_y = \frac{v_y \Delta t}{\Delta} \quad (19.3.7)$$

The expression for $|\xi|^2$ can be manipulated into the form

$$|\xi|^2 = 1 - (\sin^2 k_x \Delta + \sin^2 k_y \Delta) \left[\frac{1}{2} - (\alpha_x^2 + \alpha_y^2) \right] - \frac{1}{4}(\cos k_x \Delta - \cos k_y \Delta)^2 - (\alpha_y \sin k_x \Delta - \alpha_x \sin k_y \Delta)^2 \quad (19.3.8)$$

The last two terms are negative, and so the stability requirement $|\xi|^2 \leq 1$ becomes

$$\frac{1}{2} - (\alpha_x^2 + \alpha_y^2) \geq 0 \quad (19.3.9)$$

or

$$\Delta t \leq \frac{\Delta}{\sqrt{2}(v_x^2 + v_y^2)^{1/2}} \quad (19.3.10)$$

This is an example of the general result for the N -dimensional Courant condition: If $|v|$ is the maximum propagation velocity in the problem, then

$$\Delta t \leq \frac{\Delta}{\sqrt{N}|v|} \quad (19.3.11)$$

is the Courant condition.

Diffusion Equation in Multidimensions

Let us consider the two-dimensional diffusion equation,

$$\frac{\partial u}{\partial t} = D \left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} \right) \quad (19.3.12)$$

An explicit method, such as FTCS, can be generalized from the one-dimensional case in the obvious way. However, we have seen that diffusive problems are usually best treated implicitly. Suppose we try to implement the Crank-Nicolson scheme in two dimensions. This would give us

$$u_{j,l}^{n+1} = u_{j,l}^n + \frac{1}{2}\alpha \left(\delta_x^2 u_{j,l}^{n+1} + \delta_x^2 u_{j,l}^n + \delta_y^2 u_{j,l}^{n+1} + \delta_y^2 u_{j,l}^n \right) \quad (19.3.13)$$

Here

$$\alpha \equiv \frac{D \Delta t}{\Delta^2} \quad \Delta \equiv \Delta x = \Delta y \quad (19.3.14)$$

$$\delta_x^2 u_{j,l}^n \equiv u_{j+1,l}^n - 2u_{j,l}^n + u_{j-1,l}^n \quad (19.3.15)$$

and similarly for $\delta_y^2 u_{j,l}^n$. This is certainly a viable scheme; the problem arises in solving the coupled linear equations. Whereas in one space dimension the system was tridiagonal, that is no longer true, though the matrix is still very sparse. One possibility is to use a suitable sparse matrix technique (see §2.7 and §19.0).

Another possibility, which we generally prefer, is a slightly different way of generalizing the Crank-Nicolson algorithm. It is still second-order accurate in time and space, and unconditionally stable, but the equations are easier to solve than

(19.3.13). Called the *alternating-direction implicit method (ADI)*, this embodies the powerful concept of *operator splitting* or *time splitting*, about which we will say more below. Here, the idea is to divide each timestep into two steps of size $\Delta t/2$. In each substep, a different dimension is treated implicitly:

$$\begin{aligned} u_{j,l}^{n+1/2} &= u_{j,l}^n + \frac{1}{2}\alpha \left(\delta_x^2 u_{j,l}^{n+1/2} + \delta_y^2 u_{j,l}^n \right) \\ u_{j,l}^{n+1} &= u_{j,l}^{n+1/2} + \frac{1}{2}\alpha \left(\delta_x^2 u_{j,l}^{n+1/2} + \delta_y^2 u_{j,l}^{n+1} \right) \end{aligned} \quad (19.3.16)$$

The advantage of this method is that each substep requires only the solution of a simple tridiagonal system.

Operator Splitting Methods Generally

The basic idea of operator splitting, which is also called *time splitting* or *the method of fractional steps*, is this: Suppose you have an initial value equation of the form

$$\frac{\partial u}{\partial t} = \mathcal{L}u \quad (19.3.17)$$

where \mathcal{L} is some operator. While \mathcal{L} is not necessarily linear, suppose that it can at least be written as a linear sum of m pieces, which act additively on u ,

$$\mathcal{L}u = \mathcal{L}_1u + \mathcal{L}_2u + \cdots + \mathcal{L}_mu \quad (19.3.18)$$

Finally, suppose that for *each* of the pieces, you already know a differencing scheme for updating the variable u from timestep n to timestep $n + 1$, valid if that piece of the operator were the *only* one on the right-hand side. We will write these updatings symbolically as

$$\begin{aligned} u^{n+1} &= \mathcal{U}_1(u^n, \Delta t) \\ u^{n+1} &= \mathcal{U}_2(u^n, \Delta t) \\ &\dots \\ u^{n+1} &= \mathcal{U}_m(u^n, \Delta t) \end{aligned} \quad (19.3.19)$$

Now, one form of operator splitting would be to get from n to $n + 1$ by the following sequence of updatings:

$$\begin{aligned} u^{n+(1/m)} &= \mathcal{U}_1(u^n, \Delta t) \\ u^{n+(2/m)} &= \mathcal{U}_2(u^{n+(1/m)}, \Delta t) \\ &\dots \\ u^{n+(m-1)/m} &= \mathcal{U}_m(u^{n+(m-1)/m}, \Delta t) \end{aligned} \quad (19.3.20)$$

For example, a combined advective-diffusion equation, such as

$$\frac{\partial u}{\partial t} = -v \frac{\partial u}{\partial x} + D \frac{\partial^2 u}{\partial x^2} \quad (19.3.21)$$

might profitably use an explicit scheme for the advective term combined with a Crank-Nicolson or other implicit scheme for the diffusion term.

The alternating-direction implicit (ADI) method, equation (19.3.16), is an example of operator splitting with a slightly different twist. Let us reinterpret (19.3.19) to have a different meaning: Let \mathcal{U}_1 now denote an updating method that includes algebraically *all* the pieces of the total operator \mathcal{L} , but which is desirably *stable* only for the \mathcal{L}_1 piece; likewise $\mathcal{U}_2, \dots, \mathcal{U}_m$. Then a method of getting from u^n to u^{n+1} is

$$\begin{aligned} u^{n+1/m} &= \mathcal{U}_1(u^n, \Delta t/m) \\ u^{n+2/m} &= \mathcal{U}_2(u^{n+1/m}, \Delta t/m) \\ &\dots \\ u^{n+1} &= \mathcal{U}_m(u^{n+(m-1)/m}, \Delta t/m) \end{aligned} \quad (19.3.22)$$

The timestep for each fractional step in (19.3.22) is now only $1/m$ of the full timestep, because each partial operation acts with all the terms of the original operator.

Equation (19.3.22) is usually, though not always, stable as a differencing scheme for the operator \mathcal{L} . In fact, as a rule of thumb, it is often sufficient to have stable \mathcal{U}_i 's only for the operator pieces having the highest number of spatial derivatives — the other \mathcal{U}_i 's can be *unstable* — to make the overall scheme stable!

It is at this point that we turn our attention from initial value problems to boundary value problems. These will occupy us for the remainder of the chapter.

19.4 Fourier and Cyclic Reduction Methods for Boundary Value Problems

As discussed in §19.0, most boundary value problems (elliptic equations, for example) reduce to solving large sparse linear systems of the form

$$\mathbf{A} \cdot \mathbf{u} = \mathbf{b} \quad (19.4.1)$$

either once, for boundary value equations that are linear, or iteratively, for boundary value equations that are nonlinear.

For example, a combined advective-diffusion equation, such as

$$\frac{\partial u}{\partial t} = -v \frac{\partial u}{\partial x} + D \frac{\partial^2 u}{\partial x^2} \quad (19.3.21)$$

might profitably use an explicit scheme for the advective term combined with a Crank-Nicolson or other implicit scheme for the diffusion term.

The alternating-direction implicit (ADI) method, equation (19.3.16), is an example of operator splitting with a slightly different twist. Let us reinterpret (19.3.19) to have a different meaning: Let \mathcal{U}_1 now denote an updating method that includes algebraically *all* the pieces of the total operator \mathcal{L} , but which is desirably *stable* only for the \mathcal{L}_1 piece; likewise $\mathcal{U}_2, \dots, \mathcal{U}_m$. Then a method of getting from u^n to u^{n+1} is

$$\begin{aligned} u^{n+1/m} &= \mathcal{U}_1(u^n, \Delta t/m) \\ u^{n+2/m} &= \mathcal{U}_2(u^{n+1/m}, \Delta t/m) \\ &\dots \\ u^{n+1} &= \mathcal{U}_m(u^{n+(m-1)/m}, \Delta t/m) \end{aligned} \quad (19.3.22)$$

The timestep for each fractional step in (19.3.22) is now only $1/m$ of the full timestep, because each partial operation acts with all the terms of the original operator.

Equation (19.3.22) is usually, though not always, stable as a differencing scheme for the operator \mathcal{L} . In fact, as a rule of thumb, it is often sufficient to have stable \mathcal{U}_i 's only for the operator pieces having the highest number of spatial derivatives — the other \mathcal{U}_i 's can be *unstable* — to make the overall scheme stable!

It is at this point that we turn our attention from initial value problems to boundary value problems. These will occupy us for the remainder of the chapter.

19.4 Fourier and Cyclic Reduction Methods for Boundary Value Problems

As discussed in §19.0, most boundary value problems (elliptic equations, for example) reduce to solving large sparse linear systems of the form

$$\mathbf{A} \cdot \mathbf{u} = \mathbf{b} \quad (19.4.1)$$

either once, for boundary value equations that are linear, or iteratively, for boundary value equations that are nonlinear.

Two important techniques lead to “rapid” solution of equation (19.4.1) when the sparse matrix is of certain frequently occurring forms. The *Fourier transform method* is directly applicable when the equations have coefficients that are constant in space. The *cyclic reduction* method is somewhat more general; its applicability is related to the question of whether the equations are separable (in the sense of “separation of variables”). Both methods require the boundaries to coincide with the coordinate lines. Finally, for some problems, there is a powerful combination of these two methods called *FACR* (*Fourier Analysis and Cyclic Reduction*). We now consider each method in turn, using equation (19.0.3), with finite-difference representation (19.0.6), as a model example. Generally speaking, the methods in this section are faster, when they apply, than the simpler relaxation methods discussed in §19.5; but they are not necessarily faster than the more complicated multigrid methods discussed in §19.6.

Fourier Transform Method

The discrete inverse Fourier transform in both x and y is

$$u_{jl} = \frac{1}{JL} \sum_{m=0}^{J-1} \sum_{n=0}^{L-1} \hat{u}_{mn} e^{-2\pi i jm/J} e^{-2\pi i ln/L} \quad (19.4.2)$$

This can be computed using the FFT independently in each dimension, or else all at once via the routine `fourn` of §12.4 or the routine `r1ft3` of §12.5. Similarly,

$$\rho_{jl} = \frac{1}{JL} \sum_{m=0}^{J-1} \sum_{n=0}^{L-1} \hat{\rho}_{mn} e^{-2\pi i jm/J} e^{-2\pi i ln/L} \quad (19.4.3)$$

If we substitute expressions (19.4.2) and (19.4.3) in our model problem (19.0.6), we find

$$\hat{u}_{mn} \left(e^{2\pi im/J} + e^{-2\pi im/J} + e^{2\pi in/L} + e^{-2\pi in/L} - 4 \right) = \hat{\rho}_{mn} \Delta^2 \quad (19.4.4)$$

or

$$\hat{u}_{mn} = \frac{\hat{\rho}_{mn} \Delta^2}{2 \left(\cos \frac{2\pi m}{J} + \cos \frac{2\pi n}{L} - 2 \right)} \quad (19.4.5)$$

Thus the strategy for solving equation (19.0.6) by FFT techniques is:

- Compute $\hat{\rho}_{mn}$ as the Fourier transform

$$\hat{\rho}_{mn} = \sum_{j=0}^{J-1} \sum_{l=0}^{L-1} \rho_{jl} e^{2\pi imj/J} e^{2\pi inl/L} \quad (19.4.6)$$

- Compute \hat{u}_{mn} from equation (19.4.5).

- Compute u_{jl} by the inverse Fourier transform (19.4.2).

The above procedure is valid for periodic boundary conditions. In other words, the solution satisfies

$$u_{jl} = u_{j+J,l} = u_{j,l+L} \quad (19.4.7)$$

Next consider a Dirichlet boundary condition $u = 0$ on the rectangular boundary. Instead of the expansion (19.4.2), we now need an expansion in sine waves:

$$u_{jl} = \frac{2}{J} \frac{2}{L} \sum_{m=1}^{J-1} \sum_{n=1}^{L-1} \hat{u}_{mn} \sin \frac{\pi jm}{J} \sin \frac{\pi ln}{L} \quad (19.4.8)$$

This satisfies the boundary conditions that $u = 0$ at $j = 0, J$ and at $l = 0, L$. If we substitute this expansion and the analogous one for ρ_{jl} into equation (19.0.6), we find that the solution procedure parallels that for periodic boundary conditions:

- Compute $\hat{\rho}_{mn}$ by the sine transform

$$\hat{\rho}_{mn} = \sum_{j=1}^{J-1} \sum_{l=1}^{L-1} \rho_{jl} \sin \frac{\pi jm}{J} \sin \frac{\pi ln}{L} \quad (19.4.9)$$

(A fast sine transform algorithm was given in §12.3.)

- Compute \hat{u}_{mn} from the expression analogous to (19.4.5),

$$\hat{u}_{mn} = \frac{\Delta^2 \hat{\rho}_{mn}}{2 \left(\cos \frac{\pi m}{J} + \cos \frac{\pi n}{L} - 2 \right)} \quad (19.4.10)$$

- Compute u_{jl} by the inverse sine transform (19.4.8).

If we have inhomogeneous boundary conditions, for example $u = 0$ on all boundaries except $u = f(y)$ on the boundary $x = J\Delta$, we have to add to the above solution a solution u^H of the homogeneous equation

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0 \quad (19.4.11)$$

that satisfies the required boundary conditions. In the continuum case, this would be an expression of the form

$$u^H = \sum_n A_n \sinh \frac{n\pi x}{L\Delta} \sin \frac{n\pi y}{L\Delta} \quad (19.4.12)$$

where A_n would be found by requiring that $u = f(y)$ at $x = J\Delta$. In the discrete case, we have

$$u_{jl}^H = \frac{2}{L} \sum_{n=1}^{L-1} A_n \sinh \frac{\pi nj}{L} \sin \frac{\pi nl}{L} \quad (19.4.13)$$

If $f(y = l\Delta) \equiv f_l$, then we get A_n from the inverse formula

$$A_n = \frac{1}{\sinh(\pi n J/L)} \sum_{l=1}^{L-1} f_l \sin \frac{\pi nl}{L} \quad (19.4.14)$$

The complete solution to the problem is

$$u = u_{jl} + u_{jl}^H \quad (19.4.15)$$

By adding appropriate terms of the form (19.4.12), we can handle inhomogeneous terms on any boundary surface.

A much simpler procedure for handling inhomogeneous terms is to note that whenever boundary terms appear on the left-hand side of (19.0.6), they can be taken over to the right-hand side since they are known. The effective source term is therefore ρ_{jl} plus a contribution from the boundary terms. To implement this idea formally, write the solution as

$$u = u' + u^B \quad (19.4.16)$$

where $u' = 0$ on the boundary, while u^B vanishes everywhere *except* on the boundary. There it takes on the given boundary value. In the above example, the only nonzero values of u^B would be

$$u_{J,l}^B = f_l \quad (19.4.17)$$

The model equation (19.0.3) becomes

$$\nabla^2 u' = -\nabla^2 u^B + \rho \quad (19.4.18)$$

or, in finite-difference form,

$$\begin{aligned} u'_{j+1,l} + u'_{j-1,l} + u'_{j,l+1} + u'_{j,l-1} - 4u'_{j,l} = \\ - (u^B_{j+1,l} + u^B_{j-1,l} + u^B_{j,l+1} + u^B_{j,l-1} - 4u^B_{j,l}) + \Delta^2 \rho_{j,l} \end{aligned} \quad (19.4.19)$$

All the u^B terms in equation (19.4.19) vanish except when the equation is evaluated at $j = J - 1$, where

$$u'_{J,l} + u'_{J-2,l} + u'_{J-1,l+1} + u'_{J-1,l-1} - 4u'_{J-1,l} = -f_l + \Delta^2 \rho_{J-1,l} \quad (19.4.20)$$

Thus the problem is now equivalent to the case of zero boundary conditions, except that one row of the source term is modified by the replacement

$$\Delta^2 \rho_{J-1,l} \rightarrow \Delta^2 \rho_{J-1,l} - f_l \quad (19.4.21)$$

The case of Neumann boundary conditions $\nabla u = 0$ is handled by the cosine expansion (12.3.17):

$$u_{jl} = \frac{2}{J} \frac{2}{L} \sum_{m=0}^J \sum_{n=0}^L \hat{u}_{mn} \cos \frac{\pi jm}{J} \cos \frac{\pi ln}{L} \quad (19.4.22)$$

Here the double prime notation means that the terms for $m = 0$ and $m = J$ should be multiplied by $\frac{1}{2}$, and similarly for $n = 0$ and $n = L$. Inhomogeneous terms $\nabla u = g$ can be again included by adding a suitable solution of the homogeneous equation, or more simply by taking boundary terms over to the right-hand side. For example, the condition

$$\frac{\partial u}{\partial x} = g(y) \quad \text{at } x = 0 \quad (19.4.23)$$

becomes

$$\frac{u_{1,l} - u_{-1,l}}{2\Delta} = g_l \quad (19.4.24)$$

where $g_l \equiv g(y = l\Delta)$. Once again we write the solution in the form (19.4.16), where now $\nabla u' = 0$ on the boundary. This time ∇u^B takes on the prescribed value on the boundary, but u^B vanishes everywhere except just *outside* the boundary. Thus equation (19.4.24) gives

$$u_{-1,l}^B = -2\Delta g_l \quad (19.4.25)$$

All the u^B terms in equation (19.4.19) vanish except when $j = 0$:

$$u'_{1,l} + u'_{-1,l} + u'_{0,l+1} + u'_{0,l-1} - 4u'_{0,l} = 2\Delta g_l + \Delta^2 \rho_{0,l} \quad (19.4.26)$$

Thus u' is the solution of a zero-gradient problem, with the source term modified by the replacement

$$\Delta^2 \rho_{0,l} \rightarrow \Delta^2 \rho_{0,l} + 2\Delta g_l \quad (19.4.27)$$

Sometimes Neumann boundary conditions are handled by using a staggered grid, with the u 's defined midway between zone boundaries so that first derivatives are centered on the mesh points. You can solve such problems using similar techniques to those described above if you use the alternative form of the cosine transform, equation (12.3.23).

Cyclic Reduction

Evidently the FFT method works only when the original PDE has constant coefficients, and boundaries that coincide with the coordinate lines. An alternative algorithm, which can be used on somewhat more general equations, is called *cyclic reduction (CR)*.

We illustrate cyclic reduction on the equation

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + b(y) \frac{\partial u}{\partial y} + c(y)u = g(x, y) \quad (19.4.28)$$

This form arises very often in practice from the Helmholtz or Poisson equations in polar, cylindrical, or spherical coordinate systems. More general separable equations are treated in [1].

The finite-difference form of equation (19.4.28) can be written as a set of vector equations

$$\mathbf{u}_{j-1} + \mathbf{T} \cdot \mathbf{u}_j + \mathbf{u}_{j+1} = \mathbf{g}_j \Delta^2 \quad (19.4.29)$$

Here the index j comes from differencing in the x -direction, while the y -differencing (denoted by the index l previously) has been left in vector form. The matrix \mathbf{T} has the form

$$\mathbf{T} = \mathbf{B} - 2\mathbf{1} \quad (19.4.30)$$

where the $2\mathbf{1}$ comes from the x -differencing and the matrix \mathbf{B} from the y -differencing. The matrix \mathbf{B} , and hence \mathbf{T} , is tridiagonal with variable coefficients.

The CR method is derived by writing down three successive equations like (19.4.29):

$$\begin{aligned} \mathbf{u}_{j-2} + \mathbf{T} \cdot \mathbf{u}_{j-1} + \mathbf{u}_j &= \mathbf{g}_{j-1} \Delta^2 \\ \mathbf{u}_{j-1} + \mathbf{T} \cdot \mathbf{u}_j + \mathbf{u}_{j+1} &= \mathbf{g}_j \Delta^2 \\ \mathbf{u}_j + \mathbf{T} \cdot \mathbf{u}_{j+1} + \mathbf{u}_{j+2} &= \mathbf{g}_{j+1} \Delta^2 \end{aligned} \quad (19.4.31)$$

Matrix-multiplying the middle equation by $-\mathbf{T}$ and then adding the three equations, we get

$$\mathbf{u}_{j-2} + \mathbf{T}^{(1)} \cdot \mathbf{u}_j + \mathbf{u}_{j+2} = \mathbf{g}_j^{(1)} \Delta^2 \quad (19.4.32)$$

This is an equation of the same form as (19.4.29), with

$$\begin{aligned} \mathbf{T}^{(1)} &= 2\mathbf{1} - \mathbf{T}^2 \\ \mathbf{g}_j^{(1)} &= \Delta^2(\mathbf{g}_{j-1} - \mathbf{T} \cdot \mathbf{g}_j + \mathbf{g}_{j+1}) \end{aligned} \quad (19.4.33)$$

After one level of CR, we have reduced the number of equations by a factor of two. Since the resulting equations are of the same form as the original equation, we can repeat the process. Taking the number of mesh points to be a power of 2 for simplicity, we finally end up with a single equation for the central line of variables:

$$\mathbf{T}^{(f)} \cdot \mathbf{u}_{J/2} = \Delta^2 \mathbf{g}_{J/2}^{(f)} - \mathbf{u}_0 - \mathbf{u}_J \quad (19.4.34)$$

Here we have moved \mathbf{u}_0 and \mathbf{u}_J to the right-hand side because they are known boundary values. Equation (19.4.34) can be solved for $\mathbf{u}_{J/2}$ by the standard tridiagonal algorithm. The two equations at level $f - 1$ involve $\mathbf{u}_{J/4}$ and $\mathbf{u}_{3J/4}$. The equation for $\mathbf{u}_{J/4}$ involves \mathbf{u}_0 and $\mathbf{u}_{J/2}$, both of which are known, and hence can be solved by the usual tridiagonal routine. A similar result holds true at every stage, so we end up solving $J - 1$ tridiagonal systems.

In practice, equations (19.4.33) should be rewritten to avoid numerical instability. For these and other practical details, refer to [2].

FACR Method

The *best* way to solve equations of the form (19.4.28), including the constant coefficient problem (19.0.3), is a combination of Fourier analysis and cyclic reduction, the FACR method [3-6]. If at the r th stage of CR we Fourier analyze the equations of the form (19.4.32) along y , that is, with respect to the suppressed vector index, we will have a tridiagonal system in the x -direction for each y -Fourier mode:

$$\hat{u}_{j-2^r}^k + \lambda_k^{(r)} \hat{u}_j^k + \hat{u}_{j+2^r}^k = \Delta^2 g_j^{(r)k} \quad (19.4.35)$$

Here $\lambda_k^{(r)}$ is the eigenvalue of $\mathbf{T}^{(r)}$ corresponding to the k th Fourier mode. For the equation (19.0.3), equation (19.4.5) shows that $\lambda_k^{(r)}$ will involve terms like $\cos(2\pi k/L) - 2$ raised to a power. Solve the tridiagonal systems for \hat{u}_j^k at the levels $j = 2^r, 2 \times 2^r, 4 \times 2^r, \dots, J - 2^r$. Fourier synthesize to get the y -values on these x -lines. Then fill in the intermediate x -lines as in the original CR algorithm.

The trick is to choose the number of levels of CR so as to minimize the total number of arithmetic operations. One can show that for a typical case of a 128×128 mesh, the optimal level is $r = 2$; asymptotically, $r \rightarrow \log_2(\log_2 J)$.

A rough estimate of running times for these algorithms for equation (19.0.3) is as follows: The FFT method (in both x and y) and the CR method are roughly comparable. FACR with $r = 0$ (that is, FFT in one dimension and solve the tridiagonal equations by the usual algorithm in the other dimension) gives about a factor of two gain in speed. The optimal FACR with $r = 2$ gives another factor of two gain in speed.

19.5 Relaxation Methods for Boundary Value Problems

As we mentioned in §19.0, relaxation methods involve splitting the sparse matrix that arises from finite differencing and then iterating until a solution is found.

There is another way of thinking about relaxation methods that is somewhat more physical. Suppose we wish to solve the elliptic equation

$$\mathcal{L}u = \rho \quad (19.5.1)$$

where \mathcal{L} represents some elliptic operator and ρ is the source term. Rewrite the equation as a diffusion equation,

$$\frac{\partial u}{\partial t} = \mathcal{L}u - \rho \quad (19.5.2)$$

An initial distribution u relaxes to an equilibrium solution as $t \rightarrow \infty$. This equilibrium has all time derivatives vanishing. Therefore it is the solution of the original elliptic problem (19.5.1). We see that all the machinery of §19.2, on diffusive initial value equations, can be brought to bear on the solution of boundary value problems by relaxation methods.

Let us apply this idea to our model problem (19.0.3). The diffusion equation is

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} - \rho \quad (19.5.3)$$

If we use FTCS differencing (cf. equation 19.2.4), we get

$$u_{j,l}^{n+1} = u_{j,l}^n + \frac{\Delta t}{\Delta^2} (u_{j+1,l}^n + u_{j-1,l}^n + u_{j,l+1}^n + u_{j,l-1}^n - 4u_{j,l}^n) - \rho_{j,l} \Delta t \quad (19.5.4)$$

Recall from (19.2.6) that FTCS differencing is stable in one spatial dimension only if $\Delta t/\Delta^2 \leq \frac{1}{2}$. In two dimensions this becomes $\Delta t/\Delta^2 \leq \frac{1}{4}$. Suppose we try to take the largest possible timestep, and set $\Delta t = \Delta^2/4$. Then equation (19.5.4) becomes

$$u_{j,l}^{n+1} = \frac{1}{4} (u_{j+1,l}^n + u_{j-1,l}^n + u_{j,l+1}^n + u_{j,l-1}^n) - \frac{\Delta^2}{4} \rho_{j,l} \quad (19.5.5)$$

Thus the algorithm consists of using the average of u at its four nearest-neighbor points on the grid (plus the contribution from the source). This procedure is then iterated until convergence.

This method is in fact a classical method with origins dating back to the last century, called *Jacobi's method* (not to be confused with the Jacobi method for eigenvalues). The method is not practical because it converges too slowly. However, it is the basis for understanding the modern methods, which are always compared with it.

Another classical method is the *Gauss-Seidel* method, which turns out to be important in multigrid methods (§19.6). Here we make use of updated values of u on the right-hand side of (19.5.5) as soon as they become available. In other words, the averaging is done “in place” instead of being “copied” from an earlier timestep to a later one. If we are proceeding along the rows, incrementing j for fixed l , we have

$$u_{j,l}^{n+1} = \frac{1}{4} (u_{j+1,l}^n + u_{j-1,l}^{n+1} + u_{j,l+1}^n + u_{j,l-1}^{n+1}) - \frac{\Delta^2}{4} \rho_{j,l} \quad (19.5.6)$$

This method is also slowly converging and only of theoretical interest when used by itself, but some analysis of it will be instructive.

Let us look at the Jacobi and Gauss-Seidel methods in terms of the matrix splitting concept. We change notation and call \mathbf{u} “ \mathbf{x} ,” to conform to standard matrix notation. To solve

$$\mathbf{A} \cdot \mathbf{x} = \mathbf{b} \quad (19.5.7)$$

we can consider splitting \mathbf{A} as

$$\mathbf{A} = \mathbf{L} + \mathbf{D} + \mathbf{U} \quad (19.5.8)$$

where \mathbf{D} is the diagonal part of \mathbf{A} , \mathbf{L} is the lower triangle of \mathbf{A} with zeros on the diagonal, and \mathbf{U} is the upper triangle of \mathbf{A} with zeros on the diagonal.

In the Jacobi method we write for the r th step of iteration

$$\mathbf{D} \cdot \mathbf{x}^{(r)} = -(\mathbf{L} + \mathbf{U}) \cdot \mathbf{x}^{(r-1)} + \mathbf{b} \quad (19.5.9)$$

For our model problem (19.5.5), \mathbf{D} is simply the identity matrix. The Jacobi method converges for matrices \mathbf{A} that are “diagonally dominant” in a sense that can be made mathematically precise. For matrices arising from finite differencing, this condition is usually met.

What is the rate of convergence of the Jacobi method? A detailed analysis is beyond our scope, but here is some of the flavor: The matrix $-\mathbf{D}^{-1} \cdot (\mathbf{L} + \mathbf{U})$ is the *iteration matrix* which, apart from an additive term, maps one set of \mathbf{x} 's into the next. The iteration matrix has eigenvalues, each one of which reflects the factor by which the amplitude of a particular eigenmode of undesired residual is suppressed during one iteration. Evidently those factors had better all have modulus < 1 for the relaxation to work at all! The rate of convergence of the method is set by the rate for the slowest-decaying eigenmode, i.e., the factor with largest modulus. The modulus of this largest factor, therefore lying between 0 and 1, is called the *spectral radius* of the relaxation operator, denoted ρ_s .

The number of iterations r required to reduce the overall error by a factor 10^{-p} is thus estimated by

$$r \approx \frac{p \ln 10}{(-\ln \rho_s)} \quad (19.5.10)$$

In general, the spectral radius ρ_s goes asymptotically to the value 1 as the grid size J is increased, so that more iterations are required. For any given equation, grid geometry, and boundary condition, the spectral radius can, in principle, be computed analytically. For example, for equation (19.5.5) on a $J \times J$ grid with Dirichlet boundary conditions on all four sides, the asymptotic formula for large J turns out to be

$$\rho_s \simeq 1 - \frac{\pi^2}{2J^2} \quad (19.5.11)$$

The number of iterations r required to reduce the error by a factor of 10^{-p} is thus

$$r \simeq \frac{2pJ^2 \ln 10}{\pi^2} \simeq \frac{1}{2} p J^2 \quad (19.5.12)$$

In other words, the number of iterations is proportional to the number of mesh points, J^2 . Since 100×100 and larger problems are common, it is clear that the Jacobi method is only of theoretical interest.

The Gauss-Seidel method, equation (19.5.6), corresponds to the matrix decomposition

$$(\mathbf{L} + \mathbf{D}) \cdot \mathbf{x}^{(r)} = -\mathbf{U} \cdot \mathbf{x}^{(r-1)} + \mathbf{b} \quad (19.5.13)$$

The fact that \mathbf{L} is on the left-hand side of the equation follows from the updating in place, as you can easily check if you write out (19.5.13) in components. One can show [1-3] that the spectral radius is just the square of the spectral radius of the Jacobi method. For our model problem, therefore,

$$\rho_s \simeq 1 - \frac{\pi^2}{J^2} \quad (19.5.14)$$

$$r \simeq \frac{pJ^2 \ln 10}{\pi^2} \simeq \frac{1}{4} p J^2 \quad (19.5.15)$$

The factor of two improvement in the number of iterations over the Jacobi method still leaves the method impractical.

Successive Overrelaxation (SOR)

We get a better algorithm — one that was the standard algorithm until the 1970s — if we make an *overcorrection* to the value of $\mathbf{x}^{(r)}$ at the r th stage of Gauss-Seidel iteration, thus anticipating future corrections. Solve (19.5.13) for $\mathbf{x}^{(r)}$, add and subtract $\mathbf{x}^{(r-1)}$ on the right-hand side, and hence write the Gauss-Seidel method as

$$\mathbf{x}^{(r)} = \mathbf{x}^{(r-1)} - (\mathbf{L} + \mathbf{D})^{-1} \cdot [(\mathbf{L} + \mathbf{D} + \mathbf{U}) \cdot \mathbf{x}^{(r-1)} - \mathbf{b}] \quad (19.5.16)$$

The term in square brackets is just the residual vector $\xi^{(r-1)}$, so

$$\mathbf{x}^{(r)} = \mathbf{x}^{(r-1)} - (\mathbf{L} + \mathbf{D})^{-1} \cdot \xi^{(r-1)} \quad (19.5.17)$$

Now *overcorrect*, defining

$$\mathbf{x}^{(r)} = \mathbf{x}^{(r-1)} - \omega(\mathbf{L} + \mathbf{D})^{-1} \cdot \xi^{(r-1)} \quad (19.5.18)$$

Here ω is called the *overrelaxation parameter*, and the method is called *successive overrelaxation* (SOR).

The following theorems can be proved [1-3]:

- The method is convergent only for $0 < \omega < 2$. If $0 < \omega < 1$, we speak of *underrelaxation*.
- Under certain mathematical restrictions generally satisfied by matrices arising from finite differencing, only overrelaxation ($1 < \omega < 2$) can give faster convergence than the Gauss-Seidel method.
- If ρ_{Jacobi} is the spectral radius of the Jacobi iteration (so that the square of it is the spectral radius of the Gauss-Seidel iteration), then the *optimal* choice for ω is given by

$$\omega = \frac{2}{1 + \sqrt{1 - \rho_{\text{Jacobi}}^2}} \quad (19.5.19)$$

- For this optimal choice, the spectral radius for SOR is

$$\rho_{\text{SOR}} = \left(\frac{\rho_{\text{Jacobi}}}{1 + \sqrt{1 - \rho_{\text{Jacobi}}^2}} \right)^2 \quad (19.5.20)$$

As an application of the above results, consider our model problem for which ρ_{Jacobi} is given by equation (19.5.11). Then equations (19.5.19) and (19.5.20) give

$$\omega \simeq \frac{2}{1 + \pi/J} \quad (19.5.21)$$

$$\rho_{\text{SOR}} \simeq 1 - \frac{2\pi}{J} \quad \text{for large } J \quad (19.5.22)$$

Equation (19.5.10) gives for the number of iterations to reduce the initial error by a factor of 10^{-p} ,

$$r \simeq \frac{pJ \ln 10}{2\pi} \simeq \frac{1}{3} pJ \quad (19.5.23)$$

Comparing with equation (19.5.12) or (19.5.15), we see that optimal SOR requires of order J iterations, as opposed to of order J^2 . Since J is typically 100 or larger, this makes a tremendous difference! Equation (19.5.23) leads to the mnemonic that 3-figure accuracy ($p = 3$) requires a number of iterations equal to the number of mesh points along a side of the grid. For 6-figure accuracy, we require about twice as many iterations.

How do we choose ω for a problem for which the answer is not known analytically? That is just the weak point of SOR! The advantages of SOR obtain only in a fairly narrow window around the correct value of ω . It is better to take ω slightly too large, rather than slightly too small, but best to get it right.

One way to choose ω is to map your problem approximately onto a known problem, replacing the coefficients in the equation by average values. Note, however, that the known problem must have the same grid size and boundary conditions as the actual problem. We give for reference purposes the value of ρ_{Jacobi} for our model problem on a rectangular $J \times L$ grid, allowing for the possibility that $\Delta x \neq \Delta y$:

$$\rho_{\text{Jacobi}} = \frac{\cos \frac{\pi}{J} + \left(\frac{\Delta x}{\Delta y} \right)^2 \cos \frac{\pi}{L}}{1 + \left(\frac{\Delta x}{\Delta y} \right)^2} \quad (19.5.24)$$

Equation (19.5.24) holds for homogeneous Dirichlet or Neumann boundary conditions. For periodic boundary conditions, make the replacement $\pi \rightarrow 2\pi$.

A second way, which is especially useful if you plan to solve many similar elliptic equations each time with slightly different coefficients, is to determine the optimum value ω empirically on the first equation and then use that value for the remaining equations. Various automated schemes for doing this and for “seeking out” the best values of ω are described in the literature.

While the matrix notation introduced earlier is useful for theoretical analyses, for practical implementation of the SOR algorithm we need explicit formulas.

Consider a general second-order elliptic equation in x and y , finite differenced on a square as for our model equation. Corresponding to each row of the matrix \mathbf{A} is an equation of the form

$$a_{j,l}u_{j+1,l} + b_{j,l}u_{j-1,l} + c_{j,l}u_{j,l+1} + d_{j,l}u_{j,l-1} + e_{j,l}u_{j,l} = f_{j,l} \quad (19.5.25)$$

For our model equation, we had $a = b = c = d = 1, e = -4$. The quantity f is proportional to the source term. The iterative procedure is defined by solving (19.5.25) for $u_{j,l}$:

$$u^*_{j,l} = \frac{1}{e_{j,l}} (f_{j,l} - a_{j,l}u_{j+1,l} - b_{j,l}u_{j-1,l} - c_{j,l}u_{j,l+1} - d_{j,l}u_{j,l-1}) \quad (19.5.26)$$

Then $u_{j,l}^{\text{new}}$ is a weighted average

$$u_{j,l}^{\text{new}} = \omega u^*_{j,l} + (1 - \omega)u_{j,l}^{\text{old}} \quad (19.5.27)$$

We calculate it as follows: The residual at any stage is

$$\xi_{j,l} = a_{j,l}u_{j+1,l} + b_{j,l}u_{j-1,l} + c_{j,l}u_{j,l+1} + d_{j,l}u_{j,l-1} + e_{j,l}u_{j,l} - f_{j,l} \quad (19.5.28)$$

and the SOR algorithm (19.5.18) or (19.5.27) is

$$u_{j,l}^{\text{new}} = u_{j,l}^{\text{old}} - \omega \frac{\xi_{j,l}}{e_{j,l}} \quad (19.5.29)$$

This formulation is very easy to program, and the norm of the residual vector $\xi_{j,l}$ can be used as a criterion for terminating the iteration.

Another practical point concerns the order in which mesh points are processed. The obvious strategy is simply to proceed in order down the rows (or columns). Alternatively, suppose we divide the mesh into “odd” and “even” meshes, like the red and black squares of a checkerboard. Then equation (19.5.26) shows that the odd points depend only on the even mesh values and vice versa. Accordingly, we can carry out one half-sweep updating the odd points, say, and then another half-sweep updating the even points with the new odd values. For the version of SOR implemented below, we shall adopt odd-even ordering.

The last practical point is that in practice the asymptotic rate of convergence in SOR is not attained until of order J iterations. The error often grows by a factor of 20 before convergence sets in. A trivial modification to SOR resolves this problem. It is based on the observation that, while ω is the optimum *asymptotic* relaxation parameter, it is not necessarily a good initial choice. In SOR with *Chebyshev acceleration*, one uses odd-even ordering and changes ω at each half-sweep according to the following prescription:

$$\begin{aligned} \omega^{(0)} &= 1 \\ \omega^{(1/2)} &= 1/(1 - \rho_{\text{Jacobi}}^2/2) \\ \omega^{(n+1/2)} &= 1/(1 - \rho_{\text{Jacobi}}^2 \omega^{(n)}/4), \quad n = 1/2, 1, \dots, \infty \\ \omega^{(\infty)} &\rightarrow \omega_{\text{optimal}} \end{aligned} \quad (19.5.30)$$

The beauty of Chebyshev acceleration is that the norm of the error always decreases with each iteration. (This is the norm of the actual error in $u_{j,l}$. The norm of the residual $\xi_{j,l}$ need not decrease monotonically.) While the asymptotic rate of convergence is the same as ordinary SOR, there is never any excuse for not using Chebyshev acceleration to reduce the total number of iterations required.

Here we give a routine for SOR with Chebyshev acceleration.

```

SUBROUTINE sor(a,b,c,d,e,f,u,jmax,rjac)
INTEGER jmax,MAXITS
DOUBLE PRECISION rjac,a(jmax,jmax),b(jmax,jmax),
*      c(jmax,jmax),d(jmax,jmax),e(jmax,jmax),
*      f(jmax,jmax),u(jmax,jmax),EPS
PARAMETER (MAXITS=1000,EPS=1.d-5)
Successive overrelaxation solution of equation (19.5.25) with Chebyshev acceleration. a,
b, c, d, e, and f are input as the coefficients of the equation, each dimensioned to the
grid size JMAX × JMAX. u is input as the initial guess to the solution, usually zero, and
returns with the final value. rjac is input as the spectral radius of the Jacobi iteration,
or an estimate of it.
INTEGER ipass,j,jsw,l,lsw,n
DOUBLE PRECISION anorm,anormf,
*      omega,resid           Double precision is a good idea for JMAX bigger than about 25.
anormf=0.d0                  Compute initial norm of residual and terminate iteration when
do 12 j=2,jmax-1             norm has been reduced by a factor EPS.
   do 11 l=2,jmax-1
      anormf=anormf+abs(f(j,l))      Assumes initial u is zero.
   enddo 11
12 enddo 12
omega=1.d0
do 16 n=1,MAXITS
  anorm=0.d0
  jsw=1
  do 15 ipass=1,2               Odd-even ordering.
    lsw=jsw
    do 14 j=2,jmax-1
      do 13 l=lsw+1,jmax-1,2
        resid=a(j,l)*u(j+1,l)+b(j,l)*u(j-1,l)+
*          c(j,l)*u(j,l+1)+d(j,l)*u(j,l-1)+
*          e(j,l)*u(j,l)-f(j,l)
        anorm=anorm+abs(resid)
        u(j,l)=u(j,l)-omega*resid/e(j,l)
      enddo 13
      lsw=3-lsw
    enddo 14
    jsw=3-jsw
    if(n.eq.1.and.ipass.eq.1) then
      omega=1.d0/(1.d0-.5d0*rjac**2)
    else
      omega=1.d0/(1.d0-.25d0*rjac**2*omega)
    endif
  enddo 15
  if(anorm.lt.EPS*anormf) return
16 enddo 16
pause 'MAXITS exceeded in sor'
END

```

The main advantage of SOR is that it is very easy to program. Its main disadvantage is that it is still very inefficient on large problems.

ADI (Alternating-Direction Implicit) Method

The ADI method of §19.3 for diffusion equations can be turned into a relaxation method for elliptic equations [1-4]. In §19.3, we discussed ADI as a method for solving the time-dependent heat-flow equation

$$\frac{\partial u}{\partial t} = \nabla^2 u - \rho \quad (19.5.31)$$

By letting $t \rightarrow \infty$ one also gets an iterative method for solving the elliptic equation

$$\nabla^2 u = \rho \quad (19.5.32)$$

In either case, the operator splitting is of the form

$$\mathcal{L} = \mathcal{L}_x + \mathcal{L}_y \quad (19.5.33)$$

where \mathcal{L}_x represents the differencing in x and \mathcal{L}_y that in y .

For example, in our model problem (19.0.6) with $\Delta x = \Delta y = \Delta$, we have

$$\begin{aligned} \mathcal{L}_x u &= 2u_{j,l} - u_{j+1,l} - u_{j-1,l} \\ \mathcal{L}_y u &= 2u_{j,l} - u_{j,l+1} - u_{j,l-1} \end{aligned} \quad (19.5.34)$$

More complicated operators may be similarly split, but there is some art involved. A bad choice of splitting can lead to an algorithm that fails to converge. Usually one tries to base the splitting on the physical nature of the problem. We know for our model problem that an initial transient diffuses away, and we set up the x and y splitting to mimic diffusion in each dimension.

Having chosen a splitting, we difference the time-dependent equation (19.5.31) implicitly in two half-steps:

$$\begin{aligned} \frac{u^{n+1/2} - u^n}{\Delta t/2} &= -\frac{\mathcal{L}_x u^{n+1/2} + \mathcal{L}_y u^n}{\Delta^2} - \rho \\ \frac{u^{n+1} - u^{n+1/2}}{\Delta t/2} &= -\frac{\mathcal{L}_x u^{n+1/2} + \mathcal{L}_y u^{n+1}}{\Delta^2} - \rho \end{aligned} \quad (19.5.35)$$

(cf. equation 19.3.16). Here we have suppressed the spatial indices (j, l) . In matrix notation, equations (19.5.35) are

$$(\mathbf{L}_x + r\mathbf{1}) \cdot \mathbf{u}^{n+1/2} = (r\mathbf{1} - \mathbf{L}_y) \cdot \mathbf{u}^n - \Delta^2 \rho \quad (19.5.36)$$

$$(\mathbf{L}_y + r\mathbf{1}) \cdot \mathbf{u}^{n+1} = (r\mathbf{1} - \mathbf{L}_x) \cdot \mathbf{u}^{n+1/2} - \Delta^2 \rho \quad (19.5.37)$$

where

$$r \equiv \frac{2\Delta^2}{\Delta t} \quad (19.5.38)$$

The matrices on the left-hand sides of equations (19.5.36) and (19.5.37) are tridiagonal (and usually positive definite), so the equations can be solved by the

standard tridiagonal algorithm. Given \mathbf{u}^n , one solves (19.5.36) for $\mathbf{u}^{n+1/2}$, substitutes on the right-hand side of (19.5.37), and then solves for \mathbf{u}^{n+1} . The key question is how to choose the iteration parameter r , the analog of a choice of timestep for an initial value problem.

As usual, the goal is to minimize the spectral radius of the iteration matrix. Although it is beyond our scope to go into details here, it turns out that, for the optimal choice of r , the ADI method has the same rate of convergence as SOR. The individual iteration steps in the ADI method are much more complicated than in SOR, so the ADI method would appear to be inferior. This is in fact true if we choose the same parameter r for every iteration step. However, it is possible to choose a *different* r for each step. If this is done optimally, then ADI is generally more efficient than SOR. We refer you to the literature [1-4] for details.

Our reason for not fully implementing ADI here is that, in most applications, it has been superseded by the multigrid methods described in the next section. Our advice is to use SOR for trivial problems (e.g., 20×20), or for solving a larger problem once only, where ease of programming outweighs expense of computer time. Occasionally, the sparse matrix methods of §2.7 are useful for solving a set of difference equations directly. For production solution of large elliptic problems, however, multigrid is now almost always the method of choice.

19.6 Multigrid Methods for Boundary Value Problems

Practical multigrid methods were first introduced in the 1970s by Brandt. These methods can solve elliptic PDEs discretized on N grid points in $O(N)$ operations. The “rapid” direct elliptic solvers discussed in §19.4 solve special kinds of elliptic equations in $O(N \log N)$ operations. The numerical coefficients in these estimates are such that multigrid methods are comparable to the rapid methods in execution speed. Unlike the rapid methods, however, the multigrid methods can solve general elliptic equations with nonconstant coefficients with hardly any loss in efficiency. Even nonlinear equations can be solved with comparable speed.

Unfortunately there is not a single multigrid algorithm that solves all elliptic problems. Rather there is a multigrid technique that provides the framework for solving these problems. You have to adjust the various components of the algorithm within this framework to solve your specific problem. We can only give a brief

standard tridiagonal algorithm. Given \mathbf{u}^n , one solves (19.5.36) for $\mathbf{u}^{n+1/2}$, substitutes on the right-hand side of (19.5.37), and then solves for \mathbf{u}^{n+1} . 19.6 Multigrid Methods for Boundary Value Problems

Practical multigrid methods were first introduced in the 1970s by Brandt. These methods can solve elliptic PDEs discretized on N grid points in $O(N)$ operations. The “rapid” direct elliptic solvers discussed in §19.4 solve special kinds of elliptic equations in $O(N \log N)$ operations. The numerical coefficients in these estimates are such that multigrid methods are comparable to the rapid methods in execution speed. Unlike the rapid methods, however, the multigrid methods can solve general elliptic equations with nonconstant coefficients with hardly any loss in efficiency. Even nonlinear equations can be solved with comparable speed.

Unfortunately there is not a single multigrid algorithm that solves all elliptic problems. Rather there is a multigrid technique that provides the framework for solving these problems. You have to adjust the various components of the algorithm within this framework to solve your specific problem. We can only give a brief

introduction to the subject here. In particular, we will give two sample multigrid routines, one linear and one nonlinear. By following these prototypes and by perusing the references [1-4], you should be able to develop routines to solve your own problems.

There are two related, but distinct, approaches to the use of multigrid techniques. The first, termed “the multigrid method,” is a means for speeding up the convergence of a traditional relaxation method, as defined by you on a grid of pre-specified fineness. In this case, you need define your problem (e.g., evaluate its source terms) only on this grid. Other, coarser, grids defined by the method can be viewed as temporary computational adjuncts.

The second approach, termed (perhaps confusingly) “the full multigrid (FMG) method,” requires you to be able to define your problem on grids of various sizes (generally by discretizing the same underlying PDE into different-sized sets of finite-difference equations). In this approach, the method obtains successive solutions on finer and finer grids. You can stop the solution either at a pre-specified fineness, or you can monitor the truncation error due to the discretization, quitting only when it is tolerably small.

In this section we will first discuss the “multigrid method,” then use the concepts developed to introduce the FMG method. The latter algorithm is the one that we implement in the accompanying programs.

From One-Grid, through Two-Grid, to Multigrid

The key idea of the multigrid method can be understood by considering the simplest case of a two-grid method. Suppose we are trying to solve the linear elliptic problem

$$\mathcal{L}u = f \quad (19.6.1)$$

where \mathcal{L} is some linear elliptic operator and f is the source term. Discretize equation (19.6.1) on a uniform grid with mesh size h . Write the resulting set of linear algebraic equations as

$$\mathcal{L}_h u_h = f_h \quad (19.6.2)$$

Let \tilde{u}_h denote some approximate solution to equation (19.6.2). We will use the symbol u_h to denote the exact solution to the difference equations (19.6.2). Then the *error* in \tilde{u}_h or the *correction* is

$$v_h = u_h - \tilde{u}_h \quad (19.6.3)$$

The *residual* or *defect* is

$$d_h = \mathcal{L}_h \tilde{u}_h - f_h \quad (19.6.4)$$

(Beware: some authors define residual as minus the defect, and there is not universal agreement about which of these two quantities 19.6.4 defines.) Since \mathcal{L}_h is linear, the error satisfies

$$\mathcal{L}_h v_h = -d_h \quad (19.6.5)$$

At this point we need to make an approximation to \mathcal{L}_h in order to find v_h . The classical iteration methods, such as Jacobi or Gauss-Seidel, do this by finding, at each stage, an approximate solution of the equation

$$\widehat{\mathcal{L}}_h \widehat{v}_h = -d_h \quad (19.6.6)$$

where $\widehat{\mathcal{L}}_h$ is a “simpler” operator than \mathcal{L}_h . For example, $\widehat{\mathcal{L}}_h$ is the diagonal part of \mathcal{L}_h for Jacobi iteration, or the lower triangle for Gauss-Seidel iteration. The next approximation is generated by

$$\tilde{u}_h^{\text{new}} = \tilde{u}_h + \widehat{v}_h \quad (19.6.7)$$

Now consider, as an alternative, a completely different type of approximation for \mathcal{L}_h , one in which we “coarsify” rather than “simplify.” That is, we form some appropriate approximation \mathcal{L}_H of \mathcal{L}_h on a coarser grid with mesh size H (we will always take $H = 2h$, but other choices are possible). The residual equation (19.6.5) is now approximated by

$$\mathcal{L}_H v_H = -d_H \quad (19.6.8)$$

Since \mathcal{L}_H has smaller dimension, this equation will be easier to solve than equation (19.6.5). To define the defect d_H on the coarse grid, we need a *restriction operator* \mathcal{R} that restricts d_h to the coarse grid:

$$d_H = \mathcal{R} d_h \quad (19.6.9)$$

The restriction operator is also called the *fine-to-coarse operator* or the *injection operator*. Once we have a solution \tilde{v}_H to equation (19.6.8), we need a *prolongation operator* \mathcal{P} that prolongates or interpolates the correction to the fine grid:

$$\tilde{v}_h = \mathcal{P} \tilde{v}_H \quad (19.6.10)$$

The prolongation operator is also called the *coarse-to-fine operator* or the *interpolation operator*. Both \mathcal{R} and \mathcal{P} are chosen to be linear operators. Finally the approximation \tilde{u}_h can be updated:

$$\tilde{u}_h^{\text{new}} = \tilde{u}_h + \tilde{v}_h \quad (19.6.11)$$

One step of this *coarse-grid correction scheme* is thus:

Coarse-Grid Correction

- Compute the defect on the fine grid from (19.6.4).
- Restrict the defect by (19.6.9).
- Solve (19.6.8) exactly on the coarse grid for the correction.
- Interpolate the correction to the fine grid by (19.6.10).

- Compute the next approximation by (19.6.11).

Let's contrast the advantages and disadvantages of relaxation and the coarse-grid correction scheme. Consider the error v_h expanded into a discrete Fourier series. Call the components in the lower half of the frequency spectrum the *smooth components* and the high-frequency components the *nonsmooth components*. We have seen that relaxation becomes very slowly convergent in the limit $h \rightarrow 0$, i.e., when there are a large number of mesh points. The reason turns out to be that the smooth components are only slightly reduced in amplitude on each iteration. However, many relaxation methods reduce the amplitude of the nonsmooth components by large factors on each iteration: They are good *smoothing operators*.

For the two-grid iteration, on the other hand, components of the error with wavelengths $\lesssim 2H$ are not even representable on the coarse grid and so cannot be reduced to zero on this grid. But it is exactly these high-frequency components that can be reduced by relaxation on the fine grid! This leads us to combine the ideas of relaxation and coarse-grid correction:

Two-Grid Iteration

- Pre-smoothing: Compute \bar{u}_h by applying $\nu_1 \geq 0$ steps of a relaxation method to \tilde{u}_h .
- Coarse-grid correction: As above, using \bar{u}_h to give \bar{u}_h^{new} .
- Post-smoothing: Compute \tilde{u}_h^{new} by applying $\nu_2 \geq 0$ steps of the relaxation method to \bar{u}_h^{new} .

It is only a short step from the above two-grid method to a multigrid method. Instead of solving the coarse-grid defect equation (19.6.8) exactly, we can get an approximate solution of it by introducing an even coarser grid and using the two-grid iteration method. If the convergence factor of the two-grid method is small enough, we will need only a few steps of this iteration to get a good enough approximate solution. We denote the number of such iterations by γ . Obviously we can apply this idea recursively down to some coarsest grid. There the solution is found easily, for example by direct matrix inversion or by iterating the relaxation scheme to convergence.

One iteration of a multigrid method, from finest grid to coarser grids and back to finest grid again, is called a *cycle*. The exact structure of a cycle depends on the value of γ , the number of two-grid iterations at each intermediate stage. The case $\gamma = 1$ is called a V-cycle, while $\gamma = 2$ is called a W-cycle (see Figure 19.6.1). These are the most important cases in practice.

Note that once more than two grids are involved, the pre-smoothing steps after the first one on the finest grid need an initial approximation for the error v . This should be taken to be zero.

Smoothing, Restriction, and Prolongation Operators

The most popular smoothing method, and the one you should try first, is Gauss-Seidel, since it usually leads to a good convergence rate. If we order the mesh points from 1 to N , then the Gauss-Seidel scheme is

$$u_i = -\left(\sum_{\substack{j=1 \\ j \neq i}}^N L_{ij} u_j - f_i\right) \frac{1}{L_{ii}} \quad i = 1, \dots, N \quad (19.6.12)$$

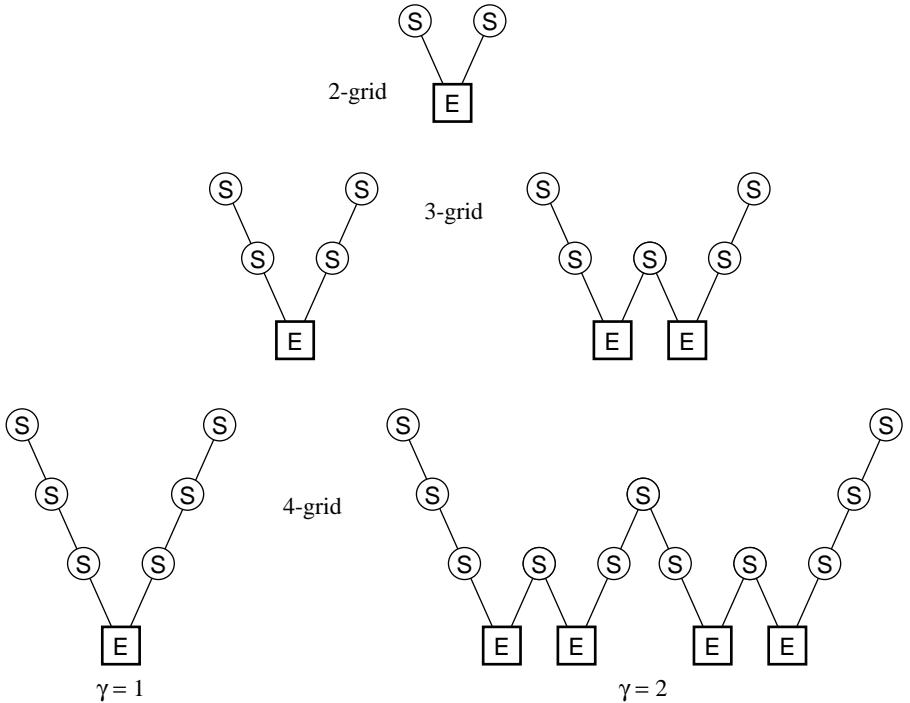

Figure 19.6.1. Structure of multigrid cycles. S denotes smoothing, while E denotes exact solution on the coarsest grid. Each descending line \ denotes restriction (\mathcal{R}) and each ascending line / denotes prolongation (\mathcal{P}). The finest grid is at the top level of each diagram. For the V-cycles ($\gamma = 1$) the E step is replaced by one 2-grid iteration each time the number of grid levels is increased by one. For the W-cycles ($\gamma = 2$), each E step gets replaced by two 2-grid iterations.

where new values of u are used on the right-hand side as they become available. The exact form of the Gauss-Seidel method depends on the ordering chosen for the mesh points. For typical second-order elliptic equations like our model problem equation (19.0.3), as differenced in equation (19.0.8), it is usually best to use red-black ordering, making one pass through the mesh updating the “even” points (like the red squares of a checkerboard) and another pass updating the “odd” points (the black squares). When quantities are more strongly coupled along one dimension than another, one should relax a whole line along that dimension simultaneously. Line relaxation for nearest-neighbor coupling involves solving a tridiagonal system, and so is still efficient. Relaxing odd and even lines on successive passes is called zebra relaxation and is usually preferred over simple line relaxation.

Note that SOR should *not* be used as a smoothing operator. The overrelaxation destroys the high-frequency smoothing that is so crucial for the multigrid method.

A succinct notation for the prolongation and restriction operators is to give their *symbol*. The symbol of \mathcal{P} is found by considering v_H to be 1 at some mesh point (x, y) , zero elsewhere, and then asking for the values of $\mathcal{P}v_H$. The most popular prolongation operator is simple bilinear interpolation. It gives nonzero values at the 9 points (x, y) , $(x + h, y), \dots, (x - h, y - h)$, where the values are $1, \frac{1}{2}, \dots, \frac{1}{4}$.

Its symbol is therefore

$$\begin{bmatrix} \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \\ \frac{1}{2} & 1 & \frac{1}{2} \\ \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \end{bmatrix} \quad (19.6.13)$$

The symbol of \mathcal{R} is defined by considering v_h to be defined everywhere on the fine grid, and then asking what is $\mathcal{R}v_h$ at (x, y) as a linear combination of these values. The simplest possible choice for \mathcal{R} is *straight injection*, which means simply filling each coarse-grid point with the value from the corresponding fine-grid point. Its symbol is “[1].” However, difficulties can arise in practice with this choice. It turns out that a safe choice for \mathcal{R} is to make it the adjoint operator to \mathcal{P} . To define the adjoint, define the scalar product of two grid functions u_h and v_h for mesh size h as

$$\langle u_h | v_h \rangle_h \equiv h^2 \sum_{x,y} u_h(x, y) v_h(x, y) \quad (19.6.14)$$

Then the adjoint of \mathcal{P} , denoted \mathcal{P}^\dagger , is defined by

$$\langle u_H | \mathcal{P}^\dagger v_h \rangle_H = \langle \mathcal{P} u_H | v_h \rangle_h \quad (19.6.15)$$

Now take \mathcal{P} to be bilinear interpolation, and choose $u_H = 1$ at (x, y) , zero elsewhere. Set $\mathcal{P}^\dagger = \mathcal{R}$ in (19.6.15) and $H = 2h$. You will find that

$$(\mathcal{R}v_h)_{(x,y)} = \frac{1}{4}v_h(x, y) + \frac{1}{8}v_h(x+h, y) + \frac{1}{16}v_h(x+h, y+h) + \dots \quad (19.6.16)$$

so that the symbol of \mathcal{R} is

$$\begin{bmatrix} \frac{1}{16} & \frac{1}{8} & \frac{1}{16} \\ \frac{1}{8} & \frac{1}{4} & \frac{1}{8} \\ \frac{1}{16} & \frac{1}{8} & \frac{1}{16} \end{bmatrix} \quad (19.6.17)$$

Note the simple rule: The symbol of \mathcal{R} is $\frac{1}{4}$ the transpose of the matrix defining the symbol of \mathcal{P} , equation (19.6.13). This rule is general whenever $\mathcal{R} = \mathcal{P}^\dagger$ and $H = 2h$.

The particular choice of \mathcal{R} in (19.6.17) is called *full weighting*. Another popular choice for \mathcal{R} is *half weighting*, “halfway” between full weighting and straight injection. Its symbol is

$$\begin{bmatrix} 0 & \frac{1}{8} & 0 \\ \frac{1}{8} & \frac{1}{2} & \frac{1}{8} \\ 0 & \frac{1}{8} & 0 \end{bmatrix} \quad (19.6.18)$$

A similar notation can be used to describe the difference operator \mathcal{L}_h . For example, the standard differencing of the model problem, equation (19.0.6), is represented by the *five-point difference star*

$$\mathcal{L}_h = \frac{1}{h^2} \begin{bmatrix} 0 & 1 & 0 \\ 1 & -4 & 1 \\ 0 & 1 & 0 \end{bmatrix} \quad (19.6.19)$$

If you are confronted with a new problem and you are not sure what \mathcal{P} and \mathcal{R} choices are likely to work well, here is a safe rule: Suppose m_p is the order of the interpolation \mathcal{P} (i.e., it interpolates polynomials of degree $m_p - 1$ exactly). Suppose m_r is the order of \mathcal{R} , and that \mathcal{R} is the adjoint of some \mathcal{P} (not necessarily the \mathcal{P} you intend to use). Then if m is the order of the differential operator \mathcal{L}_h , you should satisfy the inequality $m_p + m_r > m$. For example, bilinear interpolation and its adjoint, full weighting, for Poisson's equation satisfy $m_p + m_r = 4 > m = 2$.

Of course the \mathcal{P} and \mathcal{R} operators should enforce the boundary conditions for your problem. The easiest way to do this is to rewrite the difference equation to have homogeneous boundary conditions by modifying the source term if necessary (cf. §19.4). Enforcing homogeneous boundary conditions simply requires the \mathcal{P} operator to produce zeros at the appropriate boundary points. The corresponding \mathcal{R} is then found by $\mathcal{R} = \mathcal{P}^\dagger$.

Full Multigrid Algorithm

So far we have described multigrid as an iterative scheme, where one starts with some initial guess on the finest grid and carries out enough cycles (V-cycles, W-cycles, . . .) to achieve convergence. This is the simplest way to use multigrid: Simply apply enough cycles until some appropriate convergence criterion is met. However, efficiency can be improved by using the *Full Multigrid Algorithm* (FMG), also known as *nested iteration*.

Instead of starting with an arbitrary approximation on the finest grid (e.g., $u_h = 0$), the first approximation is obtained by interpolating from a coarse-grid solution:

$$u_h = \mathcal{P}u_H \quad (19.6.20)$$

The coarse-grid solution itself is found by a similar FMG process from even coarser grids. At the coarsest level, you start with the exact solution. Rather than proceed as in Figure 19.6.1, then, FMG gets to its solution by a series of increasingly tall “N’s,” each taller one probing a finer grid (see Figure 19.6.2).

Note that \mathcal{P} in (19.6.20) need not be the same \mathcal{P} used in the multigrid cycles. It should be at least of the same order as the discretization \mathcal{L}_h , but sometimes a higher-order operator leads to greater efficiency.

It turns out that you usually need one or at most two multigrid cycles at each level before proceeding down to the next finer grid. While there is theoretical guidance on the required number of cycles (e.g., [2]), you can easily determine it empirically. Fix the finest level and study the solution values as you increase the number of cycles per level. The asymptotic value of the solution is the exact solution of the difference equations. The difference between this exact solution and the solution for a small number of cycles is the iteration error. Now fix the number of cycles to be large, and vary the number of levels, i.e., the smallest value of h used. In this way you can estimate the truncation error for a given h . In your final production code, there is no point in using more cycles than you need to get the iteration error down to the size of the truncation error.

The simple multigrid iteration (cycle) needs the right-hand side f only at the finest level. FMG needs f at all levels. If the boundary conditions are homogeneous,

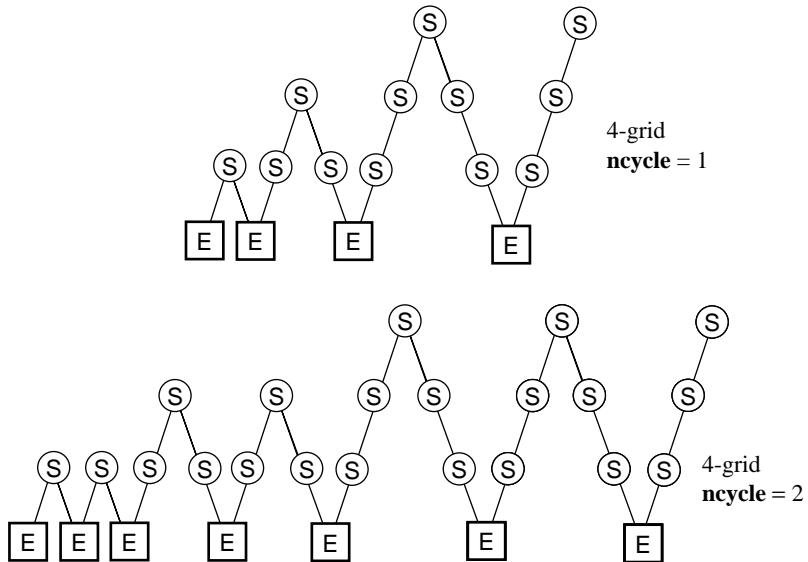

Figure 19.6.2. Structure of cycles for the full multigrid (FMG) method. This method starts on the coarsest grid, interpolates, and then refines (by “V’s”), the solution onto grids of increasing fineness.

you can use $f_H = \mathcal{R}f_h$. This prescription is not always safe for inhomogeneous boundary conditions. In that case it is better to discretize f on each coarse grid.

Note that the FMG algorithm produces the solution on all levels. It can therefore be combined with techniques like Richardson extrapolation.

We now give a routine `mglin` that implements the Full Multigrid Algorithm for a linear equation, the model problem (19.0.6). It uses red-black Gauss-Seidel as the smoothing operator, bilinear interpolation for \mathcal{P} , and half-weighting for \mathcal{R} . To change the routine to handle another linear problem, all you need do is modify the subroutines `relax`, `resid`, and `slvsml` appropriately. A feature of the routine is the dynamical allocation of storage for variables defined on the various grids. The subroutine `malloc` emulates the C function `malloc`. It allows you to write subroutines that operate on two-dimensional arrays in the usual way, but to allocate storage for these arrays in the calling program “on the fly” out of a single long one-dimensional array.

```

SUBROUTINE mglin(u,n,ncycle)
INTEGER n,ncycle,NPRE,NPOST,NG,MEMLEN
DOUBLE PRECISION u(n,n)
PARAMETER (NG=5, MEMLEN=13*2**((2*NG)/3+14*2**NG+8*NG-100/3))
PARAMETER (NPRE=1,NPOST=1)
C USES addint,copy,fill0,interp,malloc,relax,resid,rstrct,slvsml
Full Multigrid Algorithm for solution of linear elliptic equation, here the model problem
(19.0.6). On input  $u(1:n,1:n)$  contains the right-hand side  $\rho$ , while on output it returns
the solution. The dimension  $n$  is related to the number of grid levels used in the solution,
 $NG$  below, by  $n = 2^{**NG} + 1$ .  $ncycle$  is the number of V-cycles to be used at each level.
Parameters:  $NG$  is the number of grid levels used;  $MEMLEN$  is the maximum amount of
memory that can be allocated by calls to malloc;  $NPRE$  and  $NPOST$  are the number of
relaxation sweeps before and after the coarse-grid correction is computed.
INTEGER j,jcycle,jj,jpost,jpre,mem,nf,ngrid,nn,ires(NG),
*      irho(NG),irhs(NG),iu(NG),malloc
DOUBLE PRECISION z

C PARAMETER (NG=5, MEMLEN=17*2**((2*NG)/3+18*2**NG+10*NG-86/3))    for mgfas, N.B.!
INTEGER mem
DOUBLE PRECISION z
COMMON /memory/ z(MEMLEN),mem
   Dynamical storage allocation. Returns integer pointer to the starting position for len array
   elements in the array z. The preceding array element is filled with the value of len, and
   the variable mem is updated to point to the last element of z that has been used.
if (mem+len+1.gt.MEMLEN) pause 'insufficient memory in maloc'
z(mem+1)=len
maloc=mem+2
mem=mem+len+1
return
END

```

The routine `mglin` is written for clarity, not maximum efficiency, so that it is easy to modify. Several simple changes will speed up the execution time:

- The defect d_h vanishes identically at all black mesh points after a red-black Gauss-Seidel step. Thus $d_H = \mathcal{R}d_h$ for half-weighting reduces to simply copying half the defect from the fine grid to the corresponding coarse-grid point. The calls to `resid` followed by `rstrct` in the first part of the V-cycle can be replaced by a routine that loops only over the coarse grid, filling it with half the defect.
- Similarly, the quantity $\tilde{u}_h^{\text{new}} = \tilde{u}_h + \mathcal{P}\tilde{v}_H$ need not be computed at red mesh points, since they will immediately be redefined in the subsequent Gauss-Seidel sweep. This means that `addint` need only loop over black points.

- You can speed up `relax` in several ways. First, you can have a special form when the initial guess is zero, and omit the routine `fill0`. Next, you can store $h^2 f_h$ on the various grids and save a multiplication. Finally, it is possible to save an addition in the Gauss-Seidel formula by rewriting it with intermediate variables.
- On typical problems, `mglin` with `ncycle` = 1 will return a solution with the iteration error bigger than the truncation error for the given size of h . To knock the error down to the size of the truncation error, you have to set `ncycle` = 2 or, more cheaply, `npre` = 2. A more efficient way turns out to be to use a higher-order \mathcal{P} in (19.6.20) than the linear interpolation used in the V-cycle.

Implementing all the above features typically gives up to a factor of two improvement in execution time and is certainly worthwhile in a production code.

Nonlinear Multigrid: The FAS Algorithm

Now turn to solving a nonlinear elliptic equation, which we write symbolically as

$$\mathcal{L}(u) = 0 \quad (19.6.21)$$

Any explicit source term has been moved to the left-hand side. Suppose equation (19.6.21) is suitably discretized:

$$\mathcal{L}_h(u_h) = 0 \quad (19.6.22)$$

We will see below that in the multigrid algorithm we will have to consider equations where a nonzero right-hand side is generated during the course of the solution:

$$\mathcal{L}_h(u_h) = f_h \quad (19.6.23)$$

One way of solving nonlinear problems with multigrid is to use Newton's method, which produces linear equations for the correction term at each iteration. We can then use linear multigrid to solve these equations. A great strength of the multigrid idea, however, is that it can be applied *directly* to nonlinear problems. All we need is a suitable *nonlinear* relaxation method to smooth the errors, plus a procedure for approximating corrections on coarser grids. This direct approach is Brandt's Full Approximation Storage Algorithm (FAS). No nonlinear equations need be solved, except perhaps on the coarsest grid.

To develop the nonlinear algorithm, suppose we have a relaxation procedure that can smooth the residual vector as we did in the linear case. Then we can seek a smooth correction v_h to solve (19.6.23):

$$\mathcal{L}_h(\tilde{u}_h + v_h) = f_h \quad (19.6.24)$$

To find v_h , note that

$$\begin{aligned} \mathcal{L}_h(\tilde{u}_h + v_h) - \mathcal{L}_h(\tilde{u}_h) &= f_h - \mathcal{L}_h(\tilde{u}_h) \\ &= -d_h \end{aligned} \quad (19.6.25)$$

The right-hand side is smooth after a few nonlinear relaxation sweeps. Thus we can transfer the left-hand side to a coarse grid:

$$\mathcal{L}_H(u_H) - \mathcal{L}_H(\mathcal{R}\tilde{u}_h) = -\mathcal{R}d_h \quad (19.6.26)$$

that is, we solve

$$\mathcal{L}_H(u_H) = \mathcal{L}_H(\mathcal{R}\tilde{u}_h) - \mathcal{R}d_h \quad (19.6.27)$$

on the coarse grid. (This is how nonzero right-hand sides appear.) Suppose the approximate solution is \tilde{u}_H . Then the coarse-grid correction is

$$\tilde{v}_H = \tilde{u}_H - \mathcal{R}\tilde{u}_h \quad (19.6.28)$$

and

$$\tilde{u}_h^{\text{new}} = \tilde{u}_h + \mathcal{P}(\tilde{u}_H - \mathcal{R}\tilde{u}_h) \quad (19.6.29)$$

Note that $\mathcal{P}\mathcal{R} \neq 1$ in general, so $\tilde{u}_h^{\text{new}} \neq \mathcal{P}\tilde{u}_H$. This is a key point: In equation (19.6.29) the interpolation error comes only from the correction, not from the full solution \tilde{u}_H .

Equation (19.6.27) shows that one is solving for the full approximation u_H , not just the error as in the linear algorithm. This is the origin of the name FAS.

The FAS multigrid algorithm thus looks very similar to the linear multigrid algorithm. The only differences are that both the defect d_h and the relaxed approximation u_h have to be restricted to the coarse grid, where now it is equation (19.6.27) that is solved by recursive invocation of the algorithm. However, instead of implementing the algorithm this way, we will first describe the so-called *dual viewpoint*, which leads to a powerful alternative way of looking at the multigrid idea.

The dual viewpoint considers the *local truncation error*, defined as

$$\tau \equiv \mathcal{L}_h(u) - f_h \quad (19.6.30)$$

where u is the exact solution of the original continuum equation. If we rewrite this as

$$\mathcal{L}_h(u) = f_h + \tau \quad (19.6.31)$$

we see that τ can be regarded as the correction to f_h so that the solution of the fine-grid equation will be the exact solution u .

Now consider the *relative truncation error* τ_h , which is defined on the H -grid relative to the h -grid:

$$\tau_h \equiv \mathcal{L}_H(\mathcal{R}u_h) - \mathcal{R}\mathcal{L}_h(u_h) \quad (19.6.32)$$

Since $\mathcal{L}_h(u_h) = f_h$, this can be rewritten as

$$\mathcal{L}_H(u_H) = f_H + \tau_h \quad (19.6.33)$$

In other words, we can think of τ_h as the correction to f_H that makes the solution of the coarse-grid equation equal to the fine-grid solution. Of course we cannot compute τ_h , but we do have an approximation to it from using \tilde{u}_h in equation (19.6.32):

$$\tau_h \simeq \tilde{\tau}_h \equiv \mathcal{L}_H(\mathcal{R}\tilde{u}_h) - \mathcal{R}\mathcal{L}_h(\tilde{u}_h) \quad (19.6.34)$$

Replacing τ_h by $\tilde{\tau}_h$ in equation (19.6.33) gives

$$\mathcal{L}_H(u_H) = \mathcal{L}_H(\mathcal{R}\tilde{u}_h) - \mathcal{R}d_h \quad (19.6.35)$$

which is just the coarse-grid equation (19.6.27)!

Thus we see that there are two complementary viewpoints for the relation between coarse and fine grids:

- Coarse grids are used to accelerate the convergence of the smooth components of the fine-grid residuals.
- Fine grids are used to compute correction terms to the coarse-grid equations, yielding fine-grid accuracy on the coarse grids.

One benefit of this new viewpoint is that it allows us to derive a natural stopping criterion for a multigrid iteration. Normally the criterion would be

$$\|d_h\| \leq \epsilon \quad (19.6.36)$$

and the question is how to choose ϵ . There is clearly no benefit in iterating beyond the point when the remaining error is dominated by the local truncation error τ . The computable quantity is $\tilde{\tau}_h$. What is the relation between τ and $\tilde{\tau}_h$? For the typical case of a second-order accurate differencing scheme,

$$\tau = \mathcal{L}_h(u) - \mathcal{L}_h(u_h) = h^2 \tau_2(x, y) + \dots \quad (19.6.37)$$

Assume the solution satisfies $u_h = u + h^2 u_2(x, y) + \dots$. Then, assuming \mathcal{R} is of high enough order that we can neglect its effect, equation (19.6.32) gives

$$\begin{aligned}\tau_h &\simeq \mathcal{L}_H(u + h^2 u_2) - \mathcal{L}_h(u + h^2 u_2) \\ &= \mathcal{L}_H(u) - \mathcal{L}_h(u) + h^2 [\mathcal{L}'_H(u_2) - \mathcal{L}'_h(u_2)] + \dots \\ &= (H^2 - h^2) \tau_2 + O(h^4)\end{aligned}\quad (19.6.38)$$

For the usual case of $H = 2h$ we therefore have

$$\tau \simeq \frac{1}{3} \tau_h \simeq \frac{1}{3} \tilde{\tau}_h \quad (19.6.39)$$

The stopping criterion is thus equation (19.6.36) with

$$\epsilon = \alpha \|\tilde{\tau}_h\|, \quad \alpha \sim \frac{1}{3} \quad (19.6.40)$$

We have one remaining task before implementing our nonlinear multigrid algorithm: choosing a nonlinear relaxation scheme. Once again, your first choice should probably be the nonlinear Gauss-Seidel scheme. If the discretized equation (19.6.23) is written with some choice of ordering as

$$L_i(u_1, \dots, u_N) = f_i, \quad i = 1, \dots, N \quad (19.6.41)$$

then the nonlinear Gauss-Seidel schemes solves

$$L_i(u_1, \dots, u_{i-1}, u_i^{\text{new}}, u_{i+1}, \dots, u_N) = f_i \quad (19.6.42)$$

for u_i^{new} . As usual new u 's replace old u 's as soon as they have been computed. Often equation (19.6.42) is linear in u_i^{new} , since the nonlinear terms are discretized by means of its neighbors. If this is not the case, we replace equation (19.6.42) by one step of a Newton iteration:

$$u_i^{\text{new}} = u_i^{\text{old}} - \frac{L_i(u_i^{\text{old}}) - f_i}{\partial L_i(u_i^{\text{old}})/\partial u_i} \quad (19.6.43)$$

For example, consider the simple nonlinear equation

$$\nabla^2 u + u^2 = \rho \quad (19.6.44)$$

In two-dimensional notation, we have

$$\mathcal{L}(u_{i,j}) = (u_{i+1,j} + u_{i-1,j} + u_{i,j+1} + u_{i,j-1} - 4u_{i,j})/h^2 + u_{i,j}^2 - \rho_{i,j} = 0 \quad (19.6.45)$$

Since

$$\frac{\partial \mathcal{L}}{\partial u_{i,j}} = -4/h^2 + 2u_{i,j} \quad (19.6.46)$$

the Newton Gauss-Seidel iteration is

$$u_{i,j}^{\text{new}} = u_{i,j} - \frac{\mathcal{L}(u_{i,j})}{-4/h^2 + 2u_{i,j}} \quad (19.6.47)$$

Here is a routine `mgfas` that solves equation (19.6.44) using the Full Multigrid Algorithm and the FAS scheme. Restriction and prolongation are done as in `mglin`. We have included the convergence test based on equation (19.6.40). A successful multigrid solution of a problem should aim to satisfy this condition with the maximum number of V-cycles, `maxcyc`, equal to 1 or 2. The routine `mgfas` uses the same subroutines `copy`, `interp`, `malloc`, and `rstrct` as `mglin`, but with a larger storage requirement `MEMLEN` in `malloc` (be sure to change the `PARAMETER` statement in that routine, as indicated by the commented line).

```

SUBROUTINE mgfas(u,n,maxcyc)
INTEGER maxcyc,n,NPRE,NPOST,NG,MEMLEN
DOUBLE PRECISION u(n,n),ALPHA
PARAMETER (NG=5, MEMLEN=17*2**((2*NG)/3+18*2**NG+10*NG-86/3))
PARAMETER (NPRE=1,NPOST=1,ALPHA=.33d0)
C USES anorm2,copy,interp,lop,malloc,matsub,relax2,rstrct,slvsm2
Full Multigrid Algorithm for FAS solution of nonlinear elliptic equation, here equation
(19.6.44). On input  $u(1:n,1:n)$  contains the right-hand side  $\rho$ , while on output it re-
turns the solution. The dimension  $n$  is related to the number of grid levels used in the
solution, NG below, by  $n = 2^{**NG} + 1$ . maxcyc is the maximum number of V-cycles to
be used at each level.
Parameters: NG is the number of grid levels used; MEMLEN is the maximum amount of
memory that can be allocated by calls to malloc; NPRE and NPOST are the number of
relaxation sweeps before and after the coarse-grid correction is computed; ALPHA relates
the estimated truncation error to the norm of the residual.

Chapter 20. Less-Numerical Algorithms

20.0 Introduction

You can stop reading now. You are done with *Numerical Recipes*, as such. This final chapter is an idiosyncratic collection of “*less*-numerical recipes” which, for one reason or another, we have decided to include between the covers of an otherwise *more*-numerically oriented book. Authors of computer science texts, we’ve noticed, like to throw in a token numerical subject (usually quite a dull one — quadrature, for example). We find that we are not free of the reverse tendency.

Our selection of material is not completely arbitrary. One topic, Gray codes, was already used in the construction of quasi-random sequences (§7.7), and here needs only some additional explication. Two other topics, on diagnosing a computer’s floating-point parameters, and on arbitrary precision arithmetic, give additional insight into the machinery behind the casual assumption that computers are useful for doing things with numbers (as opposed to bits or characters). The latter of these topics also shows a very different use for Chapter 12’s fast Fourier transform.

The three other topics (checksums, Huffman and arithmetic coding) involve different aspects of data coding, compression, and validation. If you handle a large amount of data — numerical data, even — then a passing familiarity with these subjects might at some point come in handy. In §13.6, for example, we already encountered a good use for Huffman coding.

But again, you don’t have to read this chapter. (And you should learn about quadrature from Chapters 4 and 16, not from a computer science text!)

20.1 Diagnosing Machine Parameters

A convenient fiction is that a computer’s floating-point arithmetic is “accurate enough.” If you believe this fiction, then numerical analysis becomes a very clean subject. Roundoff error disappears from view; many finite algorithms become “exact”; only docile truncation error (§1.2) stands between you and a perfect calculation. Sounds rather naive, doesn’t it?

Yes, it is naive. Notwithstanding, it is a fiction necessarily adopted throughout most of this book. To do a good job of answering the question of how roundoff error

Chapter 20. Less-Numerical Algorithms

20.0 Introduction

You can stop reading now. You are done with *Numerical Recipes*, as such. This final chapter is an idiosyncratic collection of “*less*-numerical recipes” which, for one reason or another, we have decided to include between the covers of an otherwise *more*-numerically oriented book. Authors of computer science texts, we’ve noticed, like to throw in a token numerical subject (usually quite a dull one — quadrature, for example). We find that we are not free of the reverse tendency.

Our selection of material is not completely arbitrary. One topic, Gray codes, was already used in the construction of quasi-random sequences (§7.7), and here needs only some additional explication. Two other topics, on diagnosing a computer’s floating-point parameters, and on arbitrary precision arithmetic, give additional insight into the machinery behind the casual assumption that computers are useful for doing things with numbers (as opposed to bits or characters). The latter of these topics also shows a very different use for Chapter 12’s fast Fourier transform.

The three other topics (checksums, Huffman and arithmetic coding) involve different aspects of data coding, compression, and validation. If you handle a large amount of data — numerical data, even — then a passing familiarity with these subjects might at some point come in handy. In §13.6, for example, we already encountered a good use for Huffman coding.

But again, you don’t have to read this chapter. (And you should learn about quadrature from Chapters 4 and 16, not from a computer science text!)

20.1 Diagnosing Machine Parameters

A convenient fiction is that a computer’s floating-point arithmetic is “accurate enough.” If you believe this fiction, then numerical analysis becomes a very clean subject. Roundoff error disappears from view; many finite algorithms become “exact”; only docile truncation error (§1.2) stands between you and a perfect calculation. Sounds rather naive, doesn’t it?

Yes, it is naive. Notwithstanding, it is a fiction necessarily adopted throughout most of this book. To do a good job of answering the question of how roundoff error

propagates, or can be bounded, for every algorithm that we have discussed would be impractical. In fact, it would not be possible: Rigorous analysis of many practical algorithms has never been made, by us or anyone.

Proper numerical analysts cringe when they hear a user say, “I was getting roundoff errors with single precision, so I switched to double.” The actual meaning is, “for this particular algorithm, and my particular data, double precision *seemed* able to restore my erroneous belief in the ‘convenient fiction’.” We admit that most of the mentions of precision or roundoff in *Numerical Recipes* are only slightly more quantitative in character. That comes along with our trying to be “practical.”

It is important to know what the limitations of your machine’s floating-point arithmetic actually are — the more so when your treatment of floating-point roundoff error is going to be intuitive, experimental, or casual. Methods for determining useful floating-point parameters experimentally have been developed by Cody [1], Malcolm [2], and others, and are embodied in the routine `machar`, below, which follows Cody’s implementation.

All of `machar`’s arguments are returned values. Here is what they mean:

- `ibeta` (called B in §1.2) is the radix in which numbers are represented, almost always 2, but occasionally 16, or even 10.
- `it` is the number of base-`ibeta` digits in the floating-point mantissa M (see Figure 1.2.1).
- `machepr` is the exponent of the smallest (most negative) power of `ibeta` that, added to 1.0, gives something different from 1.0.
- `eps` is the floating-point number $\text{ibeta}^{\text{machepr}}$, loosely referred to as the “floating-point precision.”
- `negepr` is the exponent of the smallest power of `ibeta` that, subtracted from 1.0, gives something different from 1.0.
- `epsneg` is $\text{ibeta}^{-\text{negepr}}$, another way of defining floating-point precision. Not infrequently `epsneg` is 0.5 times `eps`; occasionally `eps` and `epsneg` are equal.
- `iexp` is the number of bits in the exponent (including its sign or bias).
- `minexp` is the smallest (most negative) power of `ibeta` consistent with there being no leading zeros in the mantissa.
- `xmin` is the floating-point number $\text{ibeta}^{\text{minexp}}$, generally the smallest (in magnitude) useable floating value.
- `maxexp` is the smallest (positive) power of `ibeta` that causes overflow.
- `xmax` is $(1 - \text{epsneg}) \times \text{ibeta}^{\text{maxexp}}$, generally the largest (in magnitude) useable floating value.
- `irnd` returns a code in the range 0 . . . 5, giving information on what kind of rounding is done in addition, and on how underflow is handled. See below.
- `ngrd` is the number of “guard digits” used when truncating the product of two mantissas to fit the representation.

There is a lot of subtlety in a program like `machar`, whose purpose is to ferret out machine properties that are supposed to be transparent to the user. Further, it must do so avoiding error conditions, like overflow and underflow, that might interrupt its execution. In some cases the program is able to do this only by recognizing certain characteristics of “standard” representations. For example, it recognizes the IEEE standard representation [3] by its rounding behavior, and assumes certain features of its exponent representation as a consequence. We refer you to [1] and

Sample Results Returned by <code>machar</code>			
precision	typical IEEE-compliant machine single	DEC VAX double	DEC VAX single
<code>ibeta</code>	2	2	2
<code>it</code>	24	53	24
<code>machep</code>	-23	-52	-24
<code>eps</code>	1.19×10^{-7}	2.22×10^{-16}	5.96×10^{-8}
<code>negep</code>	-24	-53	-24
<code>epsneg</code>	5.96×10^{-8}	1.11×10^{-16}	5.96×10^{-8}
<code>iexp</code>	8	11	8
<code>minexp</code>	-126	-1022	-128
<code>xmin</code>	1.18×10^{-38}	2.23×10^{-308}	2.94×10^{-39}

<code>xmax</code>	3.40×10^{38}	1.79×10^{308}	1.70×10^{38}
<code>irnd</code>	5	5	1
<code>ngrd</code>	0	0	0

references therein for details. Be aware that `machar` can give incorrect results on some nonstandard machines.

The parameter `irnd` needs some additional explanation. In the IEEE standard, bit patterns correspond to exact, “representable” numbers. The specified method for rounding an addition is to add two representable numbers “exactly,” and then round the sum to the closest representable number. If the sum is precisely halfway between two representable numbers, it should be rounded to the even one (low-order bit zero). The same behavior should hold for all the other arithmetic operations, that is, they should be done in a manner equivalent to infinite precision, and then rounded to the closest representable number.

If `irnd` returns 2 or 5, then your computer is compliant with this standard. If it returns 1 or 4, then it is doing some kind of rounding, but not the IEEE standard. If `irnd` returns 0 or 3, then it is truncating the result, not rounding it — not desirable.

The other issue addressed by `irnd` concerns underflow. If a floating value is less than `xmin`, many computers underflow its value to zero. Values `irnd` = 0, 1, or 2 indicate this behavior. The IEEE standard specifies a more graceful kind of underflow: As a value becomes smaller than `xmin`, its exponent is frozen at the smallest allowed value, while its mantissa is decreased, acquiring leading zeros and “gracefully” losing precision. This is indicated by `irnd` = 3, 4, or 5.

```

SUBROUTINE machar(ibeta,it,irnd,ngrd,machep,negep,iexp,minexp,
*      maxexp,eps,epsneg,xmin,xmax)
INTEGER ibeta,iexp,irnd,it,machep,maxexp,minexp,negep,ngrd
REAL eps,epsneg,xmax,xmin
      Determines and returns machine-specific parameters affecting floating-point arithmetic. Returned values include ibeta, the floating-point radix; it, the number of base-ibeta digits in the floating-point mantissa; eps, the smallest positive number that, added to 1.0, is not equal to 1.0; epsneg, the smallest positive number that, subtracted from 1.0, is not equal to 1.0; xmin, the smallest representable positive number; and xmax, the largest representable positive number. See text for description of other returned parameters.

Some typical values returned by `machar` are given in the table, above. IEEE-compliant machines referred to in the table include most UNIX workstations (SUN, DEC, MIPS), and Apple Macintosh IIs. IBM PCs with floating co-processors are generally IEEE-compliant, except that some compilers underflow intermediate results ungracefully, yielding `irnd` = 2 rather than 5. Notice, as in the case of a VAX (fourth column), that representations with a “phantom” leading 1 bit in the mantissa achieve a smaller `eps` for the same wordlength, but cannot underflow gracefully.

20.2 Gray Codes

A Gray code is a function $G(i)$ of the integers i , that for each integer $N \geq 0$ is one-to-one for $0 \leq i \leq 2^N - 1$, and that has the following remarkable property: The binary representation of $G(i)$ and $G(i + 1)$ differ in *exactly one bit*. An example of a Gray code (in fact, the most commonly used one) is the sequence 0000, 0001, 0011, 0010, 0110, 0111, 0101, 0100, 1100, 1101, 1111, 1110, 1010, 1011, 1001, and 1000, for $i = 0, \dots, 15$. The algorithm for generating this code is simply to form the bitwise exclusive-or (XOR) of i with $i/2$ (integer part). Think about how the carries work when you add one to a number in binary, and you will be able to see why this works. You will also see that $G(i)$ and $G(i + 1)$ differ in the bit position of the rightmost zero bit of i (prefixing a leading zero if necessary).

The spelling is “Gray,” not “gray”: The codes are named after one Frank Gray, who first patented the idea for use in shaft encoders. A shaft encoder is a wheel with concentric coded stripes each of which is “read” by a fixed conducting brush. The idea is to generate a binary code describing the angle of the wheel. The obvious, but wrong, way to build a shaft encoder is to have one stripe (the innermost, say) conducting on half the wheel, but insulating on the other half; the next stripe is conducting in quadrants 1 and 3; the next stripe is conducting in octants 1, 3, 5, and 7; and so on. The brushes together then read a direct binary code for the position of the wheel.

20.2 Gray Codes

A Gray code is a function $G(i)$ of the integers i , that for each integer $N \geq 0$ is one-to-one for $0 \leq i \leq 2^N - 1$, and that has the following remarkable property: The binary representation of $G(i)$ and $G(i + 1)$ differ in *exactly one bit*. An example of a Gray code (in fact, the most commonly used one) is the sequence 0000, 0001, 0011, 0010, 0110, 0111, 0101, 0100, 1100, 1101, 1111, 1110, 1010, 1011, 1001, and 1000, for $i = 0, \dots, 15$. The algorithm for generating this code is simply to form the bitwise exclusive-or (XOR) of i with $i/2$ (integer part). Think about how the carries work when you add one to a number in binary, and you will be able to see why this works. You will also see that $G(i)$ and $G(i + 1)$ differ in the bit position of the rightmost zero bit of i (prefixing a leading zero if necessary).

The spelling is “Gray,” not “gray”: The codes are named after one Frank Gray, who first patented the idea for use in shaft encoders. A shaft encoder is a wheel with concentric coded stripes each of which is “read” by a fixed conducting brush. The idea is to generate a binary code describing the angle of the wheel. The obvious, but wrong, way to build a shaft encoder is to have one stripe (the innermost, say) conducting on half the wheel, but insulating on the other half; the next stripe is conducting in quadrants 1 and 3; the next stripe is conducting in octants 1, 3, 5, and 7; and so on. The brushes together then read a direct binary code for the position of the wheel.

(a)

(b)

Figure 20.2.1. Single-bit operations for calculating the Gray code $G(i)$ from i (a), or the inverse (b). LSB and MSB indicate the least and most significant bits, respectively. XOR denotes exclusive-or.

The reason this method is bad, is that there is no way to guarantee that all the brushes will make or break contact *exactly* simultaneously as the wheel turns. Going from position 7 (0111) to 8 (1000), one might pass spuriously and transiently through 6 (0110), 14 (1110), and 10 (1010), as the different brushes make or break contact. Use of a Gray code on the encoding stripes guarantees that there is no transient state between 7 (0100 in the sequence above) and 8 (1100).

Of course we then need circuitry, or algorithmics, to translate from $G(i)$ to i . Figure 20.2.1 (b) shows how this is done by a cascade of XOR gates. The idea is that each output bit should be the XOR of all more significant input bits. To do N bits of Gray code inversion requires $N - 1$ steps (or gate delays) in the circuit. (Nevertheless, this is typically very fast in circuitry.) In a register with word-wide binary operations, we don't have to do N consecutive operations, but only $\ln_2 N$. The trick is to use the associativity of XOR and group the operations hierarchically. This involves sequential right-shifts by 1, 2, 4, 8, ... bits until the wordlength is exhausted. Here is a piece of code for doing both $G(i)$ and its inverse.

```

FUNCTION igray(n,is)
INTEGER igray,is,n
    For zero or positive values of is, return the Gray code of n; if is is negative, return the
    inverse Gray code of n.

    ish=ish+ish           Double the amount of shift on the next cycle.
1   goto 1
endif
return
END

```

In numerical work, Gray codes can be useful when you need to do some task that depends intimately on the bits of i , looping over many values of i . Then, if there are economies in repeating the task for values differing by only one bit, it makes sense to do things in Gray code order rather than consecutive order. We saw an example of this in §7.7, for the generation of quasi-random sequences.

20.3 Cyclic Redundancy and Other Checksums

When you send a sequence of bits from point A to point B, you want to know that it will arrive without error. A common form of insurance is the “parity bit,” attached to 7-bit ASCII characters to put them into 8-bit format. The parity bit is chosen so as to make the total number of one-bits (versus zero-bits) either always even (“even parity”) or always odd (“odd parity”). Any *single bit* error in a character will thereby be detected. When errors are sufficiently rare, and do not occur closely bunched in time, use of parity provides sufficient error detection.

Unfortunately, in real situations, a single noise “event” is likely to disrupt more than one bit. Since the parity bit has two possible values (0 and 1), it gives, on average, only a 50% chance of detecting an erroneous character with more than one wrong bit. That probability, 50%, is not nearly good enough for most applications. Most communications protocols [1] use a multibit generalization of the parity bit called a “cyclic redundancy check” or CRC. In typical applications the CRC is 16 bits long (two bytes or two characters), so that the chance of a random error going undetected is 1 in $2^{16} = 65536$. Moreover, M -bit CRCs have the mathematical property of detecting *all* errors that occur in M or fewer *consecutive* bits, for any

20.3 Cyclic Redundancy and Other Checksums

When you send a sequence of bits from point A to point B, you want to know that it will arrive without error. A common form of insurance is the “parity bit,” attached to 7-bit ASCII characters to put them into 8-bit format. The parity bit is chosen so as to make the total number of one-bits (versus zero-bits) either always even (“even parity”) or always odd (“odd parity”). Any *single bit* error in a character will thereby be detected. When errors are sufficiently rare, and do not occur closely bunched in time, use of parity provides sufficient error detection.

Unfortunately, in real situations, a single noise “event” is likely to disrupt more than one bit. Since the parity bit has two possible values (0 and 1), it gives, on average, only a 50% chance of detecting an erroneous character with more than one wrong bit. That probability, 50%, is not nearly good enough for most applications. Most communications protocols [1] use a multibit generalization of the parity bit called a “cyclic redundancy check” or CRC. In typical applications the CRC is 16 bits long (two bytes or two characters), so that the chance of a random error going undetected is 1 in $2^{16} = 65536$. Moreover, M -bit CRCs have the mathematical property of detecting *all* errors that occur in M or fewer *consecutive* bits, for any

length of message. (We prove this below.) Since noise in communication channels tends to be “bursty,” with short sequences of adjacent bits getting corrupted, this consecutive-bit property is highly desirable.

Normally CRCs lie in the province of communications software experts and chip-level hardware designers — people with bits under their fingernails. However, there are at least two kinds of situations where some understanding of CRCs can be useful to the rest of us. First, we sometimes need to be able to communicate with a lower-level piece of hardware or software that expects a valid CRC as part of its input. For example, it can be convenient to have a program generate XMODEM or Kermit [2] packets directly into the communications line rather than having to store the data in a local file.

Second, in the manipulation of large quantities of (e.g., experimental) data, it is useful to be able to tag aggregates of data (whether numbers, records, lines, or whole files) with a statistically unique “key,” its CRC. Aggregates of any size can then be compared for identity by comparing only their short CRC keys. Differing keys imply nonidentical records. Identical keys imply, to high statistical certainty, identical records. If you can’t tolerate the very small probability of being wrong, you can do a full comparison of the records when the keys are identical. When there is a possibility of files or data records being inadvertently or irresponsibly modified (for example, by a computer virus), it is useful to have their prior CRCs stored externally on a physically secure medium, like a floppy disk.

Sometimes CRCs can be used to compress data as it is recorded. If identical data records occur frequently, one can keep sorted in memory the CRCs of previously encountered records. A new record is archived in full if its CRC is different, otherwise only a pointer to a previous record need be archived. In this application one might desire a 4- or 8-byte CRC, to make the odds of mistakenly discarding a different data record be tolerably small; or, if previous records can be randomly accessed, a full comparison can be made to decide whether records with identical CRCs are in fact identical.

Now let us briefly discuss the theory of CRCs. After that, we will give implementations of various (related) CRCs that are used by the official or de facto standard protocols [1-3] listed in the accompanying table.

The mathematics underlying CRCs is “polynomials over the integers modulo 2.” Any binary message can be thought of as a polynomial with coefficients 0 and 1. For example, the message “1100001101” is the polynomial $x^9 + x^8 + x^3 + x^2 + 1$. Since 0 and 1 are the only integers modulo 2, a power of x in the polynomial is either present (1) or absent (0). A polynomial over the integers modulo 2 may be irreducible, meaning that it can’t be factored. A subset of the irreducible polynomials are the “primitive” polynomials. These generate maximum length sequences when used in shift registers, as described in §7.4. The polynomial $x^2 + 1$ is not irreducible: $x^2 + 1 = (x+1)(x+1)$, so it is also not primitive. The polynomial $x^4 + x^3 + x^2 + x + 1$ is irreducible, but it turns out not to be primitive. The polynomial $x^4 + x + 1$ is both irreducible and primitive.

An M -bit long CRC is based on a primitive polynomial of degree M , called the generator polynomial. Alternatively, the generator is chosen to be a primitive polynomial times $(1+x)$ (this finds all parity errors). For 16-bit CRC’s, the CCITT (Comité Consultatif International Télégraphique et Téléphonique) has anointed the “CCITT polynomial,” which is $x^{16} + x^{12} + x^5 + 1$. This polynomial is used by all of the

Conventions and Test Values for Various CRC Protocols						
	icrc args		Test Values (C_2C_1 in hex)		Packet	
Protocol	jinit	jrev	T	CatMouse987654321	Format	CRC
XMODEM	0	1	1A71	E556	$S_1S_2 \dots S_N C_2C_1$	0
X.25	255	-1	1B26	F56E	$S_1S_2 \dots S_N \overline{C_1C_2}$	F0B8
(no name)	255	-1	1B26	F56E	$S_1S_2 \dots S_N C_1C_2$	0
SDLC (IBM)	same as X.25					
HDLC (ISO)	same as X.25					
CRC-CCITT	0	-1	14A1	C28D	$S_1S_2 \dots S_N C_1C_2$	0
(no name)	0	-1	14A1	C28D	$S_1S_2 \dots S_N \overline{C_1C_2}$	F0B8
Kermit	same as CRC-CCITT				see Notes	
Notes:	Overbar denotes bit complement. $S_1 \dots S_N$ are character data. C_1 is CRC's least significant 8 bits, C_2 is its most significant 8 bits, so $CRC = 256 C_2 + C_1$ (shown in hex). Kermit (block check level 3) sends the CRC as 3 printable ASCII characters (sends value +32). These contain, respectively, 4 most significant bits, 6 middle bits, 6 least significant bits.					

protocols listed in the table. Another common choice is the “CRC-16” polynomial $x^{16} + x^{15} + x^2 + 1$, which is used for EBCDIC messages in IBM’s BISYNCH [1]. A common 12-bit choice, “CRC-12,” is $x^{12} + x^{11} + x^3 + x + 1$. A common 32-bit choice, “AUTODIN-II,” is $x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$. For a table of some other primitive polynomials, see §7.4.

Given the generator polynomial G of degree M (which can be written either in polynomial form or as a bit-string, e.g., 10001000000100001 for CCITT), here is how you compute the CRC for a sequence of bits S : First, multiply S by x^M , that is, append M zero bits to it. Second divide — by long division — G into Sx^M . Keep in mind that the subtractions in the long division are done modulo 2, so that there are never any “borrows”: Modulo 2 subtraction is the same as logical exclusive-or (XOR). Third, ignore the quotient you get. Fourth, when you eventually get to a remainder, it is the CRC, call it C . C will be a polynomial of degree $M - 1$ or less, otherwise you would not have finished the long division. Therefore, in bit string form, it has M bits, which may include leading zeros. (C might even be all zeros, see below.) See [3] for a worked example.

If you work through the above steps in an example, you will see that most of what you write down in the long-division tableau is superfluous. You are actually just left-shifting sequential bits of S , from the right, into an M -bit register. Every time a 1 bit gets shifted off the left end of this register, you zap the register by an XOR with the M low order bits of G (that is, all the bits of G except its leading 1). When a 0 bit is shifted off the left end you don’t zap the register. When the last bit that was originally part of S gets shifted off the left end of the register, what remains is the CRC.

You can immediately recognize how efficiently this procedure can be implemented in hardware. It requires only a shift register with a few hard-wired XOR taps into it. That is how CRCs are computed in communications devices, by a single chip (or small part of one). In software, the implementation is not so elegant, since

bit-shifting is not generally very efficient. One therefore typically finds (as in our implementation below) table-driven routines that pre-calculate the result of a bunch of shifts and XORs, say for each of 256 possible 8-bit inputs [4].

We can now see how the CRC gets its ability to detect all errors in M consecutive bits. Suppose two messages, S and T , differ only within a frame of M bits. Then their CRCs differ by an amount that is the remainder when G is divided into $(S - T)x^M \equiv D$. Now D has the form of leading zeros (which can be ignored), followed by some 1's in an M -bit frame, followed by trailing zeros (which are just multiplicative factors of x): $D = x^n F$ where F is a polynomial of degree at most $M - 1$ and $n > 0$. Since G is always primitive or primitive times $(1 + x)$, it is not divisible by x . So G cannot divide D . Therefore S and T must have different CRCs.

In most protocols, a transmitted block of data consists of some N data bits, directly followed by the M bits of their CRC (or the CRC XORed with a constant, see below). There are two equivalent ways of validating a block at the receiving end. Most obviously, the receiver can compute the CRC of the data bits, and compare it to the transmitted CRC bits. Less obviously, but more elegantly, the receiver can simply compute the CRC of the total block, with $N + M$ bits, and verify that a result of zero is obtained. Proof: The total block is the polynomial $Sx^M + C$ (data left-shifted to make room for the CRC bits). The definition of C is that $Sx^m = QG + C$, where Q is the discarded quotient. But then $Sx^M + C = QG + C + C = QG$ (remember modulo 2), which is a perfect multiple of G . It remains a multiple of G when it gets multiplied by an additional x^M on the receiving end, so it has a zero CRC, q.e.d.

A couple of small variations on the basic procedure need to be mentioned [1,3]: First, when the CRC is computed, the M -bit register need not be initialized to zero. Initializing it to some other M -bit value (e.g., all 1's) in effect prefaces all blocks by a phantom message that would have given the initialization value as its remainder. It is advantageous to do this, since the CRC described thus far otherwise cannot detect the addition or removal of any number of initial zero bits. (Loss of an initial bit, or insertion of zero bits, are common “clocking errors.”) Second, one can add (XOR) any M -bit constant K to the CRC before it is transmitted. This constant can either be XORed away at the receiving end, or else it just changes the expected CRC of the whole block by a known amount, namely the remainder of dividing G into Kx^M . The constant K is frequently “all bits,” changing the CRC into its ones complement. This has the advantage of detecting another kind of error that the CRC would otherwise not find: deletion of an initial 1 bit in the message with spurious insertion of a 1 bit at the end of the block.

The accompanying function `icrc` implements the above CRC calculation, including the possibility of the mentioned variations. Input to the function is the starting address of an array of characters, and the length of that array. (In practice, FORTRAN allows you to use the address of *any* data structure; `icrc` will treat it as a byte array.) Output is in both of two formats. The function value returns the CRC as a 4-byte integer in the range 0 to 65535. The character array `crc`, of length 2, returns the CRC as two 8-bit characters. `icrc` has two “switch” arguments that specify variations in the CRC calculation. A zero or positive value of `jinit` causes the 16-bit register to have each byte initialized with the value `jinit`. A negative value of `jrev` causes each input character to be interpreted as its bit-reverse image, and a similar bit reversal to be done on the output CRC. You do not have to understand this; just use the values of `jinit` and `jrev` specified in the table.

(If you *insist* on knowing, the explanation is that serial data ports send characters *least-significant bit first* (!), and many protocols shift bits into the CRC register in exactly the order received.) The table shows how to construct a block of characters from the input array and output CRC of `icrc`. You should not need to do any additional bit-reversal outside of `icrc`.

The switch `jinit` has one additional use: When negative it causes the input value of the array `crc` to be used as initialization of the register. If `crc` is unmodified since the last call to `icrc`, this in effect appends the current input array to that of the previous call or calls. Use this feature, for example, to build up the CRC of a whole file a line at a time, without keeping the whole file in memory.

At initialization, the routine `icrc` figures out the order in which the bytes occur when a 4-byte character array is equivalenced to a 4-byte integer. This is not strictly portable FORTRAN, but it should work on all machines with 32-bit word lengths. `icrc` is loosely based on a more portable C function in [4], a good place to turn if you have trouble running the program here.

Here is how to understand the operation of `icrc`: First look at the function `icrc1`. This incorporates one input character into a 16-bit CRC register. The only trick used is that character bits are XORed into the most significant bits, eight at a time, instead of being fed into the least significant bit, one bit at a time, at the time of the register shift. This works because XOR is associative and commutative — we can feed in character bits *any* time before they will determine whether to zap with the generator polynomial. (The decimal constant 4129 has the generator's bits in it.)

```
FUNCTION icrc1(crc,onech,ib1,ib2,ib3)
INTEGER icrc1,ib1,ib2,ib3
      Given a remainder up to now, return the new CRC after one character is added. This routine
      is functionally equivalent to icrc(,,1,-1,1), but slower. It is used by icrc to initialize
      its table.
      INTEGER i,ichr,ireg

      EQUIVALENCE (creg,ireg)
      ireg=0
      creg(ib1)=crc(ib1)           Here is where the character is folded into the register.
      creg(ib2)=char(ieor(ichar(crc(ib2)),ichar(onech)))
      do 11 i=1,8                Here is where 8 one-bit shifts, and some XORs with the gen-
          ichr=ichar(creg(ib2))    erator polynomial, are done.
          ireg=ireg+ichr
          creg(ib3)=char(0)
          if(ichr.gt.127)ireg=ieor(ireg,4129)
11    enddo 11
      icrc1=ireg
      return
END
```

Now look at `icrc`. There are two parts to understand, how it builds a table when it initializes, and how it uses that table later on. Go back to thinking about a character's bits being shifted into the CRC register from the least significant end. The key observation is that while 8 bits are being shifted into the register's low end, all the generator zapping is being determined by the bits already in the high end. Since XOR is commutative and associative, all we need is a table of the result of all this zapping, for each of 256 possible high-bit configurations. Then we can play catch-up and XOR an input character into the result of a lookup into this table. The routine makes repeated use of an equivalenced 4-byte integer and 4-byte character array to

get at different 8-bit chunks. The only other content to `icrc` is the construction at initialization time of an 8-bit bit-reverse table from the 4-bit table stored in `it`, and the logic associated with doing the bit reversals. References [4-6] give further details on table-driven CRC computations.

```

FUNCTION icrc(crc,bufptr,len,jinit,jrev)
INTEGER icrc,jinit,jrev,len
CHARACTER*1 bufptr(*),crc(2)
C   USES icrc1
      Computes a 16-bit Cyclic Redundancy Check for an array bufptr of length len bytes,
      using any of several conventions as determined by the settings of jinit and jrev (see
      accompanying table). The result is returned both as an integer icrc and as a 2-byte array
      crc. If jinit is negative, then crc is used on input to initialize the remainder register, in
      effect concatenating bufptr to the previous call.
      INTEGER ich,init,ireg,j,icrctb(0:255),it(0:15),icrc1,ib1,ib2,ib3
      CHARACTER*1 creg(4),rchr(0:255)
      SAVE icrctb,rchr,init,it,ib1,ib2,ib3
      EQUIVALENCE (creg,ireg)      Used to get at the 4 bytes in an integer.
      DATA it/0,8,4,12,2,10,6,14,1,9,5,13,3,11,7,15/, init /0/
      Table of 4-bit bit-reverses, and flag for initialization.
      if (init.eq.0) then          Do we need to initialize tables?
          init=1
          ireg=256*(256*ichar('3')+ichar('2'))+ichar('1')
          do 11 j=1,4                Figure out which component of creg addresses which
              if (creg(j).eq.'1') ib1=j      byte of ireg.
              if (creg(j).eq.'2') ib2=j
              if (creg(j).eq.'3') ib3=j
          enddo 11
          do 12 j=0,255               The two tables are: CRCs of all characters, and bit-reverses
              ireg=j*256                  of all characters.
              icrctb(j)=icrc1(creg,char(0),ib1,ib2,ib3)
              ich=it(mod(j,16))*16+it(j/16)
              rchr(j)=char(ich)
          enddo 12
      endif
      if (jinit.ge.0) then          Initialize the remainder register.
          crc(1)=char(jinit)
          crc(2)=char(jinit)
      else if (jrev.lt.0) then     If not initializing, do we reverse the register?
          ich=ichar(crc(1))
          crc(1)=rchr(ichar(crc(2)))
          crc(2)=rchr(ich)
      endif
      do 13 j=1,len                Main loop over the characters in the array.
          ich=ichar(bufptr(j))
          if(jrev.lt.0)ich=ichar(rchr(ich))
          ireg=icrctb(ieor(ich,ichar(crc(2))))
          crc(2)=char(ieor(ichar(creg(ib2)),ichar(crc(1))))
          crc(1)=creg(ib1)
      enddo 13
      if (jrev.ge.0) then          Do we need to reverse the output?
          creg(ib1)=crc(1)
          creg(ib2)=crc(2)
      else
          creg(ib2)=rchr(ichar(crc(1)))
          creg(ib1)=rchr(ichar(crc(2)))
          crc(1)=creg(ib1)
          crc(2)=creg(ib2)
      endif
      icrc=ireg
      return
END

```

What if you need a 32-bit checksum? For a true 32-bit CRC, you will need to rewrite the routines given to work with a longer generating polynomial. For example, $x^{32} + x^7 + x^5 + x^3 + x^2 + x + 1$ is primitive modulo 2, and has nonleading, nonzero bits only in its least significant byte (which makes for some simplification). The idea of table lookup on only the most significant byte of the CRC register goes through unchanged. Pay attention to the fact that FORTRAN does not have unsigned integers, so half of your CRCs will appear to be negative in integer format.

If you do not care about the M -consecutive bit property of the checksum, but rather only need a statistically random 32 bits, then you can use `icrc` as given here: Call it once with `jrev = 1` to get 16 bits, and *again* with `jrev = -1` to get another 16 bits. The internal bit reversals make these two 16-bit CRCs in effect totally independent of each other.

Other Kinds of Checksums

Quite different from CRCs are the various techniques used to append a decimal “check digit” to numbers that are handled by human beings (e.g., typed into a computer). Check digits need to be proof against the kinds of highly structured errors that humans tend to make, such as transposing consecutive digits. Wagner and Putter [7] give an interesting introduction to this subject, including specific algorithms.

Checksums now in widespread use vary from fair to poor. The 10-digit ISBN (International Standard Book Number) that you find on most books, including this one, uses the check equation

$$10d_1 + 9d_2 + 8d_3 + \cdots + 2d_9 + d_{10} = 0 \pmod{11} \quad (20.3.1)$$

where d_{10} is the right-hand check digit. The character “X” is used to represent a check digit value of 10. Another popular scheme is the so-called “IBM check,” often used for account numbers (including, e.g., MasterCard). Here, the check equation is

$$2\#d_1 + d_2 + 2\#d_3 + d_4 + \cdots = 0 \pmod{10} \quad (20.3.2)$$

where $2\#d$ means, “multiply d by two and add the resulting decimal digits.” United States banks code checks with a 9-digit processing number whose check equation is

$$3a_1 + 7a_2 + a_3 + 3a_4 + 7a_5 + a_6 + 3a_7 + 7a_8 + a_9 = 0 \pmod{10} \quad (20.3.3)$$

The bar code put on many envelopes by the U.S. Postal Service is decoded by removing the single tall marker bars at each end, and breaking the remaining bars into 6 or 10 groups of five. In each group the five bars signify (from left to right) the values 7,4,2,1,0. Exactly two of them will be tall. Their sum is the represented digit, except that zero is represented as 7 + 4. The 5- or 9-digit Zip Code is followed by a check digit, with the check equation

$$\sum d_i = 0 \pmod{10} \quad (20.3.4)$$

None of these schemes is close to optimal. An elegant scheme due to Verhoeff is described in [7]. The underlying idea is to use the ten-element *dihedral group* D_5 ,

which corresponds to the symmetries of a pentagon, instead of the cyclic group of the integers modulo 10. The check equation is

$$a_1 * f(a_2) * f^2(a_3) * \dots * f^{n-1}(a_n) = 0 \quad (20.3.5)$$

where $*$ is (noncommutative) multiplication in D_5 , and f^i denotes the i th iteration of a certain fixed permutation. Verhoeff's method finds *all* single errors in a string, and *all* adjacent transpositions. It also finds about 95% of twin errors ($aa \rightarrow bb$), jump transpositions ($acb \rightarrow bca$), and jump twin errors ($aca \rightarrow bcb$). Here is an implementation:

```

LOGICAL FUNCTION decchk(string,n,ch)
INTEGER n
CHARACTER string*(*),ch*1
      Decimal check digit computation or verification. Returns as ch a check digit for appending
      to string(1:n), that is, for storing into string(n+1:n+1). In this mode, ignore the
      returned logical value. If string(1:n) already ends with a check digit (string(n:n)), returns
      the function value .true. if the check digit is valid, otherwise .false. In this
      mode, ignore the returned value of ch. Note that string and ch contain ASCII characters
      corresponding to the digits 0-9, not byte values in that range. Other ASCII characters are
      allowed in string, and are ignored in calculating the check digit.
INTEGER ij(10,10),ip(10,8),i,j,k,m
SAVE ij,ip                               Group multiplication and permutation tables.

20.4 Huffman Coding and Compression of Data

A lossless data compression algorithm takes a string of symbols (typically ASCII characters or bytes) and translates it *reversibly* into another string, one that is *on the average* of shorter length. The words “on the average” are crucial; it is obvious that no reversible algorithm can make all strings shorter — there just aren’t enough short strings to be in one-to-one correspondence with longer strings. Compression algorithms are possible only when, on the input side, some strings, or some input symbols, are more common than others. These can then be encoded in fewer bits than rarer input strings or symbols, giving a net average gain.

There exist many, quite different, compression techniques, corresponding to different ways of detecting and using departures from equiprobability in input strings. In this section and the next we shall consider only *variable length codes* with *defined word* inputs. In these, the input is sliced into fixed units, for example ASCII characters, while the corresponding output comes in chunks of variable size. The simplest such method is Huffman coding [1], discussed in this section. Another example, *arithmetic compression*, is discussed in §20.5.

At the opposite extreme from defined-word, variable length codes are schemes that divide up the *input* into units of variable length (words or phrases of English text, for example) and then transmit these, often with a fixed-length output code. The most widely used code of this type is the Ziv-Lempel code [2]. References [3-6] give the flavor of some other compression techniques, with references to the large literature.

The idea behind Huffman coding is simply to use shorter bit patterns for more common characters. We can make this idea quantitative by considering the concept of *entropy*. Suppose the input alphabet has N_{ch} characters, and that these occur in the input string with respective probabilities p_i , $i = 1, \dots, N_{ch}$, so that $\sum p_i = 1$. Then the fundamental theorem of information theory says that strings consisting of independently random sequences of these characters (a conservative, but not always realistic assumption) require, on the average, at least

$$H = - \sum p_i \log_2 p_i \quad (20.4.1)$$

bits per character. Here H is the entropy of the probability distribution. Moreover, coding schemes exist which approach the bound arbitrarily closely. For the case of equiprobable characters, with all $p_i = 1/N_{ch}$, one easily sees that $H = \log_2 N_{ch}$, which is the case of no compression at all. Any other set of p_i ’s gives a smaller entropy, allowing some useful compression.

Notice that the bound of (20.4.1) would be achieved if we could encode character i with a code of length $L_i = -\log_2 p_i$ bits: Equation (20.4.1) would then be the average $\sum p_i L_i$. The trouble with such a scheme is that $-\log_2 p_i$ is not generally an integer. How can we encode the letter “Q” in 5.32 bits? Huffman coding makes a stab at this by, in effect, approximating all the probabilities p_i by integer powers of 1/2, so that all the L_i ’s are integral. If all the p_i ’s are in fact of this form, then a Huffman code does achieve the entropy bound H .

The construction of a Huffman code is best illustrated by example. Imagine a language, Vowellish, with the $N_{ch} = 5$ character alphabet A, E, I, O, and U, occurring with the respective probabilities 0.12, 0.42, 0.09, 0.30, and 0.07. Then the construction of a Huffman code for Vowellish is accomplished in the following table:

20.4 Huffman Coding and Compression of Data

A lossless data compression algorithm takes a string of symbols (typically ASCII characters or bytes) and translates it *reversibly* into another string, one that is *on the average* of shorter length. The words “on the average” are crucial; it is obvious that no reversible algorithm can make all strings shorter — there just aren’t enough short strings to be in one-to-one correspondence with longer strings. The most widely used code of this type is the Ziv-Lempel code [2]. References [3-6] give the flavor of some other compression techniques, with references to the large literature.

The idea behind Huffman coding is simply to use shorter bit patterns for more common characters. We can make this idea quantitative by considering the concept of *entropy*. Suppose the input alphabet has N_{ch} characters, and that these occur in the input string with respective probabilities p_i , $i = 1, \dots, N_{ch}$, so that $\sum p_i = 1$. Then the fundamental theorem of information theory says that strings consisting of independently random sequences of these characters (a conservative, but not always realistic assumption) require, on the average, at least

$$H = - \sum p_i \log_2 p_i \quad (20.4.1)$$

bits per character. Here H is the entropy of the probability distribution. Moreover, coding schemes exist which approach the bound arbitrarily closely. For the case of equiprobable characters, with all $p_i = 1/N_{ch}$, one easily sees that $H = \log_2 N_{ch}$, which is the case of no compression at all. Any other set of p_i ’s gives a smaller entropy, allowing some useful compression.

Notice that the bound of (20.4.1) would be achieved if we could encode character i with a code of length $L_i = -\log_2 p_i$ bits: Equation (20.4.1) would then be the average $\sum p_i L_i$. The trouble with such a scheme is that $-\log_2 p_i$ is not generally an integer. How can we encode the letter “Q” in 5.32 bits? Huffman coding makes a stab at this by, in effect, approximating all the probabilities p_i by integer powers of 1/2, so that all the L_i ’s are integral. If all the p_i ’s are in fact of this form, then a Huffman code does achieve the entropy bound H .

The construction of a Huffman code is best illustrated by example. Imagine a language, Vowellish, with the $N_{ch} = 5$ character alphabet A, E, I, O, and U, occurring with the respective probabilities 0.12, 0.42, 0.09, 0.30, and 0.07. Then the construction of a Huffman code for Vowellish is accomplished in the following table:

Node	Stage:	1	2	3	4	5
1	A:	0.12	0.12 ■			
2	E:	0.42	0.42	0.42	0.42 ■	
3	I:	0.09 ■				
4	O:	0.30	0.30	0.30 ■		
5	U:	0.07 ■				
6		UI:	0.16 ■			
7			AUI:	0.28 ■		
8				AUIO:	0.58 ■	
9					EAUIO:	1.00

Here is how it works, proceeding in sequence through N_{ch} stages, represented by the columns of the table. The first stage starts with N_{ch} nodes, one for each letter of the alphabet, containing their respective relative frequencies. At each stage, the two smallest probabilities are found, summed to make a new node, and then dropped from the list of active nodes. (A “block” denotes the stage where a node is dropped.) All active nodes (including the new composite) are then carried over to the next stage (column). In the table, the names assigned to new nodes (e.g., AUI) are inconsequential. In the example shown, it happens that (after stage 1) the two smallest nodes are always an original node and a composite one; this need not be true in general: The two smallest probabilities might be both original nodes, or both composites, or one of each. At the last stage, all nodes will have been collected into one grand composite of total probability 1.

Now, to see the code, you redraw the data in the above table as a tree (Figure 20.4.1). As shown, each node of the tree corresponds to a node (row) in the table, indicated by the integer to its left and probability value to its right. Terminal nodes, so called, are shown as circles; these are single alphabetic characters. The branches of the tree are labeled 0 and 1. The code for a character is the sequence of zeros and ones that lead to it, from the top down. For example, E is simply 0, while U is 1010.

Any string of zeros and ones can now be decoded into an alphabetic sequence. Consider, for example, the string 1011111010. Starting at the top of the tree we descend through 1011 to I, the first character. Since we have reached a terminal node, we reset to the top of the tree, next descending through 11 to O. Finally 1010 gives U. The string thus decodes to IOU.

These ideas are embodied in the following routines. Input to the first routine `hufmak` is an integer vector of the frequency of occurrence of the $nchin \equiv N_{ch}$ alphabetic characters, i.e., a set of integers proportional to the p_i ’s. `hufmak`, along with `hufapp`, which it calls, performs the construction of the above table, and also the tree of Figure 20.4.1. The routine utilizes a heap structure (see §8.3) for efficiency; for a detailed description, see Sedgewick [7].

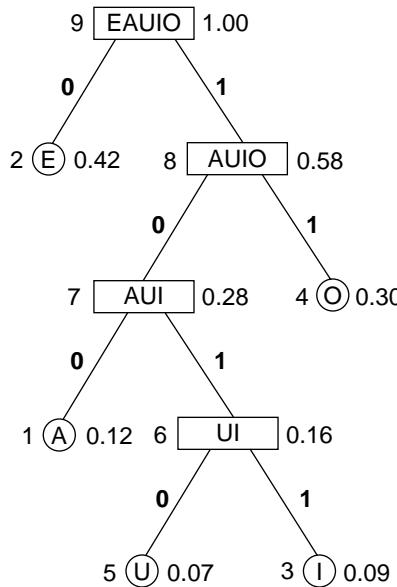

Figure 20.4.1. Huffman code for the fictitious language Vowellish, in tree form. A letter (A, E, I, O, or U) is encoded or decoded by traversing the tree from the top down; the code is the sequence of 0's and 1's on the branches. The value to the right of each node is its probability; to the left, its node number in the accompanying table.

```

SUBROUTINE hufmak(nfreq,nchin,ilong,nlong)

```

SUBROUTINE hufapp(index,nprob,m,l)
INTEGER m,l,MC,MQ
PARAMETER (MC=512,MQ=2*MC-1)
INTEGER index(MQ),nprob(MQ)
Used by hufmak to maintain a heap structure in the array index(1:l).
INTEGER i,j,k,n
n=m
i=l
k=index(i)
2  if(i.le.n/2)then
    j=i+i
    if (j.lt.n.and.nprob(index(j)).gt.nprob(index(j+1))) j=j+1
    if (nprob(k).le.nprob(index(j))) goto 3
    index(i)=index(j)
    i=j
  goto 2
  endif
3  index(i)=k
return
END

```

Once the code is constructed, one encodes a string of characters by repeated calls to hufenc, which simply does a table lookup of the code and appends it to the output message.

```
SUBROUTINE hufenc(ich,code,lcode,nb)
INTEGER ich,lcode,nb,MC,MQ
PARAMETER (MC=512,MQ=2*MC-1)
Huffman encode the single character ich (in the range 0..nch-1), write the result to the
character array code(1:lcode) starting at bit nb (whose smallest valid value is zero),
and increment nb appropriately. This routine is called repeatedly to encode consecutive
characters in a message, but must be preceded by a single initializing call to hufmak.
INTEGER k,l,n,nc,nch,nodemx,ntmp,ibset
INTEGER icod(MQ),left(MQ),iright(MQ),ncod(MQ),nprob(MQ)
LOGICAL btest
CHARACTER*1 code(*)
COMMON /hufcom/ icod,ncod,nprob,left,iright,nch,nodemx
SAVE /hufcom/
k=ich+1           Convert character range 0..nch-1 to array index range 1..nch.
if(k.gt.nch.or.k.lt.1)pause 'ich out of range in hufenc.'
do :: n=ncod(k),1,-1      Loop over the bits in the stored Huffman code for ich.
  nc=nb/8+1
  if (nc.gt.lcode) pause 'lcode too small in hufenc.'
  l=mod(nb,8)
  if (l.eq.0) code(nc)=char(0)
  if(btest(icod(k),n-1))then Set appropriate bits in code.
    ntmp=ibset(ichar(code(nc)),1)
    code(nc)=char(ntmp)
  endif
  nb=nb+1
enddo :: 
return
END
```

Decoding a Huffman-encoded message is slightly more complicated. The coding tree must be traversed from the top down, using up a variable number of bits:

```
SUBROUTINE hufdec(ich,code,lcode,nb)
INTEGER ich,lcode,nb,MC,MQ
PARAMETER (MC=512,MQ=2*MC-1)
Starting at bit number nb in the character array code(1:lcode), use the Huffman code
stored in common block /hufcom/ to decode a single character (returned as ich in the
range 0..nch-1) and increment nb appropriately. Repeated calls, starting with nb = 0
will return successive characters in a compressed message. The returned value ich=nch
indicates end-of-message. This routine must be preceded by a single initializing call to
hufmak.
Parameters: MC is the maximum value of nch, the input alphabet size.
INTEGER l,nc,nch,node,nodemx
INTEGER icod(MQ),left(MQ),iright(MQ),ncod(MQ),nprob(MQ)
LOGICAL btest
CHARACTER*1 code(lcode)
COMMON /hufcom/ icod,ncod,nprob,left,iright,nch,nodemx
SAVE /hufcom/
node=nodemx          Set node to the top of the decoding tree.
1 continue           Loop until a valid character is obtained.
  nc=nb/8+1
  if (nc.gt.lcode)then Ran out of input; with ich=nch indicating end of message.
    ich=nch
    return
  endif
  l=mod(nb,8)         Now decoding this bit.
  nb=nb+1
```

```

if(btest(ichar(code(nc)),1))then Branch left or right in tree, depending on its
    node=iright(node) value.
else
    node=left(node)
endif
if(node.le.nch)then If we reach a terminal node, we have a complete character
    ich=node-1 and can return.
    return
endif
goto 1
END

```

For simplicity, hufdec quits when it runs out of code bytes; if your coded message is not an integral number of bytes, and if N_{ch} is less than 256, hufdec can return a spurious final character or two, decoded from the spurious trailing bits in your last code byte. If you have independent knowledge of the number of characters sent, you can readily discard these. Otherwise, you can fix this behavior by providing a bit, not byte, count, and modifying the routine accordingly. (When N_{ch} is 256 or larger, hufdec will normally run out of code in the middle of a spurious character, and it will be discarded.)

Run-Length Encoding

For the compression of highly correlated bit-streams (for example the black or white values along a facsimile scan line), Huffman compression is often combined with *run-length encoding*: Instead of sending each bit, the input stream is converted to a series of integers indicating how many consecutive bits have the same value. These integers are then Huffman-compressed. The Group 3 CCITT facsimile standard functions in this manner, with a fixed, immutable, Huffman code, optimized for a set of eight standard documents [8,9].

20.5 Arithmetic Coding

We saw in the previous section that a perfect (entropy-bounded) coding scheme would use $L_i = -\log_2 p_i$ bits to encode character i (in the range $1 \leq i \leq N_{ch}$), if p_i is its probability of occurrence. Huffman coding gives a way of rounding the L_i 's to close integer values and constructing a code with those lengths. *Arithmetic coding* [1], which we now discuss, actually does manage to encode characters using noninteger numbers of bits! It also provides a convenient way to output the result not as a stream of bits, but as a stream of symbols in any desired radix. This latter property is particularly useful if you want, e.g., to convert data from bytes (radix 256) to printable ASCII characters (radix 94), or to case-independent alphanumeric sequences containing only A-Z and 0-9 (radix 36).

In arithmetic coding, an input message of any length is represented as a real number R in the range $0 \leq R < 1$. The longer the message, the more precision required of R . This is best illustrated by an example, so let us return to the fictitious language, Vowellish, of the previous section. Recall that Vowellish has a 5 character alphabet (A, E, I, O, U), with occurrence probabilities 0.12, 0.42, 0.09, 0.30, and 0.07, respectively. Figure 20.5.1 shows how a message beginning “IOU” is encoded: The interval $[0, 1)$ is divided into segments corresponding to the 5 alphabetical characters; the length of a segment is the corresponding p_i . We see that the first message character, “I”, narrows the range of R to $0.37 \leq R < 0.46$. This interval is now subdivided into five subintervals, again with lengths proportional to the p_i 's. The second message character, “O”, narrows the range of R to $0.3763 \leq R < 0.4033$. The “U” character further narrows the range to $0.37630 \leq R < 0.37819$. Any value of R in this range can be sent as encoding “IOU”. In particular, the binary fraction .011000001 is in this range, so “IOU” can be sent in 9 bits. (Huffman coding took 10 bits for this example, see §20.4.)

Of course there is the problem of knowing when to stop decoding. The fraction .011000001 represents not simply “IOU,” but “IOU...,” where the ellipses represent an infinite string of successor characters. To resolve this ambiguity, arithmetic coding generally assumes the existence of a special $N_{ch} + 1$ th character, EOM (end of message), which occurs only once at the end of the input. Since EOM has a low probability of occurrence, it gets allocated only a very tiny piece of the number line.

In the above example, we gave R as a binary fraction. We could just as well have output it in any other radix, e.g., base 94 or base 36, whatever is convenient for the anticipated storage or communication channel.

You might wonder how one deals with the seemingly incredible precision required of R for a long message. The answer is that R is never actually represented all at once. At any give stage we have upper and lower bounds for R represented as a finite number of digits in the output radix. As digits of the upper and lower bounds become identical, we can left-shift them away and bring in new digits at the low-significance end. The routines below have a parameter NWK for the number of working digits to keep around. This must be large enough to make the chance of an accidental degeneracy vanishingly small. (The routines signal if a degeneracy ever occurs.) Since the process of discarding old digits and bringing in new ones is performed identically on encoding and decoding, everything stays synchronized.

20.5 Arithmetic Coding

Any value of R in this range can be sent as encoding “IOU”. In particular, the binary fraction .011000001 is in this range, so “IOU” can be sent in 9 bits. (Huffman coding took 10 bits for this example, see §20.4.)

Of course there is the problem of knowing when to stop decoding. The fraction .011000001 represents not simply “IOU,” but “IOU...,” where the ellipses represent an infinite string of successor characters. To resolve this ambiguity, arithmetic coding generally assumes the existence of a special $N_{ch} + 1$ th character, EOM (end of message), which occurs only once at the end of the input. Since EOM has a low probability of occurrence, it gets allocated only a very tiny piece of the number line.

In the above example, we gave R as a binary fraction. We could just as well have output it in any other radix, e.g., base 94 or base 36, whatever is convenient for the anticipated storage or communication channel.

You might wonder how one deals with the seemingly incredible precision required of R for a long message. The answer is that R is never actually represented all at once. At any give stage we have upper and lower bounds for R represented as a finite number of digits in the output radix. As digits of the upper and lower bounds become identical, we can left-shift them away and bring in new digits at the low-significance end. The routines below have a parameter NWK for the number of working digits to keep around. This must be large enough to make the chance of an accidental degeneracy vanishingly small. (The routines signal if a degeneracy ever occurs.) Since the process of discarding old digits and bringing in new ones is performed identically on encoding and decoding, everything stays synchronized.

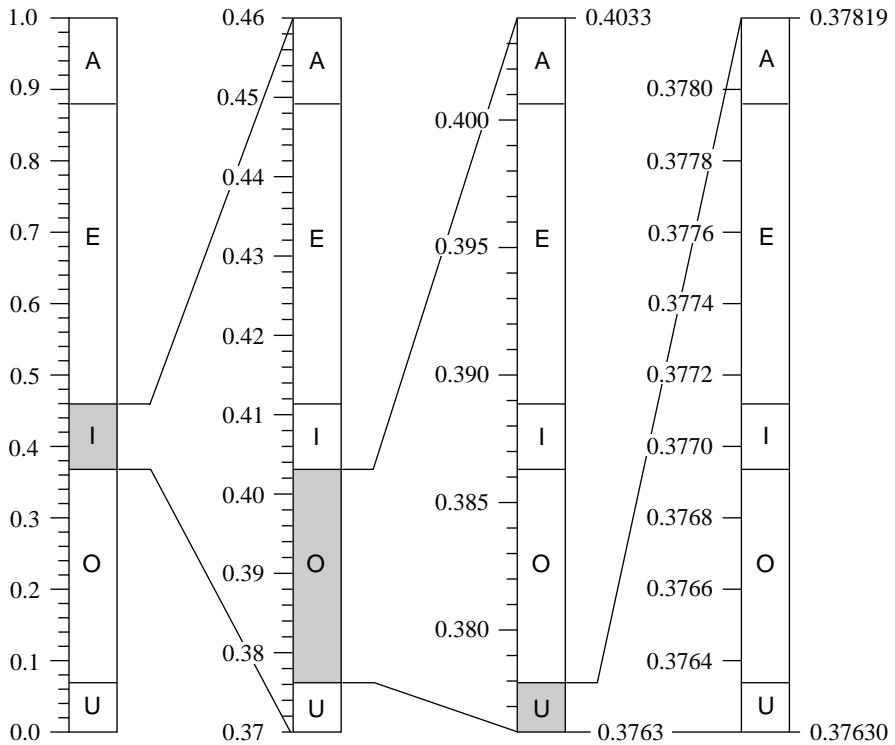

Figure 20.5.1. Arithmetic coding of the message “IOU...” in the fictitious language Vowellish. Successive characters give successively finer subdivisions of the initial interval between 0 and 1. The final value can be output as the digits of a fraction in any desired radix. Note how the subinterval allocated to a character is proportional to its probability of occurrence.

The routine `arcnak` constructs the cumulative frequency distribution table used to partition the interval at each stage. In the principal routine `arcode`, when an interval of size `jdif` is to be partitioned in the proportions of some `n` to some `ntot`, say, then we must compute $(n*jdif)/ntot$. With integer arithmetic, the numerator is likely to overflow; and, unfortunately, an expression like `jdif/(ntot/n)` is not equivalent. In the implementation below, we resort to double precision floating arithmetic for this calculation. Not only is this inefficient, but different roundoff errors can (albeit very rarely) make different machines encode differently, though any one type of machine will decode exactly what it encoded, since identical roundoff errors occur in the two processes. For serious use, one needs to replace this floating calculation with an integer computation in a double register (not available to the FORTRAN programmer).

The internally set variable `minint`, which is the minimum allowed number of discrete steps between the upper and lower bounds, determines when new low-significance digits are added. `minint` must be large enough to provide resolution of all the input characters. That is, we must have $p_i \times \text{minint} > 1$ for all i . A value of $100N_{ch}$, or $1.1/\text{min } p_i$, whichever is larger, is generally adequate. However, for safety, the routine below takes `minint` to be as large as possible, with the product `minint*nradd` just smaller than overflow. This results in some time inefficiency, and in a few unnecessary characters being output at the end of a message. You can

decrease `minint` if you want to live closer to the edge.

A final safety feature in `arcmak` is its refusal to believe zero values in the table `nfreq`; a 0 is treated as if it were a 1. If this were not done, the occurrence in a message of a single character whose `nfreq` entry is zero would result in scrambling the entire rest of the message. If you want to live dangerously, with a very slightly more efficient coding, you can delete the `max(, 1)` operation.

```
SUBROUTINE arc当地 (nfreq,nchh,nradd)
INTEGER nchh,nradd,nfreq(nchh),MC,NWK,MAXINT
PARAMETER (MC=512,NWK=20,MAXINT=2147483647)
   Given a table nfreq(1:nchh) of the frequency of occurrence of nchh symbols, and given
   a desired output radix nradd, initialize the cumulative frequency table and other variables
   for arithmetic compression.
   Parameters: MC is largest anticipated value of nchh; NWK is the number of working digits
   (see text); MAXINT is a large positive integer that does not overflow.
   INTEGER j,jdif,minint,nc,nch,nrad,ncum,
   *      ncumfq(MC+2),ilob(NWK),iupb(NWK)
   COMMON /arccom/ ncumfq,iupb,ilob,nch,nrad,minint,jdif,nc,ncum
   SAVE /arccom/
   if(nchh.gt.MC)pause 'MC too small in arc当地'
   if(nradd.gt.256)pause 'nradd may not exceed 256 in arc当地'
   minint=MAXINT/nradd
   nch=nchh
   nrad=nradd
   ncumfq(1)=0
   do 11 j=2,nch+1
      ncumfq(j)=ncumfq(j-1)+max(nfreq(j-1),1)
  11 enddo
   ncumfq(nch+2)=ncumfq(nch+1)+1
   ncum=ncumfq(nch+2)
   return
END
```

Individual characters in a message are coded or decoded by the routine `arc当地`, which in turn uses the utility `arcsum`.

```
SUBROUTINE arc当地 (ich,code,lcode,lcd,isign)
INTEGER ich,isign,lcd,lcode,MC,NWK
CHARACTER*1 code(lcode)
PARAMETER (MC=512,NWK=20)
C USES arcsum
   Compress (isign = 1) or decompress (isign = -1) the single character ich into or out
   of the character array code(1:lcode), starting with byte code(lcd) and (if necessary)
   incrementing lcd so that, on return, lcd points to the first unused byte in code. Note
   that this routine saves the result of previous calls until a new byte of code is produced, and
   only then increments lcd. An initializing call with isign=0 is required for each different
   array code. The routine arc当地 must have previously been called to initialize the common
   block /arccom/. A call with ich=nch (as set in arc当地) has the reserved meaning "end
   of message."
   INTEGER ihi,j,ja,jdif,jh,jl,k,m,minint,nc,nch,nrad,ilob(NWK),
   *      iupb(NWK),ncumfq(MC+2),ncum,JTRY
   COMMON /arccom/ ncumfq,iupb,ilob,nch,nrad,minint,jdif,nc,ncum
   SAVE /arccom/
   The following statement function is used to calculate (k*j)/m without overflow. Program
   efficiency can be improved by substituting an assembly language routine that does integer
   multiply to a double register.
   JTRY(j,k,m)=int((dble(k)*dble(j))/dble(m))
   if (isign.eq.0) then                                Initialize enough digits of the upper and lower bounds.
      jdif=nrad-1
      do 11 j=NWK,1,-1

20.6 Arithmetic at Arbitrary Precision

Let's compute the number π to a couple of thousand decimal places. In doing so, we'll learn some things about multiple precision arithmetic on computers and meet quite an unusual application of the fast Fourier transform (FFT). We'll also develop a set of routines that you can use for other calculations at any desired level of arithmetic precision.

To start with, we need an analytic algorithm for π . Useful algorithms are quadratically convergent, i.e., they double the number of significant digits at each iteration. Quadratically convergent algorithms for π are based on the *AGM* (*arithmetic geometric mean*) method, which also finds application to the calculation of elliptic integrals (cf. §6.11) and in advanced implementations of the ADI method for elliptic partial differential equations (§19.5). Borwein and Borwein [1] treat this subject, which is beyond our scope here. One of their algorithms for π starts with the initializations

$$\begin{aligned} X_0 &= \sqrt{2} \\ \pi_0 &= 2 + \sqrt{2} \\ Y_0 &= \sqrt[4]{2} \end{aligned} \tag{20.6.1}$$

```

SUBROUTINE arcsum(iin,iout,ja,nwk,nrad,nc)

20.6 Arithmetic at Arbitrary Precision

Let's compute the number π to a couple of thousand decimal places. In doing so, we'll learn some things about multiple precision arithmetic on computers and meet quite an unusual application of the fast Fourier transform (FFT). We'll also develop a set of routines that you can use for other calculations at any desired level of arithmetic precision.

To start with, we need an analytic algorithm for π . Useful algorithms are quadratically convergent, i.e., they double the number of significant digits at each iteration. Quadratically convergent algorithms for π are based on the *AGM* (*arithmetic geometric mean*) method, which also finds application to the calculation of elliptic integrals (cf. §6.11) and in advanced implementations of the ADI method for elliptic partial differential equations (§19.5). Borwein and Borwein [1] treat this subject, which is beyond our scope here. One of their algorithms for π starts with the initializations

$$\begin{aligned} X_0 &= \sqrt{2} \\ \pi_0 &= 2 + \sqrt{2} \\ Y_0 &= \sqrt[4]{2} \end{aligned} \tag{20.6.1}$$

and then, for $i = 0, 1, \dots$, repeats the iteration

$$\begin{aligned} X_{i+1} &= \frac{1}{2} \left(\sqrt{X_i} + \frac{1}{\sqrt{X_i}} \right) \\ \pi_{i+1} &= \pi_i \left(\frac{X_{i+1} + 1}{Y_i + 1} \right) \\ Y_{i+1} &= \frac{Y_i \sqrt{X_{i+1}} + \frac{1}{\sqrt{X_{i+1}}}}{Y_i + 1} \end{aligned} \quad (20.6.2)$$

The value π emerges as the limit π_∞ .

Now, to the question of how to do arithmetic to arbitrary precision: In a high-level language like FORTRAN, a natural choice is to work in radix (base) 256, so that character arrays can be directly interpreted as strings of digits. At the very end of our calculation, we will want to convert our answer to radix 10, but that is essentially a frill for the benefit of human ears, accustomed to the familiar chant, “three point one four one five nine . . .” For any less frivolous calculation, we would likely never leave base 256 (or the thence trivially reachable hexadecimal, octal, or binary bases).

We will adopt the convention of storing digit strings in the “human” ordering, that is, with the first stored digit in an array being most significant, the last stored digit being least significant. The opposite convention would, of course, also be possible. “Carries,” where we need to partition a number larger than 255 into a low-order byte and a high-order carry, present a minor programming annoyance, solved, in the routines below, by the use of FORTRAN’s EQUIVALENCE facility, and some initial testing of the order in which bytes are stored in a FORTRAN integer.

It is easy at this point, following Knuth [2], to write a routine for the “fast” arithmetic operations: short addition (adding a single byte to a string), addition, subtraction, short multiplication (multiplying a string by a single byte), short division, ones-complement negation; and a couple of utility operations, copying and left-shifting strings.

```
SUBROUTINE mpops(w,u,v)
CHARACTER*1 w(*),u(*),v(*)
  Multiple precision arithmetic operations done on character strings, interpreted as radix 256
  numbers. This routine collects the simpler operations.
INTEGER i,ireg,j,n,ir,is,iv,ii1,ii2
CHARACTER*1 creg(4)
SAVE ii1,ii2
EQUIVALENCE (ireg,creg)
  It is assumed that with the above equivalence, creg(ii1) addresses the low-order byte of
  ireg, and creg(ii2) addresses the next higher order byte. The values ii1 and ii2 are
  set by an initial call to mpinit.
ENTRY mpinit
  ireg=256*ichar('2')+ichar('1')
  do 11 j=1,4           Figure out the byte ordering.
    if (creg(j).eq.'1') ii1=j
    if (creg(j).eq.'2') ii2=j
  enddo 11
  return
ENTRY mpadd(w,u,v,n)
  Adds the unsigned radix 256 integers u(1:n) and v(1:n) yielding the unsigned integer
  w(1:n+1).
  ireg=0
  do 12 j=n,1,-1
```

```

    ireg=ichar(u(j))+ichar(v(j))+ichar(creg(ii2))
    w(j+1)=creg(ii1)
  enddo 12
  w(1)=creg(ii2)
return
ENTRY mpsub(is,w,u,v,n)
  Subtracts the unsigned radix 256 integer v(1:n) from u(1:n) yielding the unsigned integer
  w(1:n). If the result is negative (wraps around), is is returned as -1; otherwise it is
  returned as 0.
  ireg=256
  do 13 j=n,1,-1
    ireg=255+ichar(u(j))-ichar(v(j))+ichar(creg(ii2))
    w(j)=creg(ii1)
  enddo 13
  is=ichar(creg(ii2))-1
return
ENTRY mpsad(w,u,n,iv)
  Short addition: the integer iv (in the range  $0 \leq iv \leq 255$ ) is added to the unsigned radix
  256 integer u(1:n), yielding w(1:n+1).
  ireg=256*iv
  do 14 j=n,1,-1
    ireg=ichar(u(j))+ichar(creg(ii2))
    w(j+1)=creg(ii1)
  enddo 14
  w(1)=creg(ii2)
return
ENTRY mpsmu(w,u,n,iv)
  Short multiplication: the unsigned radix 256 integer u(1:n) is multiplied by the integer iv
  (in the range  $0 \leq iv \leq 255$ ), yielding w(1:n+1).
  ireg=0
  do 15 j=n,1,-1
    ireg=ichar(u(j))*iv+ichar(creg(ii2))
    w(j+1)=creg(ii1)
  enddo 15
  w(1)=creg(ii2)
return
ENTRY mpsdv(w,u,n,iv,ir)
  Short division: the unsigned radix 256 integer u(1:n) is divided by the integer iv (in the
  range  $0 \leq iv \leq 255$ ), yielding a quotient w(1:n) and a remainder ir (with  $0 \leq ir \leq 255$ ).
  ir=0
  do 16 j=1,n
    i=256*ir+ichar(u(j))
    w(j)=char(i/iv)
    ir=mod(i,iv)
  enddo 16
return
ENTRY mpneg(u,n)
  Ones-complement negate the unsigned radix 256 integer u(1:n).
  ireg=256
  do 17 j=n,1,-1
    ireg=255-ichar(u(j))+ichar(creg(ii2))
    u(j)=creg(ii1)
  enddo 17
return
ENTRY mpmove(u,v,n)
  Move v(1:n) onto u(1:n).
  do 18 j=1,n
    u(j)=v(j)
  enddo 18
return
ENTRY mplsh(u,n)
  Left shift u(2..n+1) onto u(1:n).
  do 19 j=1,n
    u(j)=u(j+1)

```

```

enddo 19
return
END

```

Full multiplication of two digit strings, if done by the traditional hand method, is not a fast operation: In multiplying two strings of length N , the multiplicand would be short-multiplied in turn by each byte of the multiplier, requiring $O(N^2)$ operations in all. We will see, however, that *all* the arithmetic operations on numbers of length N can in fact be done in $O(N \times \log N \times \log \log N)$ operations.

The trick is to recognize that multiplication is essentially a *convolution* (§13.1) of the digits of the multiplicand and multiplier, followed by some kind of carry operation. Consider, for example, two ways of writing the calculation 456×789 :

$$\begin{array}{r}
 \begin{array}{r}
 456 \\
 \times 789 \\
 \hline
 4104 \\
 3648 \\
 3192 \\
 \hline
 359784
 \end{array}
 \qquad
 \begin{array}{r}
 4 \ 5 \ 6 \\
 \times 7 \ 8 \ 9 \\
 \hline
 36 \ 45 \ 54 \\
 32 \ 40 \ 48 \\
 28 \ 35 \ 42 \\
 \hline
 28 \ 67 \ 118 \ 93 \ 54 \\
 \hline
 3 \ 5 \ 9 \ 7 \ 8 \ 4
 \end{array}
 \end{array}$$

The tableau on the left shows the conventional method of multiplication, in which three separate short multiplications of the full multiplicand (by 9, 8, and 7) are added to obtain the final result. The tableau on the right shows a different method (sometimes taught for mental arithmetic), where the single-digit cross products are all computed (e.g. $8 \times 6 = 48$), then added in columns to obtain an incompletely carried result (here, the list 28, 67, 118, 93, 54). The final step is a single pass from right to left, recording the single least-significant digit and carrying the higher digit or digits into the total to the left (e.g. $93 + 5 = 98$, record the 8, carry 9).

You can see immediately that the column sums in the right-hand method are components of the convolution of the digit strings, for example $118 = 4 \times 9 + 5 \times 8 + 6 \times 7$. In §13.1 we learned how to compute the convolution of two vectors by the fast Fourier transform (FFT): Each vector is FFT'd, the two complex transforms are multiplied, and the result is inverse-FFT'd. Since the transforms are done with floating arithmetic, we need sufficient precision so that the exact integer value of each component of the result is discernible in the presence of roundoff error. We should therefore allow a (conservative) few times $\log_2(\log_2 N)$ bits for roundoff in the FFT. A number of length N bytes in radix 256 can generate convolution components as large as the order of $(256)^2 N$, thus requiring $16 + \log_2 N$ bits of precision for exact storage. If it is the number of bits in the floating mantissa (cf. §20.1), we obtain the condition

$$16 + \log_2 N + \text{few} \times \log_2 \log_2 N < it \quad (20.6.3)$$

We see that single precision, say with $it = 24$, is inadequate for any interesting value of N , while double precision, say with $it = 53$, allows N to be greater than 10^6 , corresponding to some millions of decimal digits. The following routine

therefore presumes double precision versions of `realft` (§12.3) and `four1` (§12.2), here called `drealft` and `dfour1`. (These routines are included on the *Numerical Recipes* diskettes.)

```

SUBROUTINE mpmul(w,u,v,n,m)
INTEGER m,n,NMAX
CHARACTER*1 w(n+m),u(n),v(m)
DOUBLE PRECISION RX
PARAMETER (NMAX=8192,RX=256.D0)
C USES drealft           DOUBLE PRECISION version of realft.
C   Uses Fast Fourier Transform to multiply the unsigned radix 256 integers u(1:n) and
C   v(1:m), yielding a product w(1:n+m).
INTEGER j,nn,nn
DOUBLE PRECISION cy,t,a(NMAX),b(NMAX)
mn=max(m,n)
nn=1                   Find the smallest useable power of two for the transform.
1 if(nn.lt.mn) then
    nn=nn+nn
goto 1
endif
nn=nn+nn
if(nn.gt.NMAX)pause 'NMAX too small in fftmul'
do 11 j=1,n            Move U to a double precision floating array.
    a(j)=ichar(u(j))
enddo 11
do 12 j=n+1,nn
    a(j)=0.D0
enddo 12
do 13 j=1,m            Move V to a double precision floating array.
    b(j)=ichar(v(j))
enddo 13
do 14 j=m+1,nn
    b(j)=0.D0
enddo 14
call drealft(a,nn,1)    Perform the convolution: First, the two Fourier transforms.
call drealft(b,nn,1)
b(1)=b(1)*a(1)
b(2)=b(2)*a(2)
do 15 j=3,nn,2
    t=b(j)
    b(j)=t*a(j)-b(j+1)*a(j+1)
    b(j+1)=t*a(j+1)+b(j+1)*a(j)
enddo 15
call drealft(b,nn,-1)   Then do the inverse Fourier transform.
cy=0.                   Make a final pass to do all the carries.
do 16 j=nn,1,-1
    t=b(j)/(nn/2)+cy+0.5D0  The 0.5 allows for roundoff error.
    b(j)=mod(t,RX)
    cy=int(t/RX)
enddo 16
if (cy.ge.RX) pause 'cannot happen in fftmul'
w(1)=char(int(cy))      Copy answer to output.
do 17 j=2,n+m
    w(j)=char(int(b(j-1)))
enddo 17
return
END

```

With multiplication thus a “fast” operation, division is best performed by multiplying the dividend by the reciprocal of the divisor. The reciprocal of a value

V is calculated by iteration of Newton's rule,

$$U_{i+1} = U_i(2 - VU_i) \quad (20.6.4)$$

which results in the quadratic convergence of U_∞ to $1/V$, as you can easily prove. (Many supercomputers and RISC machines actually use this iteration to perform divisions.) We can now see where the operations count $N \log N \log \log N$, mentioned above, originates: $N \log N$ is in the Fourier transform, with the iteration to converge Newton's rule giving an additional factor of $\log \log N$.

```
SUBROUTINE mpinv(u,v,n,m)
INTEGER m,n,MF,NMAX
CHARACTER*1 u(n),v(m)
REAL BI
PARAMETER (MF=4,BI=1./256.,NMAX=8192)
Character string v(1:m) is interpreted as a radix 256 number with the radix point after
(nonzero) v(1); u(1:n) is set to the most significant digits of its reciprocal, with the radix
point after u(1).
C USES mpmove,mpmul,mpneg
INTEGER i,j,mm
REAL fu,fv
CHARACTER*1 rr(2*NMAX+1),s(NMAX)
if(max(n,m).gt.NMAX)pause 'NMAX too small in mpinv'
mm=min(MF,m)
fv=ichar(v(mm))                                Use ordinary floating arithmetic to get an initial ap-
do 11 j=mm-1,1,-1                               proximation.
    fv=fv*BI+ichar(v(j))
11 enddo 11
fv=1./fv
do 12 j=1,n
    i=int(fv)
    u(j)=char(i)
    fv=256.*(fv-i)
12 enddo 12
1 continue                                         Iterate Newton's rule to convergence.
call mpmul(rr,u,v,n,m)                         Construct  $2 - UV$  in  $S$ .

call mpmul(r,s,u,n,n)
call mpmove(u,r(2),n)
goto 1
END

```

We already mentioned that radix conversion to decimal is a merely cosmetic operation that should normally be omitted. The simplest way to convert a fraction to decimal is to multiply it repeatedly by 10, picking off (and subtracting) the resulting integer part. This, has an operations count of $O(N^2)$, however, since each liberated decimal digit takes an $O(N)$ operation. It is possible to do the radix conversion as a fast operation by a “divide and conquer” strategy, in which the fraction is (fast) multiplied by a large power of 10, enough to move about half the desired digits to the left of the radix point. The integer and fractional pieces are now processed independently, each further subdivided. If our goal were a few billion digits of π , instead of a few thousand, we would need to implement this scheme. For present purposes, the following lazy routine is adequate:

```
SUBROUTINE mp2dfr(a,s,n,m)
INTEGER m,n,IAZ
CHARACTER*1 a(*),s(*)
PARAMETER (IAZ=48)
C USES mplsh,mpsmu
    Converts a radix 256 fraction a(1:n) (radix point before a(1)) to a decimal fraction
    represented as an ascii string s(1:m), where m is a returned value. The input array a(1:n)
    is destroyed. NOTE: For simplicity, this routine implements a slow ( $\propto N^2$ ) algorithm. Fast
    ( $\propto N \ln N$ ), more complicated, radix conversion algorithms do exist.
INTEGER j
m=2.408*n
do 11 j=1,m
    call mp smu(a,a,n,10)
    s(j)=char(ichar(a(1))+IAZ)
    call mplsh(a,n)
11 enddo 11
return
END
```

Finally, then, we arrive at a routine implementing equations (20.6.1) and (20.6.2):

```
SUBROUTINE mppi(n)
INTEGER n,IAOFF,NMAX
PARAMETER (IAOFF=48,NMAX=8192)
C USES mpinit,mp2dfr,mpadd,mpinv,mplsh,mpmov,mpmul,mpsdv,mpsqrt
    Demonstrate multiple precision routines by calculating and printing the first n bytes of  $\pi$ .
INTEGER ir,j,m
CHARACTER*1 x(NMAX),y(NMAX),sx(NMAX),sxi(NMAX),t(NMAX),s(3*NMAX),
*          pi(NMAX)
call mpinit
t(1)=char(2)                                     Set  $T = 2$ .
do 11 j=2,n
    t(j)=char(0)
11 enddo 11
call mpsqrt(x,x,t,n,n)                         Set  $X_0 = \sqrt{2}$ .
call mpadd(pi,t,x,n)                           Set  $\pi_0 = 2 + \sqrt{2}$ .
call mplsh(pi,n)
call mpsqrt(sx,sxi,x,n,n)                      Set  $Y_0 = 2^{1/4}$ .
call mpmove(y,sx,n)
1 continue
    call mpadd(x,sx,sxi,n)                     Set  $X_{i+1} = (X_i^{1/2} + X_i^{-1/2})/2$ .
    call mpdrv(x,x(2),n,2,ir)
    call mpsqrt(sx,sxi,x,n,n)
    call mpmul(t,y,sx,n,n)
    call mpadd(t(2),t(2),sxi,n)
    x(1)=char(ichar(x(1))+1)                   Form the temporary  $T = Y_i X_{i+1}^{1/2} + X_{i+1}^{-1/2}$ .
                                                Increment  $X_{i+1}$  and  $Y_i$  by 1.
```

```

Figure 20.6.1. The first 2398 decimal digits of π , computed by the routines in this section.

```

y(1)=char(ichar(y(1))+1)
call mpinv(s,y,n,n)           Set  $Y_{i+1} = T/(Y_i + 1)$ .
call mpmul(y,t(3),s,n,n)
call mplsh(y,n)
call mpmul(t,x,s,n,n)         Form temporary  $T = (X_{i+1} + 1)/(Y_i + 1)$ .
continue                         If  $T = 1$  then we have converged.
      m=mod(255+ichar(t(2)),256)
      do 12 j=3,n
         if(ichar(t(j)).ne.m)goto 2
      enddo 12
      if (abs(ichar(t(n+1))-m).gt.1)goto 2
      write (*,*) 'pi='
      s(1)=char(ichar(pi(1))+IAOFF)
      s(2)='.'
      call mpdfr(pi(2),s(3),n-1,m)
      Convert to decimal for printing. NOTE: The conversion routine, for this demonstration
      only, is slow ( $\propto N^2$ ) algorithm. Fast ( $\propto N \ln N$ ), more complicated, radix
      conversion algorithms do exist.
      write (*,'(1x,64a1)') (s(j),j=1,m+1)
      return
2     continue
      call mpmul(s,pi,t(2),n,n)      Set  $\pi_{i+1} = T\pi_i$ .
      call mpmov(pi,s(2),n)
      goto 1
END

```

Figure 20.6.1 gives the result, computed with $n = 1000$. As an exercise, you might enjoy checking the first hundred digits of the figure against the first 12 terms of Ramanujan's celebrated identity [3]

$$\frac{1}{\pi} = \frac{\sqrt{8}}{9801} \sum_{n=0}^{\infty} \frac{(4n)! (1103 + 26390n)}{(n! 396^n)^4} \quad (20.6.6)$$

using the above routines. You might also use the routines to verify that the number $2^{512} + 1$ is not a prime, but has factors 2,424,833 and 7,455,602,825,647,884,208,337,395,736,200,454,918,783,366,342,657 (which are in fact prime; the remaining prime factor being about 7.416×10^{98}) [4].

References

The references collected here are those of general usefulness, usually cited in more than one section of this book. More specialized sources, usually cited in a single section, are not repeated here.

We first list a small number of books that form the nucleus of a recommended personal reference collection on numerical methods, numerical analysis, and closely related subjects. These are the books that we like to have within easy reach.

Index of Programs and Dependencies

The following table lists, in alphabetical order, all the routines in *Numerical Recipes*. When a routine requires subsidiary routines, either from this book or else user-supplied, the full dependency tree is shown: A routine calls directly all routines to which it is connected by a solid line in the column immediately to its right; it calls indirectly the connected routines in all columns to its right. Typographical conventions: Routines from this book are in typewriter font (e.g., `eulsum`, `gammLn`). The smaller, slanted font is used for the second and subsequent occurrences of a routine in a single dependency tree. (When you are getting routines from the *Numerical Recipes* diskettes, or their archive files, you need only specify names in the larger, upright font.) User-supplied routines are indicated by the use of text font and square brackets, e.g., [funcv]. Consult the text for individual specifications of these routines. The right-hand side of the table lists section and page numbers for each program.

General Index to Volumes 1 and 2

In this index, page numbers 1 through 934 refer to Volume 1, *Numerical Recipes in Fortran 77*, while page numbers 935 through 1446 refer to Volume 2, *Numerical Recipes in Fortran 90*. Front matter in Volume 1 is indicated by page numbers in the range 1/i through 1/xxxi, while front matter in Volume 2 is indicated 2/i through 2/xx.

Preface to Volume 2

Fortran 90 is not just the long-awaited updating of the Fortran language to modern computing practices. It is also the vanguard of a much larger revolution in computing, that of multiprocessor computers and widespread parallel programming. Parallel computing has been a feature of the largest supercomputers for quite some time. Now, however, it is rapidly moving towards the desktop.

As we watched the gestation and birth of Fortran 90 by its governing “X3J3 Committee” (a process interestingly described by a leading committee member, Michael Metcalf, in the Foreword that follows), it became clear to us that the right moment for moving Numerical Recipes from Fortran 77 to Fortran 90 was sooner, rather than later.

Fortran 90 compilers are now widely available. Microsoft’s Fortran PowerStation for Windows 95 brings that firm’s undeniable marketing force to PC desktop; we have tested this compiler thoroughly on our code and found it excellent in compatibility and performance. In the UNIX world, we have similarly tested, and had generally fine experiences with, DEC’s Fortran 90 for Alpha AXP and IBM’s xlf for RS/6000 and similar machines. NAG’s Fortran 90 compiler also brings excellent Fortran 90 compatibility to a variety of UNIX platforms. There are no doubt other excellent compilers, both available and on the way. Fortran 90 is completely backwards compatible with Fortran 77, by the way, so you don’t have to throw away your legacy code, or keep an old compiler around.

There have been previous special versions of Fortran for parallel supercomputers, but always specific to a particular hardware. Fortran 90, by contrast, is designed to provide a general, architecture-independent framework for parallel computation. Equally importantly, it is an international standard, agreed upon by a large group of computer hardware and software manufacturers and international standards bodies.

With the Fortran 90 language as a tool, we want this volume to be your complete guide for learning how to “think parallel.” The language itself is very general in this regard, and applicable to many present and future computers, or even to other parallel computing languages as they come along. Our treatment emphasizes general

 principles, but we are also not shy about pointing out parallelization “tricks” that have frequent applicability. These are not only discussed in this volume’s principal text chapters (Chapters 21–23), but are also sprinkled throughout the chapters of Fortran 90 code, called out by a special “parallel hint” logo (left, above). Also scattered throughout the code chapters  are specific “Fortran 90 tips,” with their own distinct graphic call-out (left). After you read the text chapters, you might want simply to browse among these hints and tips.

A special note to C programmers: Right now, there is no effort at producing a parallel version of C that is comparable to Fortran 90 in maturity, acceptance, and stability. We think, therefore, that C programmers will be well served by using this volume for an educational excursion into Fortran 90, its parallel programming constructions, and the numerical algorithms that capitalize on them. C and C++ programming have not been far from our minds as we have written this volume, and we think that you will find that time spent in absorbing its principal lessons (in Chapters 21–23) will be amply repaid in the future, as C and C++ eventually develop standard parallel extensions.

A final word of truth in packaging: **Don't buy this volume unless you also buy (or already have) Volume 1** (now retitled *Numerical Recipes in Fortran 77*). Volume 2 does not repeat any of the discussion of what individual programs actually do, or of the mathematical methods they utilize, or how to use them. While our Fortran 90 code is thoroughly commented, and includes a header comment for each routine that describes its input and output quantities, these comments are *not* supposed to be a complete description of the programs; the complete descriptions are in Volume 1, which we reference frequently. But here's a money-saving hint to our previous readers: If you already own a Second Edition version whose title is *Numerical Recipes in FORTRAN* (which doesn't indicate either "Volume 1" or "Volume 2" on its title page) then take a marking pen and write in the words "Volume 1." There! (Differences between the previous reprintings and the newest reprinting, the one labeled "Volume 1," are minor.)

Acknowledgments

We continue to be in the debt of many colleagues who give us the benefit of their numerical and computational experience. Many, though not all, of these are listed by name in the preface to the second edition, in Volume 1. To that list we must now certainly add George Marsaglia, whose ideas have greatly influenced our new discussion of random numbers in this volume (Chapter B7).

With this volume, we must acknowledge our additional gratitude and debt to a number of people who generously provided advice, expertise, and time (a great deal of time, in some cases) in the areas of parallel programming and Fortran 90. The original inspiration for this volume came from Mike Metcalf, whose clear lectures on Fortran 90 (in this case, overlooking the beautiful Adriatic at Trieste) convinced us that Fortran 90 could serve as the vehicle for a book with the larger scope of parallel programming generally, and whose continuing advice throughout the project has been indispensable. Gyan Bhanot also played a vital early role in the development of this book; his first translations of our Fortran 77 programs taught us a lot about parallel programming. We are also grateful to Greg Lindhorst, Charles Van Loan, Amos Yahil, Keith Kimball, Malcolm Cohen, Barry Caplin, Loren Meissner, Mitsu Sakamoto, and George Schnurer for helpful correspondence and/or discussion of Fortran 90's subtler aspects.

We once again express in the strongest terms our gratitude to programming consultant Seth Finkelstein, whose contribution to both the coding and the thorough testing of all the routines in this book (against multiple compilers and in sometimes-buggy, and always challenging, early versions) cannot be overstated.

WHP and SAT acknowledge the continued support of the U.S. National Science Foundation for their research on computational methods.

Foreword

by **Michael Metcalf**

Sipping coffee on a sunbaked terrace can be surprisingly productive. One of the *Numerical Recipes* authors and I were each lecturing at the International Center for Theoretical Physics in Trieste, Italy, he on numerical analysis and I on Fortran 90. The numerical analysis community had made important contributions to the development of the new Fortran standard, and so, unsurprisingly, it became quickly apparent that the algorithms for which *Numerical Recipes* had become renowned could, to great advantage, be recast in a new mold. These algorithms had, hitherto, been expressed in serial form, first in Fortran 77 and then in C, Pascal, and Basic. Now, nested iterations could be replaced by array operations and assignments, and the other features of a rich array language could be exploited. Thus was the idea of a “Numerical Recipes in Fortran 90” first conceived and, after three years’ gestation, it is a delight to assist at the birth.

But what *is* Fortran 90? How did it begin, what shaped it, and how, after nearly foundering, did its driving forces finally steer it to a successful conclusion?

The Birth of a Standard

Back in 1966, the version of Fortran now known as Fortran 66 was the first language ever to be standardized, by the predecessor of the present American National Standards Institute (ANSI). It was an all-American affair. Fortran had first been developed by John Backus of IBM in New York, and it was the dominant scientific programming language in North America. Many Europeans preferred Algol (in which Backus had also had a hand). Eventually, however, the mathematicians who favored Algol for its precisely expressible syntax began to defer to the scientists and engineers who appreciated Fortran’s pragmatic, even natural, style. In 1978, the upgraded Fortran 77 was standardized by the ANSI technical committee, X3J3, and subsequently endorsed by other national bodies and by ISO in Geneva, Switzerland. Its dominance in all fields of scientific and numerical computing grew as new, highly optimizing compilers came onto the market. Although newer languages, particularly Pascal, Basic, PL/1, and later Ada attracted their own adherents, scientific users throughout the 1980s remained true to Fortran. Only towards the end of that decade did C draw increasing support from scientific programmers who had discovered the power of structures and pointers.

During all this time, X3J3 kept functioning, developing the successor version to Fortran 77. It was to be a decade of strife and contention. The early plans, in the late 1970s, were mainly to add to Fortran 77 features that had had to be left out of that standard. Among these were dynamic storage and an array language, enabling it to map directly onto the architecture of supercomputers, then coming onto the market. The intention was to have this new version ready within five years, in 1982. But two new factors became significant at that time. The first was the decision that the next standard should not just codify existing practice, as had largely been the case in 1966 and 1978, but also extend the functionality of the language through

innovative additions (even though, for the array language, there was significant borrowing from John Iverson's APL and from DAP Fortran). The second factor was that X3J3 no longer operated under only American auspices. In the course of the 1980s, the standardization of programming languages came increasingly under the authority of the international body, ISO. Initially this was in an advisory role, but now ISO is the body that, through its technical committee WG5 (in full, ISO/IEC JTC1/SC22/WG5), is responsible for determining the course of the language. WG5 also steers the work of the development body, then as now, the highly skilled and competent X3J3. As we shall see, this shift in authority was crucial at the most difficult moment of Fortran 90's development.

The internationalization of the standards effort was reflected in the welcome given by X3J3 to six or seven European members; they, and about one-third of X3J3's U.S. members, provided the overlapping core of membership of X3J3 and WG5 that was vital in the final years in bringing the work to a successful conclusion. X3J3 membership, which peaked at about 45, is restricted to one voting member per organization, and significant decisions require a majority of two-thirds of those voting. Nationality plays no role, except in determining the U.S. position on an international issue. Members, who are drawn mainly from the vendors, large research laboratories, and academia, must be present or represented at two-thirds of all meetings in order to retain voting rights.

In 1980, X3J3 reported on its plans to the forerunner of WG5 in Amsterdam, Holland. Fortran 8x, as it was dubbed, was to have a basic array language, new looping constructs, a bit data type, data structures, a free source form, a mechanism to "group" procedures, and another to manage the global name space. Old features, including COMMON, EQUIVALENCE, and the arithmetic-IF, were to be consigned to a so-called obsolete module, destined to disappear in a subsequent revision. This was part of the "core plus modules" architecture, for adding new features and retiring old ones, an aid to backwards compatibility. Even though Fortran 77 compilers were barely available, the work seemed well advanced and the mood was optimistic. Publication was intended to take place in 1985. It was not to be.

One problem was the sheer number of new features that were proposed as additions to the language, most of them worthwhile in themselves but with the totality being too large. This became a recurrent theme throughout the development of the standard. One example was the suggestion of Lawrie Schonfelder (Liverpool University), at a WG5 meeting in Vienna, Austria, in 1982, that certain features already proposed as additions could be combined to provide a full-blown derived data type facility, thus providing Fortran with abstract data types. This idea was taken up by X3J3 and has since come to be recognized, along with the array language, as one of the two main advances brought about by what became Fortran 90. However, the ramifications go very deep: all the technical details of how to handle arrays of objects of derived types that in turn have array components that have the pointer attribute, and so forth, have to be precisely defined and rigorously specified.

Conflict

The meetings of X3J3 were often full of drama. Most compiler vendors were represented as a matter of course but, for many, their main objective appeared to be to maintain the status quo and to ensure that Fortran 90 never saw the light of

day. One vendor's extended (and much-copied) version of Fortran 77 had virtually become an industry standard, and it saw as its mission the maintenance of this lead. A new standard would cost it its perceived precious advantage. Other large vendors had similar points of view, although those marketing supercomputers were clearly keen on the array language. Most users, on the other hand, were hardly prepared to invest large amounts of their employers' and their own resources in simply settling for a trivial set of improvements to the existing standard. However, as long as X3J3 worked under a simple-majority voting rule, at least some apparent progress could be made, although the underlying differences often surfaced. These were even sometimes between users — those who wanted Fortran to become a truly modern language and those wanting to maintain indefinite backwards compatibility for their billions of lines of existing code.

At a watershed meeting, in Scranton, Pennsylvania, in 1986, held in an atmosphere that sometimes verged on despair, a fragile compromise was reached as a basis for further work. One breakthrough was to weaken the procedures for removing outdated features from the language, particularly by removing no features whatsoever from the next standard and by striking storage association (i.e., COMMON and EQUIVALENCE) from the list of features to be designated as obsolescent (as they are now known). A series of votes definitively removed from the language all plans to add: arrays of arrays, exception handling, nesting of internal procedures, the FORALL statement (now in Fortran 95), and a means to access skew array sections. There were other features on this list that, although removed, were reinstated at later meetings: user-defined operators, operator overloading, array and structure constructors, and vector-valued subscripts. After many more travails, the committee voted, a year later, by 26 votes to 9, to forward the document for what was to become the first of three periods of public comment.

While the document was going through the formal standards bureaucracy and being placed before the public, X3J3 polished it further. X3J3 also prepared procedures for processing the comments it anticipated receiving from the public, and to each of which, under the rules, it would have to reply individually. It was just as well. Roughly 400 replies flooded in, many of them very detailed and, disappointingly for those of us wanting a new standard quickly, unquestionably negative towards our work. For many it was too radical, but many others pleaded for yet more modern features, such as pointers.

Now the committee was deadlocked. Given that a document had already been published, any further change required not a simple but a two-thirds majority. The conservatives and the radicals could each block a move to modify the draft standard, or to accept a revised one for public review — and just that happened, in Champagne-Urbana, Illinois, in 1988. Any change, be it on the one hand to modify the list of obsolescent features, to add the pointers or bit data type wanted by the public, to add multi-byte characters to support Kanji and other non-European languages or, on the other hand, to emasculate the language by removing modules or operator overloading, and hence abstract data types, to name but some suggestions, none of these could be done individually or collectively in a way that would achieve consensus. I wrote:

“In my opinion, no standard can now emerge without either a huge concession by the users to the vendors (MODULE / USE) and/or a major change in the composition of the committee. I do not see how members who have worked for up to a decade or more, devoting time and intellectual energy far beyond the call of duty, can be

expected to make yet more personal sacrifices if no end to the work is in sight, or if that end is nothing but a travesty of what had been designed and intended as a modern scientific programming language. . . . I think the August meeting will be a watershed — if no progress is achieved there will be dramatic resignations, and ISO could even remove the work from ANSI, which is failing conspicuously in its task."

(However, the same notes began with a quotation from *The Taming of the Shrew*: "And do as adversaries do in law, / Strive mightily, but eat and drink / as friend." That we always did, copiously.)

Resolution

The "August meeting" was, unexpectedly, imbued with a spirit of compromise that had been so sadly lacking at the previous one. Nevertheless, after a week of discussing four separate plans to rescue the standard, no agreement was reached. Now the question seriously arose: Was X3J3 incapable of producing a new Fortran standard for the international community, doomed to eternal deadlock, a victim of ANSI procedures?

Breakthrough was achieved at a traumatic meeting of WG5 in Paris, France, a month later. The committee spent several extraordinary days drawing up a detailed list of what *it* wanted to be in Fortran 8x. Finally, it set X3J3 an ultimatum that was unprecedented in the standards world: The ANSI committee was to produce a new draft document, corresponding to WG5's wishes, within five months! Failing that, WG5 would assume responsibility and produce the new standard itself.

This decision was backed by the senior U.S. committee, X3, which effectively directed X3J3 to carry out WG5's wishes. And it did! The following November, it implemented most of the technical changes, adding pointers, bit manipulation intrinsic procedures, and vector-valued subscripts, and removing user-defined elemental functions (now in Fortran 95). The actual list of changes was much longer. X3J3 and WG5, now collaborating closely, often in gruelling six-day meetings, spent the next 18 months and two more periods of (positive) public comment putting the finishing touches to what was now called Fortran 90, and it was finally adopted, after some cliff-hanging votes, for forwarding as a U.S. and international standard on April 11, 1991, in Minneapolis, Minnesota.

Among the remaining issues that were decided along the way were whether pointers should be a data type or be defined in terms of an attribute of a variable, implying strong typing (the latter was chosen), whether the new standard should coexist alongside the old one rather than definitively replace it (it coexisted for a while in the U.S., but was a replacement elsewhere, under ISO rules), and whether, in the new free source form, blanks should be significant (fortunately, they are).

Fortran 90

The main new features of Fortran 90 are, first and foremost, the array language and abstract data types. The first is built on whole array operations and assignments, array sections, intrinsic procedures for arrays, and dynamic storage. It was designed with optimization in mind. The second is built on modules and module procedures, derived data types, operator overloading and generic interfaces, together with pointers. Also important are the new facilities for numerical computation including

a set of numeric inquiry functions, the parametrization of the intrinsic types, new control constructs — SELECT CASE and new forms of DO, internal and recursive procedures and optional and keyword arguments, improved I/O facilities, and many new intrinsic procedures. Last but not least are the new free source form, an improved style of attribute-oriented specifications, the IMPLICIT NONE statement, and a mechanism for identifying redundant features for subsequent removal from the language. The requirement on compilers to be able to identify, for example, syntax extensions, and to report why a program has been rejected, are also significant. The resulting language is not only a far more powerful tool than its successor, but a safer and more reliable one too. Storage association, with its attendant dangers, is not abolished, but rendered unnecessary. Indeed, experience shows that compilers detect errors far more frequently than before, resulting in a faster development cycle. The array syntax and recursion also allow quite compact code to be written, a further aid to safe programming.

No programming language can succeed if it consists simply of a definition (witness Algol 68). Also required are robust compilers from a wide variety of vendors, documentation at various levels, and a body of experience. The first Fortran 90 compiler appeared surprisingly quickly, in 1991, especially in view of the widely touted opinion that it would be very difficult to write one. Even more remarkable was that it was written by one person, Malcolm Cohen of NAG, in Oxford, U.K. There was a gap before other compilers appeared, but now they exist as native implementations for almost all leading computers, from the largest to PCs. For the most part, they produce very efficient object code; where, for certain new features, this is not the case, work is in progress to improve them.

The first book, *Fortran 90 Explained*, was published by John Reid and me shortly before the standard itself was published. Others followed in quick succession, including excellent texts aimed at the college market. At the time of writing there are at least 19 books in English and 22 in various other languages: Chinese, Dutch, French, Japanese, Russian, and Swedish. Thus, the documentation condition is fulfilled.

The body of experience, on the other hand, has yet to be built up to a critical size. Teaching of the language at college level has only just begun. However, I am certain that this present volume will contribute decisively to a significant breakthrough, as it provides models not only of the numerical algorithms for which previous editions are already famed, but also of an excellent Fortran 90 style, something that can develop only with time. Redundant features are abjured. It shows that, if we abandon these features and use new ones in their place, the appearance of code can initially seem unfamiliar, but, in fact, the advantages become rapidly apparent. This new edition of *Numerical Recipes* stands as a landmark in this regard.

Fortran Evolution

The formal procedures under which languages are standardized require them either to evolve or to die. A standard that has not been revised for some years must either be revised and approved anew, or be withdrawn. This matches the technical pressure on the language developers to accommodate the increasing complexity both of the problems to be tackled in scientific computation and of the underlying hardware on which programs run. Increasing problem complexity requires more powerful

features and syntax; new hardware needs language features that map onto it well.

Thus it was that X3J3 and WG5, having finished Fortran 90, began a new round of improvement. They decided very quickly on new procedures that would avoid the disputes that bedevilled the previous work: WG5 would decide on a plan for future standards, and X3J3 would act as the so-called development body that would actually produce them. This would be done to a strict timetable, such that any feature that could not be completed on time would have to wait for the next round. It was further decided that the next major revision should appear a decade after Fortran 90 but, given the somewhat disconcerting number of requests for interpretation that had arrived, about 200, that a minor revision should be prepared for mid-term, in 1995. This should contain only “corrections, clarifications and interpretations” and a very limited number (some thought none) of minor improvements.

At the same time, scientific programmers were becoming increasingly concerned at the variety of methods that were necessary to gain efficient performance from the ever-more widely used parallel architectures. Each vendor provided a different set of parallel extensions for Fortran, and some academic researchers had developed yet others. On the initiative of Ken Kennedy of Rice University, a High-Performance Fortran Forum was established. A coalition of vendors and users, its aim was to produce an ad hoc set of extensions to Fortran that would become an informal but widely accepted standard for portable code. It set itself the daunting task of achieving that in just one year, and succeeded. Melding existing dialects like Fortran D, CM Fortran, and Vienna Fortran, and adopting the new Fortran 90 as a base, because of its array syntax, High-Performance Fortran (HPF) was published in 1993 and has since become widely implemented. However, although HPF was designed for data parallel codes and mainly implemented in the form of directives that appear to non-HPF processors as comment lines, an adequate functionality could not be achieved without extending the Fortran syntax. This was done in the form of the PURE attribute for functions — an assertion that they contain no side effects — and the FORALL construct — a form of array assignment expressed with the help of indices.

The dangers of having diverging or competing forms of Fortran 90 were immediately apparent, and the standards committees wisely decided to incorporate these two syntactic changes also into Fortran 95. But they didn’t stop there. Two further extensions, useful not only for their expressive power but also to access parallel hardware, were added: elemental functions, ones written in terms of scalars but that accept array arguments of any permitted shape or size, and an extension to allow nesting of WHERE constructs, Fortran’s form of masked assignment. To readers of *Numerical Recipes*, perhaps the most relevant of the minor improvements that Fortran 95 brings are the ability to distinguish between a negative and a positive real zero, automatic deallocation of allocatable arrays, and a means to initialize the values of components of objects of derived data types and to initialize pointers to null.

The medium-term objective of a relatively minor upgrade has been achieved on schedule. But what does the future hold? Developments in the underlying principles of procedural programming languages have not ceased. Early Fortran introduced the concepts of expression abstraction ($X=Y+Z$) and later control expression (e.g., the DO loop). Fortran 77 continued this with the `if-then-else`, and Fortran 90 with the DO and SELECT CASE constructs. Fortran 90 has a still higher level of expression abstraction (array assignments and expressions) as well as data structures and even full-blown abstract data types. However, during the 1980s the concept of objects

came to the fore, with methods bound to the objects on which they operate. Here, one particular language, C++, has come to dominate the field. Fortran 90 lacks a means to point to functions, but otherwise has most of the necessary features in place, and the standards committees are now faced with the dilemma of deciding whether to make the planned Fortran 2000 a fully object-oriented language. This could possibly jeopardize its powerful, and efficient, numerical capabilities by too great an increase in language complexity, so should they simply batten down the hatches and not defer to what might be only a passing storm? At the time of writing, this is an open issue. One issue that is not open is Fortran's lack of in-built exception handling. It is virtually certain that such a facility, much requested by the numerical community, and guided by John Reid, will be part of the next major revision. The list of other requirements is long but speculative, but some at the top of the list are conditional compilation, command line argument handling, I/O for objects of derived type, and asynchronous I/O (which is also planned for the next release of HPF). In the meantime, some particularly pressing needs have been identified, for the handling of floating-point exceptions, interoperability with C, and allowing allocatable arrays as structure components, dummy arguments, and function results. These have led WG5 to begin processing these three items using a special form of fast track, so that they might become optional but standard extensions well before Fortran 2000 itself is published in the year 2001.

Conclusion

Writing a book is always something of a gamble. Unlike a novel that stands or falls on its own, a book devoted to a programming language is dependent on the success of others, and so the risk is greater still. However, this new *Numerical Recipes in Fortran 90* volume is no ordinary book, since it comes as the continuation of a highly successful series, and so great is its significance that it can, in fact, influence the outcome in its own favor. I am entirely confident that its publication will be seen as an important event in the story of Fortran 90, and congratulate its authors on having performed a great service to the field of numerical computing.

*Geneva, Switzerland
January 1996*

Michael Metcalf

License Information

Read this section if you want to use the programs in this book on a computer. You'll need to read the following Disclaimer of Warranty, get the programs onto your computer, and acquire a Numerical Recipes software license. (Without this license, which can be the free "immediate license" under terms described below, the book is intended as a text and reference book, for reading purposes only.)

Disclaimer of Warranty

We make no warranties, express or implied, that the programs contained in this volume are free of error, or are consistent with any particular standard of merchantability, or that they will meet your requirements for any particular application. They should not be relied on for solving a problem whose incorrect solution could result in injury to a person or loss of property. If you do use the programs in such a manner, it is at your own risk. The authors and publisher disclaim all liability for direct or consequential damages resulting from your use of the programs.

How to Get the Code onto Your Computer

Pick one of the following methods:

- You can type the programs from this book directly into your computer. In this case, the *only* kind of license available to you is the free "immediate license" (see below). You are not authorized to transfer or distribute a machine-readable copy to any other person, nor to have any other person type the programs into a computer on your behalf. We do not want to hear bug reports from you if you choose this option, because experience has shown that *virtually all* reported bugs in such cases are typing errors!
- You can download the Numerical Recipes programs electronically from the Numerical Recipes On-Line Software Store, located at our Web site (<http://www.nr.com>). They are packaged as a single compressed file, and you'll need to purchase a license to download and unpack them. Any number of single-screen licenses can be purchased instantly (with discount for multiple screens) from the On-Line Store, with fees that depend on your operating system (Windows or Macintosh versus Linux or UNIX) and whether you are affiliated with an educational institution. Purchasing a single-screen license is also the way to start if you want to acquire a more general (site or corporate) license; your single-screen cost will be subtracted from the cost of any later license upgrade.
- You can purchase media containing the programs from Cambridge University Press. A diskette version is available for Windows machines. CDROM versions in ISO-9660 format for Windows, Macintosh, and UNIX/Linux systems are also available; these include Fortran, C, and C++ versions on a single CDROM (as well as versions in Pascal and BASIC from the first edition). Diskettes purchased from Cambridge University Press include

a single-screen license for Windows only. The CDROM is available with a single-screen license for Windows or Macintosh (order ISBN 0 521 750350), or (at a slightly higher price) with a single-screen license for UNIX/Linux workstations (order ISBN 0 521 750369). Orders for media from Cambridge University Press can be placed at 800 872-7423 (North America only) or by email to orders@cup.org (North America) or directcustserv@cambridge.org (rest of world). Or, visit the Web site <http://www.cambridge.org>.

Types of License Offered

Here are the types of licenses that we offer. Note that some types are automatically acquired with the purchase of media from Cambridge University Press, or of an unlocking password from the Numerical Recipes On-Line Software Store, while other types of licenses require that you communicate specifically with Numerical Recipes Software (email: orders@nr.com or fax: 781 863-1739). Our Web site <http://www.nr.com> has additional information.

- [“Immediate License”] If you are the individual owner of a copy of this book and you type one or more of its routines into your computer, we authorize you to use them on that computer for your own personal and noncommercial purposes. You are not authorized to transfer or distribute machine-readable copies to any other person, or to use the routines on more than one machine, or to distribute executable programs containing our routines. This is the only free license.
- [“Single-Screen License”] This is the most common type of low-cost license, with terms governed by our Single Screen (Shrinkwrap) License document (complete terms available through our Web site). Basically, this license lets you use Numerical Recipes routines on any one screen (PC, workstation, X-terminal, etc.). You may also, under this license, transfer pre-compiled, executable programs incorporating our routines to other, unlicensed, screens or computers, providing that (i) your application is noncommercial (i.e., does not involve the selling of your program for a fee), (ii) the programs were first developed, compiled, and successfully run on a licensed screen, and (iii) our routines are bound into the programs in such a manner that they cannot be accessed as individual routines and cannot practicably be unbound and used in other programs. That is, under this license, your program user must not be able to use our programs as part of a program library or “mix-and-match” workbench. Conditions for other types of commercial or noncommercial distribution may be found on our Web site (<http://www.nr.com>).
- [“Multi-Screen, Server, Site, and Corporate Licenses”] The terms of the Single Screen License can be extended to designated groups of machines, defined by number of screens, number of machines, locations, or ownership. Significant discounts from the corresponding single-screen

prices are available when the estimated number of screens exceeds 40. Contact Numerical Recipes Software (email: orders@nr.com or fax: 781 863-1739) for details.

- [“Course Right-to-Copy License”] Instructors at accredited educational institutions who have adopted this book for a course, and who have already purchased a Single Screen License (either acquired with the purchase of media, or from the Numerical Recipes On-Line Software Store), may license the programs for use in that course as follows: Mail your name, title, and address; the course name, number, dates, and estimated enrollment; and advance payment of \$5 per (estimated) student to Numerical Recipes Software, at this address: P.O. Box 243, Cambridge, MA 02238 (USA). You will receive by return mail a license authorizing you to make copies of the programs for use by your students, and/or to transfer the programs to a machine accessible to your students (but only for the duration of the course).

About Copyrights on Computer Programs

Like artistic or literary compositions, computer programs are protected by copyright. Generally it is an infringement for you to copy into your computer a program from a copyrighted source. (It is also not a friendly thing to do, since it deprives the program’s author of compensation for his or her creative effort.) Under copyright law, all “derivative works” (modified versions, or translations into another computer language) also come under the same copyright as the original work.

Copyright does not protect ideas, but only the expression of those ideas in a particular form. In the case of a computer program, the ideas consist of the program’s methodology and algorithm, including the necessary sequence of steps adopted by the programmer. The expression of those ideas is the program source code (particularly any arbitrary or stylistic choices embodied in it), its derived object code, and any other derivative works.

If you analyze the ideas contained in a program, and then express those ideas in your own completely different implementation, then that new program implementation belongs to you. That is what we have done for those programs in this book that are not entirely of our own devising. When programs in this book are said to be “based” on programs published in copyright sources, we mean that the ideas are the same. The expression of these ideas as source code is our own. We believe that no material in this book infringes on an existing copyright.

Trademarks

Several registered trademarks appear within the text of this book: Sun is a trademark of Sun Microsystems, Inc. SPARC and SPARCstation are trademarks of SPARC International, Inc. Microsoft, Windows 95, Windows NT, PowerStation, and MS are trademarks of Microsoft Corporation. DEC, VMS, Alpha AXP, and ULTRIX are trademarks of Digital Equipment Corporation. IBM is a trademark of International Business Machines Corporation. Apple and Macintosh are trademarks of Apple Computer, Inc. UNIX is a trademark licensed exclusively through X/Open

Co. Ltd. IMSL is a trademark of Visual Numerics, Inc. NAG refers to proprietary computer software of Numerical Algorithms Group (USA) Inc. PostScript and Adobe Illustrator are trademarks of Adobe Systems Incorporated. Last, and no doubt least, Numerical Recipes (when identifying products) is a trademark of Numerical Recipes Software.

Attributions

The fact that ideas are legally “free as air” in no way supersedes the ethical requirement that ideas be credited to their known originators. When programs in this book are based on known sources, whether copyrighted or in the public domain, published or “handed-down,” we have attempted to give proper attribution. Unfortunately, the lineage of many programs in common circulation is often unclear. We would be grateful to readers for new or corrected information regarding attributions, which we will attempt to incorporate in subsequent printings.

Chapter 22. Introduction to Parallel Programming

22.0 Why Think Parallel?

In recent years we Numerical Recipes authors have increasingly become convinced that a certain revolution, cryptically denoted by the words “parallel programming,” is about to burst forth from its gestation and adolescence in the community of supercomputer users, and become the mainstream methodology for all computing.

Let’s review the past: Take a screwdriver and open up the computer (workstation or PC) that sits on your desk. (Don’t blame us if this voids your warranty; and be sure to unplug it first!) Count the integrated circuits — just the bigger ones, with more than a million gates (transistors). As we write, in 1995, even lowly memory chips have one or four million gates, and this number will increase rapidly in coming years. You’ll probably count at least dozens, and often hundreds, of such chips in your computer.

Next ask, how many of these chips are CPUs? That is, how many implement von Neumann processors capable of executing arbitrary, stored program code? For most computers, in 1995, the answer is: about one. A significant number of computers do have secondary processors that offload input-output and/or video functions. So, two or three is often a more accurate answer, but only one is usually under the user’s direct control.

Why do our desktop computers have dozens or hundreds of memory chips, but most often only one (user-accessible) CPU? Do CPU chips intrinsically cost more to manufacture? No. Are CPU chips more expensive than memory chips? Yes, primarily because fixed development and design costs must be distributed over a smaller number of units sold. We have been in a kind of economic equilibrium: CPU’s are relatively expensive because there is only one per computer; and there is only one per computer, because they are relatively expensive.

Stabilizing this equilibrium has been the fact that there has been no standard, or widely taught, methodology for parallel programming. Except for the special case of scientific computing on supercomputers (where large problems often have a regular or geometric character), it is not too much of an exaggeration to say that nobody *really knows how* to program multiprocessor machines. Symmetric multiprocessor

operating systems, for example, have been very slow in developing; and efficient, parallel methodologies for query-serving on large databases are even now a subject of continuing research.

However, things are now changing. We consider it an easy prognostication that, by the first years of the new century, the typical desktop computer will have 4 to 8 user-accessible CPUs; ten years after that, the typical number will be between 16 and 512. It is not coincidence that these numbers are characteristic of supercomputers (including some quite different architectures) in 1995. The rough rule of ten years' lag from supercomputer to desktop has held firm for quite some time now.

Scientists and engineers have the advantage that techniques for parallel computation in their disciplines *have* already been developed. With multiprocessor workstations right around the corner, we think that now is the right time for scientists and engineers who use computers to start *thinking parallel*. We don't mean that you should put an axe through the screen of your fast serial (single-CPU) workstation. We do mean, however, that you should start programming somewhat differently on that workstation, indeed, start thinking a bit differently about the way that you approach numerical problems in general.

In this volume of *Numerical Recipes in Fortran*, our pedagogical goal is to show you that there are conceptual and practical benefits in parallel thinking, even if you are using a serial machine today. These benefits include conciseness and clarity of code, reusability of code in wider contexts, and (not insignificantly) increased portability of code to today's parallel supercomputers. Of course, on parallel machines, either supercomputers today or desktop machines tomorrow, the benefits of thinking parallel are much more tangible: They translate into significant improvements in efficiency and computational capability.

Thinking Parallel with Fortran 90

Until very recently, a strong inhibition to thinking parallel was the lack of any standard, architecture-independent, computer language in which to think. That has changed with the finalization of the Fortran 90 language standard, and with the availability of good, optimizing Fortran 90 compilers on a variety of platforms.

There is a significant body of opinion (with which we, however, disagree) that there is no such thing as architecture-independent parallel programming. Proponents of this view, who are generally committed wizards at programming on one or another particular architecture, point to the fact that algorithms that are optimized to one architecture can run hundreds of times more slowly on other architectures. And, they are correct!

Our opposing point of view is one of pragmatism. We think that it is not hard to learn, in a general way, what kinds of architectures are in general use, and what kinds of parallel constructions work well (or poorly) on each kind. With this knowledge (much of which we hope to develop in this book) the user can, we think, write good, general-purpose parallel code that works on a variety of architectures — including, importantly, on purely serial machines. Equally important, the user will be aware of when certain parts of a code can be significantly improved on some, but not other, architectures.

Fortran 90 is a good test-bench for this point of view. It is not the perfect language for parallel programming. But it is *a* language, and it is the only

cross-platform *standard* language now available. The committee that developed the language between 1978 and 1991 (known technically as X3J3) had strong representation from both a traditional “vectorization” viewpoint (e.g., from the Cray XMP and YMP series of computers), and also from the “data parallel” or “SIMD” viewpoints of parallel machines like the CM-2 and CM-5 from Thinking Machines, Inc. Language compromises were made, and a few (in our view) almost essential features were left out (see §22.5). But, by and large, the necessary tools are there: If you learn to think parallel in Fortran 90, you will easily be able to transfer the skill to future parallel standards, whether they are Fortran-based, C-based, or other.

22.1 Fortran 90 Data Parallelism: Arrays and Intrinsics

The underlying model for parallel computation in Fortran 90 is *data parallelism*, implemented by the use of arrays of data, and by the provision of operations and intrinsic functions that act on those arrays in parallel, in a manner optimized by the compiler for each particular hardware architecture. We will not try to draw a fine definitional distinction between “data parallelism” and so-called SIMD (single instruction multiple data) programming. For our purposes the two terms mean about the same thing: The programmer writes a single operation, “+” say, and the compiler causes it to be carried out on multiple pieces of data in as parallel a manner as the underlying hardware allows.

Any kind of parallel computing that is not SIMD is generally called MIMD (multiple instruction multiple data). A parallel programming language with MIMD features might allow, for example, several different subroutines — acting on different parts of the data — to be called into execution simultaneously. Fortran 90 has few, if any, MIMD constructions. A Fortran 90 compiler might, on some machines, execute MIMD code in implementing some Fortran 90 intrinsic functions (pack or unpack, e.g.), but this will be hidden from the Fortran 90 user. Some extensions of Fortran 90, like HPF, do implement MIMD features explicitly; but we will not consider these in this book. Fortran 95’s `forall` and `PURE` extensions (see §21.6) will allow some significantly greater access to MIMD features (see §22.5).

Array Parallel Operations

We have already met the most basic, and most important, parallel facility of Fortran 90, namely, the ability to use whole arrays in expressions and assignments, with the indicated operations being effected in parallel across the array. Suppose, for example, we have the two-dimensional matrices `a`, `b`, and `c`,

```
REAL, DIMENSION(30,30) :: a,b,c
```

Then, instead of the serial construction,

```
do j=1,30
    do k=1,30
        c(j,k)=a(j,k)+b(j,k)
    end do
end do
```

which is of course perfectly valid Fortran 90 code, we can simply write

```
c=a+b
```

The compiler deduces from the declaration statement that *a*, *b*, and *c* are matrices, and what their bounding dimensions are.

Let us dwell for a moment on the conceptual differences between the serial code and parallel code for the above matrix addition. Although one is perhaps used to seeing the nested do-loops as simply an idiom for “do-the-enclosed-on-all-components,” it in fact, according to the rules of Fortran, specifies a very particular time-ordering for the desired operations. The matrix elements are added by rows, in order ($j=1, 30$), and within each row, by columns, in order ($k=1, 30$).

In fact, the serial code above *overspecifies* the desired task, since it is guaranteed by the laws of mathematics that the order in which the element operations are done is of no possible relevance. Over the 50 year lifetime of serial von Neuman computers, we programmers have been brainwashed to break up all problems into single executable streams *in the time dimension only*. Indeed, the major design problem for supercomputer compilers for the last 20 years has been to *undo* such serial constructions and recover the underlying “parallel thoughts,” for execution in vector or parallel processors. Now, rather than taking this expensive detour into and out of serial-land, we are asked simply to say what we mean in the first place, $c=a+b$.

The essence of parallel programming is *not* to force “into the time dimension” (i.e., to serialize) operations that naturally extend across a span of data, that is, “in the space dimension.” If it were not for 50-year-old collective habits, and the languages designed to support them, parallel programming would probably strike us as more natural than its serial counterpart.

Broadcasts and Dimensional Expansion: SSP vs. MMP

We have previously mentioned the Fortran 90 rule that a scalar variable is conformable with any shape array. Thus, we can implement a calculation such as

$$y_i = x_i + s, \quad i = 1, \dots, n \quad (22.1.1)$$

with code like

```
y=x+s
```

where we of course assume previous declarations like

```
REAL(SP) :: s
REAL(SP), DIMENSION(n) :: x,y
```

with *n* a compile-time constant or dummy argument. (Hereafter, we will omit the declarations in examples that are this simple.)

This seemingly simple construction actually hides an important underlying parallel capability, namely, that of *broadcast*. The sums in $y=x+s$ are done in parallel

on different CPUs, each CPU accessing different components of x and y . Yet, they all must access the same scalar value s . If the hardware has local memory for each CPU, the value of s must be replicated and transferred to each CPU's local memory. On the other hand, if the hardware implements a single, global memory space, it is vital to do something that mitigates the traffic jam potentially caused by all the CPUs trying to access the same memory location at the same time. (We will use the term "broadcast" to refer equally to both cases.) Although hidden from the user, Fortran 90's ability to do broadcasts is an essential feature of it as a parallel language.

Broadcasts can be more complicated than the above simple example. Consider, for example, the calculation

$$w_i = \sum_{j=1}^n |x_i + x_j|, \quad i = 1, \dots, n \quad (22.1.2)$$

Here, we are doing n^2 operations: For each of n values of i there is a sum over n values of j .

Serial code for this calculation might be

```
do i=1,n
  w(i)=0.
  do j=1,n
    w(i)=w(i)+abs(x(i)+x(j))
  end do
end do
```

The obvious immediate parallelization in Fortran 90 uses the `sum` intrinsic function to eliminate the inner do-loop. This would be a suitable amount of parallelization for a small-scale parallel machine, with a few processors:

```
do i=1,n
  w(i)=sum(abs(x(i)+x))
end do
```

Notice that the conformability rule implies that a new value of $x(i)$, a scalar, is being broadcast to all the processors involved in the `abs` and `sum`, with each iteration of the loop over i .

What about the outer do-loop? Do we need, or want, to eliminate it, too? That depends on the architecture of your computer, and on the tradeoff between time and memory in your problem (a common feature of all computing, no less so parallel computing). Here is an implementation that is free of all do-loops, in principle capable of being executed in a small number (independent of n) of parallel operations:

```
REAL(SP), DIMENSION(n,n) :: a
...
a = spread(x,dim=2,ncopies=n)+spread(x,dim=1,ncopies=n)
w = sum(abs(a),dim=1)
```

This is an example of what we call *dimensional expansion*, as implemented by the `spread` intrinsic. Although the above may strike you initially as quite a cryptic construction, it is easy to learn to read it. In the first assignment line, a matrix is constructed with all possible values of $x(i)+x(j)$. In the second assignment line, this matrix is collapsed back to a vector by applying the `sum` operation to the absolute value of its elements, across one of its dimensions.

More explicitly, the first line creates a matrix \mathbf{a} by adding two matrices each constructed via `spread`. In `spread`, the `dim` argument specifies which argument is *duplicated*, so that the first term *varies* across its first (row) dimension, and vice versa for the second term:

$$\begin{aligned} a_{ij} &= x_i + x_j \\ &= \begin{pmatrix} x_1 & x_1 & x_1 & \dots \\ x_2 & x_2 & x_2 & \dots \\ x_3 & x_3 & x_3 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} + \begin{pmatrix} x_1 & x_2 & x_3 & \dots \\ x_1 & x_2 & x_3 & \dots \\ x_1 & x_2 & x_3 & \dots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix} \end{aligned} \quad (22.1.3)$$

Since equation (22.1.2) above is symmetric in i and j , it doesn't really matter what value of `dim` we put in the `sum` construction, but the value `dim=1` corresponds to summing across the rows, that is, down each column of equation (22.1.3).

Be sure that you understand that the `spread` construction changed an $O(n)$ memory requirement into an $O(n^2)$ one! If your values of n are large, this is an impossible burden, and the previous implementation with a single do-loop remains the only practical one. On the other hand, if you are working on a massively parallel machine, whose number of processors is comparable to n^2 (or at least much larger than n), then the `spread` construction, and the underlying broadcast capability that it invokes, leads to a big win: All n^2 operations can be done in parallel. This distinction between small-scale parallel machines — which we will hereafter refer to as *SSP machines* — and massively multiprocessor machines — which we will refer to as *MMP machines* — is an important one. A main goal of parallelism is to saturate the available number of processors, and algorithms for doing so are often different in the SSP and MMP opposite limits. Dimensional expansion is one method for saturating processors in the MMP case.

Masks and “Index Loss”

An instructive extension of the above example is the following case of a product that omits one term (the diagonal one):

$$w_i = \prod_{\substack{j=1 \\ j \neq i}}^n (x_j - x_i), \quad i = 1, \dots, n \quad (22.1.4)$$

Formulas like equation (22.1.4) frequently occur in the context of interpolation, where all the x_i 's are known to be distinct, so let us for the moment assume that this is the case.

Serial code for equation (22.1.4) could be

```
do i=1,n
  w(i)=1.0_sp
  do j=1,n
    if (j /= i) w(i)=w(i)*(x(j)-x(i))
  end do
end do
```

Parallel code for SSP machines, or for large enough n on MMP machines, could be

```

do i=1,n
  w(i)=product( x-x(i), mask=(x/=x(i)) )
end do

```

Here, the `mask` argument in the `product` intrinsic function causes the diagonal term to be omitted from the product, as we desire. There are some features of this code, however, that bear commenting on.

First, notice that, according to the rules of conformability, the expression $x \neq x(i)$ broadcasts the scalar $x(i)$ and generates a logical array of length n , suitable for use as a `mask` in the `product` intrinsic. It is quite common in Fortran 90 to generate masks “on the fly” in this way, particularly if the mask is to be used only once.

Second, notice that the j index has disappeared completely. It is now implicit in the two occurrences of x (equivalent to $x(1:n)$) on the right-hand side. With the disappearance of the j index, we also lose the ability to do the test on i and j , but must use, in essence, $x(i)$ and $x(j)$ instead! That is a very general feature in Fortran 90: when an operation is done in parallel across an array, there is *no associated index* available within the operation. This “index loss,” as we will see in later discussion, can sometimes be quite an annoyance.

A language construction present in CM [Connection Machine] Fortran, the so-called `forall`, which would have allowed access to an associated index in many cases, was eliminated from Fortran 90 by the X3J3 committee, in a controversial decision. Such a construction will come into the language in Fortran 95.

What about code for an MMP machine, where we are willing to use dimensional expansion to achieve greater parallelism? Here, we can write,

```

a = spread(x,dim=2,ncopies=n)-spread(x,dim=1,ncopies=n)
w = product(a,dim=1,mask=(a/=0.))

```

This time it does matter that the value of `dim` in the `product` intrinsic is 1 rather than 2. If you write out the analog of equation (22.1.3) for the present example, you’ll see that the above fragment is the right way around. The problem of index loss is still with us: we have to construct a mask from the array `a`, not from its indices, *both* of which are now lost to us!

In most cases, there are workarounds (more, or less, awkward as they may be) for the problem of index loss. In the worst cases, which are quite rare, you have to create objects to hold, and thus bring back into play, the lost indices. For example,

```

INTEGER(I4B), DIMENSION(n) :: jj
...
jj = (/ (i,i=1,n) /)
do i=1,n
  w(i)=product( x-x(i), mask=(jj/=i) )
end do

```

Now the array `jj` is filled with the “lost” j index, so that it is available for use in the mask. A similar technique, involving spreads of `jj`, can be used in the above MMP code fragment, which used dimensional expansion. (Fortran 95’s `forall` construction will make index loss much less of a problem. See §21.6.)

Incidentally, the above Fortran 90 construction, $(/ (i,i=1,n) /)$, is called an *array constructor with implied do list*. For reasons to be explained in §22.2, we almost never use this construction, in most cases substituting a Numerical Recipes utility function for generating arithmetical progressions, which we call `arth`.

Interprocessor Communication Costs

It is both a blessing and a curse that Fortran 90 completely hides from the user the underlying machinery of interprocessor communication, that is, the way that data values computed by (or stored locally near) one CPU make their way to a different CPU that might need them next. The blessing is that, by and large, the Fortran 90 programmer need not be concerned with how this machinery works. If you write

$$a(1:10,1:10) = b(1:10,1:10) + c(10:1:-1,10:1:-1)$$

the required upside-down-and-backwards values of the array *c* are just *there*, no matter that a great deal of routing and switching may have taken place. An ancillary blessing is that this book, unlike so many other (more highly technical) books on parallel programming (see references below) need not be filled with complex and subtle discussions of CPU connectivity, topology, routing algorithms, and so on.

The curse is, just as you might expect, that the Fortran 90 programmer can't control the interprocessor communication, even when it is desirable to do so. A few regular communication patterns are "known" to the compiler through Fortran 90 intrinsic functions, for example *b=transpose(a)*. These, presumably, are done in an optimal way. However, many other regular patterns of communication, which might also allow highly optimized implementations, don't have corresponding intrinsic functions. (An obvious example is the "butterfly" pattern of communication that occurs in fast Fourier transforms.) These, if coded in Fortran 90 by using general vector subscripts (e.g., *barr=arr(iarr)* or *barr(jarr)=arr*, where *iarr* and *jarr* are integer arrays), lose all possibility of being optimized. The compiler can't distinguish a communication step with regular structure from one with general structure, so it must assume the worst case, potentially resulting in very slow execution.

About the only thing a Fortran 90 programmer can do is to start with a general awareness of the kind of apparently parallel constructions that *might* be quite slow on his/her parallel machine, and then to refine that awareness by actual experience and experiment. Here is our list of constructions most likely to cause interprocessor communication bottlenecks:

- vector subscripts, like *barr=arr(iarr)* or *barr(jarr)=arr* (that is, general gather/scatter operations)
- the pack and unpack intrinsic functions
- mixing positive strides and negative strides in a single expression (as in the above *b(1:10,1:10)+c(10:1:-1,10:1:-1)*)
- the reshape intrinsic when used with the order argument
- possibly, the cshift and eoshift extrinsics, especially for nonsmall values of the shift.

On the other hand, the fact is that these constructions *are* parallel, and *are* there for you to use. If the alternative to using them is strictly serial code, you should almost always give them a try.

Linear Algebra

You should be alert for opportunities to use combinations of the *matmul*, *spread*, and *dot_product* intrinsics to perform complicated linear algebra calculations. One useful intrinsic that is not provided in Fortran 90 is the *outer product*

of two vectors,

$$c_{ij} = a_i b_j \quad (22.1.5)$$

We already know how to implement this (cf. equation 22.1.3):

```
c = spread(a,dim=2,ncopies=size(b))*spread(b,dim=1,ncopies=size(a))
```

In fact, this operation occurs frequently enough to justify making it a utility function, `outerprod`, which we will do in Chapter 23. There we also define other “outer” operations between vectors, where the multiplication in the outer product is replaced by another binary operation, such as addition or division.

Here is an example of using these various functions: Many linear algebra routines require that a submatrix be updated according to a formula like

$$a_{jk} = a_{jk} + b_i a_{ji} \sum_{p=i}^m a_{pi} a_{pk}, \quad j = i, \dots, m, \quad k = l, \dots, n \quad (22.1.6)$$

where i, m, l , and n are fixed values. Using an array slice like `a(:,i)` to turn a_{pi} into a vector indexed by p , we can code the sum with a `matmul`, yielding a vector indexed by k :

```
temp(1:n)=b(i)*matmul(a(i:m,i),a(i:m,1:n))
```

Here we have also included the multiplication by b_i , a scalar for fixed i . The vector `temp`, along with the vector $a_{ji} = a(:,i)$, is then turned into a matrix by the `outerprod` utility and used to increment a_{jk} :

```
a(i:m,1:n)=a(i:m,1:n)+outerprod(a(i:m,i),temp(1:n))
```

Sometimes the update formula is similar to (22.1.6), but with a slight permutation of the indices. Such cases can be coded as above if you are careful about the order of the quantities in the `matmul` and the `outerprod`.

22.2 Linear Recurrence and Related Calculations

We have already seen that Fortran 90's *array constructor with implied do list* can be used to generate simple series of integers, like `(/ (i, i=1, n) /)`. Slightly more generally, one might want to generate an arithmetic progression, by the formula

$$v_j = b + (j - 1)a, \quad j = 1, \dots, n \quad (22.2.1)$$

This is readily coded as

```
v(1:n) = (/ (b+(j-1)*a, j=1,n) /)
```

Although it is concise, and valid, *we don't like this coding*. The reason is that it violates the fundamental rule of “thinking parallel”: it turns a parallel operation across a data vector into a serial do-loop over the components of that vector. Yes, we know that the compiler might be smart enough to generate parallel code for implied do lists; but it also might *not* be smart enough, here or in more complicated examples.

Equation (22.2.1) is also the simplest example of a *linear recurrence relation*. It can be rewritten as

$$v_1 = b, \quad v_j = v_{j-1} + a, \quad j = 2, \dots, n \quad (22.2.2)$$

In this form (assuming that, in more complicated cases, one doesn't know an explicit solution like equation 22.2.1) one can't write an explicit array constructor. Code like

```
v(1) = b
v(2:n) = (/ (v(j-1)+a, j=2,n) /) ! wrong
```

is legal Fortran 90 syntax, but illegal semantics; it does *not* do the desired recurrence! (The rules of Fortran 90 require that all the components of *v* on the right-hand side be evaluated before any of the components on the left-hand side are set.) Yet, as we shall see, techniques for accomplishing the evaluation in parallel are available.

With this as our starting point, we now survey some particular tricks of the (parallel) trade.

Subvector Scaling: Arithmetic and Geometric Progressions

For explicit arithmetic progressions like equation (22.2.1), the simplest parallel technique is *subvector scaling* [1]. The idea is to work your way through the desired vector in larger and larger parallel chunks:

$$\begin{aligned} v_1 &= b \\ v_2 &= b + a \\ v_{3\dots 4} &= v_{1\dots 2} + 2a \\ v_{5\dots 8} &= v_{1\dots 4} + 4a \\ v_{9\dots 16} &= v_{1\dots 8} + 8a \end{aligned} \tag{22.2.3}$$

And so on, until you reach the length of your vector. (The last step will not necessarily go all the way to the next power of 2, therefore.) The powers of 2, times a , can of course be obtained by successive doublings, rather than the explicit multiplications shown above.

You can see that subvector scaling requires about $\log_2 n$ parallel steps to process a vector of length n . Equally important for serial machines, or SSP machines, the scalar operation count for subvector scaling is no worse than entirely serial code: each new component v_i is produced by a single addition.

If addition is replaced by multiplication, the identical algorithm will produce geometric progressions, instead of arithmetic progressions. In Chapter 23, we will use subvector scaling to implement our utility functions `arth` and `geop` for these two progressions. (You can then call one of these functions instead of recoding equation 22.2.3 every time you need it.)

Vector Reduction: Evaluation of Polynomials

Logically related to subvector scaling is the case where a calculation can be parallelized across a vector that *shrinks* by a factor of 2 in each iteration, until a desired *scalar* result is reached. A good example of this is the parallel evaluation of a polynomial [2]

$$P(x) = \sum_{j=0}^N c_j x^j \tag{22.2.4}$$

For clarity we take the special case of $N = 5$. Start with the vector of coefficients (imagining appended zeros, as shown):

$$c_0, \quad c_1, \quad c_2, \quad c_3, \quad c_4, \quad c_5, \quad 0, \quad \dots$$

Now, add the elements by pairs, multiplying the second of each pair by x :

$$c_0 + c_1x, \quad c_2 + c_3x, \quad c_4 + c_5x, \quad 0, \quad \dots$$

Now, the same operation, but with the multiplier x^2 :

$$(c_0 + c_1x) + (c_2 + c_3x)x^2, \quad (c_4 + c_5x) + (0)x^2, \quad 0, \quad \dots$$

And a final time, with multiplier x^4 :

$$[(c_0 + c_1x) + (c_2 + c_3x)x^2] + [(c_4 + c_5x) + (0)x^2]x^4, \quad 0, \quad \dots$$

We are left with a vector of (active) length 1, whose value is the desired polynomial evaluation. (You can see that the zeros are just a bookkeeping device for taking account of the case where the active subvector has odd length.) The key point is that the combining by pairs is a parallel operation at each stage.

As in subvector scaling, there are about $\log_2 n$ parallel stages. Also as in subvector scaling, our total operations count is only negligibly different from purely scalar code: We do one add and one multiply for each original coefficient c_j . The only extra operations are $\log_2 n$ successive squarings of x ; but this comes with the extra benefit of better roundoff properties than the standard scalar coding. In Chapter 23 we use vector reduction to implement our utility function `poly` for polynomial evaluation.

Recursive Doubling: Linear Recurrence Relations

Please don't confuse our use of the word "recurrence" (as in "recurrence relation," "linear recurrence," or equation 22.2.2) with the words "recursion" and "recursive," which both refer to the idea of a subroutine calling itself to obtain an efficient or concise algorithm. There are ample grounds for confusion, because recursive algorithms are in fact a good way of obtaining parallel solutions to linear recurrence relations, as we shall now see!

Consider the general first order linear recurrence relation

$$u_j = a_j + b_{j-1}u_{j-1}, \quad j = 2, 3, \dots, n \quad (22.2.5)$$

with initial value $u_1 = a_1$. On a serial machine, we evaluate such a recurrence with a simple do-loop. To parallelize the recurrence, we can employ the powerful general strategy of *recursive doubling*. Write down equation (22.2.5) for $2j$ and for $2j - 1$:

$$u_{2j} = a_{2j} + b_{2j-1}u_{2j-1} \quad (22.2.6)$$

$$u_{2j-1} = a_{2j-1} + b_{2j-2}u_{2j-2} \quad (22.2.7)$$

Substitute equation (22.2.7) in equation (22.2.6) to eliminate u_{2j-1} and get

$$u_{2j} = (a_{2j} + a_{2j-1}b_{2j-1}) + (b_{2j-2}b_{2j-1})u_{2j-2} \quad (22.2.8)$$

This is a new recurrence of the same form as (22.2.5) but over only the even u_j , and hence involving only $n/2$ terms. Clearly we can continue this process recursively, halving the number of terms in the recurrence at each stage, until we are left with a recurrence of length 1 or 2 that we can do explicitly. Each time we finish a subpart of the recursion, we fill in the odd terms in the recurrence, using equation (22.2.7). In practice, it's even easier than it sounds. Turn to Chapter B5 to see a straightforward implementation of this algorithm as the recipe `recur1`.

On a machine with more processors than n , all the arithmetic at each stage of the recursion can be done simultaneously. Since there are of order $\log n$ stages in the

recursion, the execution time is $O(\log n)$. The total number of operations carried out is of order $n + n/2 + n/4 + \dots = O(n)$, the same as for the obvious serial do-loop.

In the utility routines of Chapter 23, we will use recursive doubling to implement the routines `poly_term`, `cumsum`, and `cumprod`. We *could* use recursive doubling to implement parallel versions of `arth` and `geop` (arithmetic and geometric progressions), and `zroots_unity` (complex n th roots of unity), but these can be done slightly more efficiently by subvector scaling, as discussed above.

Cyclic Reduction: Linear Recurrence Relations

There is a variant of recursive doubling, called *cyclic reduction*, that can be implemented with a straightforward iteration loop, instead of a recursive procedure call. [3] Here we start by writing down the recurrence (22.2.5) for *all* adjacent terms u_j and u_{j-1} (not just the even ones, as before). Eliminating u_{j-1} , just as in equation (22.2.8), gives

$$u_j = (a_j + a_{j-1}b_{j-1}) + (b_{j-2}b_{j-1})u_{j-2} \quad (22.2.9)$$

which is a first order recurrence with new coefficients a'_j and b'_j . Repeating this process gives successive formulas for u_j in terms of u_{j-2} , u_{j-4} , u_{j-8}, \dots . The procedure terminates when we reach u_{j-n} (for n a power of 2), which is zero for all j . Thus the last step gives u_j equal to the last set of a'_j 's.

Here is a code fragment that implements cyclic reduction by direct iteration. The quantities a'_j are stored in the variable `recur1`.

```

recur1=a
bb=b
j=1
do
    if (j >= n) exit
    recur1(j+1:n)=recur1(j+1:n)+bb(j:n-1)*recur1(1:n-j)
    bb(2*j:n-1)=bb(2*j:n-1)*bb(j:n-j-1)
    j=2*j
enddo

```

In cyclic reduction the length of the vector u_j that is updated at each stage does *not* decrease by a factor of 2 at each stage, but rather only decreases from $\sim n$ to $\sim n/2$ during all $\log_2 n$ stages. Thus the total number of operations carried out is $O(n \log n)$, as opposed to $O(n)$ for recursive doubling. For a serial machine or SSP machine, therefore, cyclic reduction is rarely superior to recursive doubling when the latter can be used. For an MMP machine, however, the issue is less clear cut, because the pattern of communication in cyclic reduction is quite different (and, for some parallel architectures, possibly more favorable) than that of recursive doubling.

Second Order Recurrence Relations

Consider the second order recurrence relation

$$y_j = a_j + b_{j-2}y_{j-1} + c_{j-2}y_{j-2}, \quad j = 3, 4, \dots, n \quad (22.2.10)$$

with initial values

$$y_1 = a_1, \quad y_2 = a_2 \quad (22.2.11)$$

Our labeling of subscripts is designed to make it easy to enter the coefficients in a computer program: You need to supply a_1, \dots, a_n , b_1, \dots, b_{n-2} , and c_1, \dots, c_{n-2} . Rewrite the recurrence relation in the form ([3])

$$\begin{pmatrix} y_j \\ y_{j+1} \end{pmatrix} = \begin{pmatrix} 0 \\ a_{j+1} \end{pmatrix} + \begin{pmatrix} 0 & 1 \\ c_{j-1} & b_{j-1} \end{pmatrix} \begin{pmatrix} y_{j-1} \\ y_j \end{pmatrix}, \quad j = 2, \dots, n-1 \quad (22.2.12)$$

that is,

$$\mathbf{u}_j = \mathbf{a}_j + \mathbf{b}_{j-1} \cdot \mathbf{u}_{j-1}, \quad j = 2, \dots, n-1 \quad (22.2.13)$$

where

$$\mathbf{u}_j = \begin{pmatrix} y_j \\ y_{j+1} \end{pmatrix}, \quad \mathbf{a}_j = \begin{pmatrix} 0 \\ a_{j+1} \end{pmatrix}, \quad \mathbf{b}_{j-1} = \begin{pmatrix} 0 & 1 \\ c_{j-1} & b_{j-1} \end{pmatrix}, \quad j = 2, \dots, n-1 \quad (22.2.14)$$

and

$$\mathbf{u}_1 = \mathbf{a}_1 = \begin{pmatrix} y_1 \\ y_2 \end{pmatrix} = \begin{pmatrix} a_1 \\ a_2 \end{pmatrix} \quad (22.2.15)$$

This is a first order recurrence relation for the vectors \mathbf{u}_j , and can be solved by the algorithm described above (and implemented in the recipe `recur1`). The only difference is that the multiplications are matrix multiplications with the 2×2 matrices \mathbf{b}_j . After the first recursive call, the zeros in \mathbf{a} and \mathbf{b} are lost, so we have to write the routine for general two-dimensional vectors and matrices.

Note that this algorithm does not avoid the potential instability problems associated with second order recurrences that are discussed in §5.5 of Volume 1. Also note that the algorithm generalizes in the obvious way to higher-order recurrences: An n th order recurrence can be written as a first order recurrence involving n -dimensional vectors and matrices.

Parallel Solution of Tridiagonal Systems

Closely related to recurrence relations, recursive doubling, and cyclic reduction is the parallel solution of tridiagonal systems. Since Fortran 90 vectors “know their own size,” it is most logical to number the components of both the sub- and super-diagonals of the tridiagonal matrix from 1 to $N - 1$. Thus equation (2.4.1), here written in the special case of $N = 7$, becomes (blank elements denoting zero),

$$\left[\begin{array}{ccc} b_1 & c_1 & & & & & \\ a_1 & b_2 & c_2 & & & & \\ & a_2 & b_3 & c_3 & & & \\ & & a_3 & b_4 & c_4 & & \\ & & & a_4 & b_5 & c_5 & \\ & & & & a_5 & b_6 & c_6 \\ & & & & & a_6 & b_7 \end{array} \right] \cdot \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ u_5 \\ u_6 \\ u_7 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_2 \\ r_3 \\ r_4 \\ r_5 \\ r_6 \\ r_7 \end{bmatrix} \quad (22.2.16)$$

The basic idea for solving equation (22.2.16) on a parallel computer is to partition the problem into even and odd elements, recurse to solve the former, and

then solve the latter in parallel. Specifically, we first rewrite (22.2.16), by permuting its rows and columns, as

$$\begin{bmatrix} b_1 & & c_1 & & \\ & b_3 & & a_2 & c_3 \\ & & b_5 & & a_4 & c_5 \\ & & & b_7 & & a_6 \\ a_1 & c_2 & & b_2 & & \\ a_3 & c_4 & & b_4 & & \\ a_5 & c_6 & & b_6 & & \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_3 \\ u_5 \\ u_7 \\ u_2 \\ u_4 \\ u_6 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_3 \\ r_5 \\ r_7 \\ r_2 \\ r_4 \\ r_6 \end{bmatrix} \quad (22.2.17)$$

Now observe that, by row operations that subtract multiples of the first four rows from each of the last three rows, we can eliminate all nonzero elements in the lower-left quadrant. The price we pay is bringing some new elements into the lower-right quadrant, whose nonzero elements we now call x 's, y 's, and z 's. We call the modified right-hand sides q . The transformed problem is now

$$\begin{bmatrix} b_1 & & c_1 & & \\ & b_3 & & a_2 & c_3 \\ & & b_5 & & a_4 & c_5 \\ & & & b_7 & & a_6 \\ & & & & y_1 & z_1 \\ & & & & x_1 & y_2 & z_2 \\ & & & & x_2 & y_3 & \end{bmatrix} \cdot \begin{bmatrix} u_1 \\ u_3 \\ u_5 \\ u_7 \\ u_2 \\ u_4 \\ u_6 \end{bmatrix} = \begin{bmatrix} r_1 \\ r_3 \\ r_5 \\ r_7 \\ q_1 \\ q_2 \\ q_3 \end{bmatrix} \quad (22.2.18)$$

Notice that the last three rows form a new, smaller, tridiagonal problem, which we can solve simply by recursing! Once its solution is known, the first four rows can be solved by a simple, parallelizable, substitution. This algorithm is implemented in `tridag` in Chapter B2.

The above method is essentially cyclic reduction, but in the case of the tridiagonal problem, it does not “unwind” into a simple iteration; on the contrary, a recursive subroutine is required. For discussion of this and related methods for parallelizing tridiagonal systems, and references to the literature, see Hockney and Jesshope [3].

Recursive doubling can also be used to solve tridiagonal systems, the method requiring the parallel solution (as above) of both a first order recurrence and a second order recurrence [3,4]. For tridiagonal systems, however, cyclic reduction is usually more efficient than recursive doubling.

22.3 Parallel Synthetic Division and Related Algorithms

There are several techniques for parallelization that relate to synthetic division but that can also find application in wider contexts, as we shall see.

Cumulants of a Polynomial

Suppose we have a polynomial

$$P(x) = \sum_{j=0}^N c_j x^{N-j} \quad (22.3.1)$$

(Note that, here, the c_j 's are indexed from highest degree to lowest, the reverse of the usual convention.) Then we can define the *cumulants* of the polynomial to be partial sums that occur in the polynomial's usual, serial evaluation,

$$\begin{aligned} P_0 &= c_0 \\ P_1 &= c_0 x + c_1 \\ &\dots \\ P_N &= c_0 x^N + \dots + c_N = P(x) \end{aligned} \quad (22.3.2)$$

Evidently, the cumulants satisfy a simple, linear first order recurrence relation,

$$P_0 = c_0, \quad P_j = c_j + x P_{j-1}, \quad j = 2, \dots, N \quad (22.3.3)$$

This is slightly simpler than the general first order recurrence, because the value of x does not depend on j . We already know, from §22.2's discussion of recursive doubling, how to parallelize equation (22.3.3) via a recursive subroutine. In Chapter 23, the utility routine `poly_term` will implement just such a procedure. An example of a routine that calls `poly_term` to evaluate a recurrence equivalent to equation (22.3.3) is `eulsum` in Chapter B5.

Notice that while we could use equation (22.3.3), parallelized by recursive doubling, simply to evaluate the polynomial $P(x) = P_N$, this is likely somewhat slower than the alternative technique of vector reduction, also discussed in §22.2, and implemented in the utility function `poly`. Equation (22.3.3) should be saved for cases where the rest of the P_j 's (not just P_N) can be put to good use.

Synthetic Division by a Monomial

We now show that evaluation of the cumulants of a polynomial is equivalent to synthetic division of the polynomial by a monomial, also called *deflation* (see §9.5 in Volume 1). To review briefly, and by example, here is a standard tableau from high school algebra for the (long) division of a polynomial $2x^3 - 7x^2 + x + 3$ by the monomial factor $x - 3$.

$$\begin{array}{r}
 \begin{array}{c} 2x^2 - x - 2 \\ x - 3 \end{array} \overline{) 2x^3 - 7x^2 + x + 3} \\
 \begin{array}{r} 2x^3 - 6x^2 \\ -x^2 + x \\ -x^2 + 3x \\ -2x + 3 \\ -2x + 6 \\ -3 \text{ (remainder)} \end{array}
 \end{array} \tag{22.3.4}$$

Now, here is the same calculation written as a *synthetic division*, really the same procedure as tableau (22.3.4), but with unnecessary notational baggage omitted (and also a changed sign for the monomial's constant, so that subtractions become additions):

$$\begin{array}{r}
 \begin{array}{ccc} 6 & -3 & -6 \\ 3 & | & \end{array} \\
 \begin{array}{cccc} 2 & -7 & +1 & +3 \\ 2 & -1 & -2 & -3 \end{array}
 \end{array} \tag{22.3.5}$$

If we substitute symbols for the above quantities with the correspondence

$$\begin{array}{r}
 \begin{array}{cccc} c_0 & c_1 & c_2 & c_3 \\ P_0 & P_1 & P_2 & P_3 \end{array} \\
 x \mid
 \end{array} \tag{22.3.6}$$

then it is immediately clear that the P_j 's in equation (22.3.6) are simply the P_j 's of equation (22.3.3); the calculation is thus parallelizable by recursive doubling. In this context, the utility routine `poly-term` is used by the routine `zroots` in Chapter B9.

Repeated Synthetic Division

It is well known from high-school algebra that repeated synthetic division of a polynomial yields, as the remainders that occur, first the value of the polynomial, next the value of its first derivative, and then (up to multiplication by the factorial of an integer) the values of higher derivatives.

If you want to parallelize the calculation of the value of a polynomial and one or two of its derivatives, it is not unreasonable to evaluate equation (22.3.3), parallelized by recursive doubling, two or three times. Our routine `ddpoly` in Chapter B5 is meant for such use, and it does just this, as does the routine `laguer` in Chapter B9.

There are other cases, however, for which you want to perform repeated synthetic division and “go all the way,” until only a constant remains. For example, this is the preferred way of “shifting a polynomial,” that is, evaluating the coefficients of a polynomial in a variable y that differs from the original variable x by an additive constant. (The recipe `pcshft` has this as its assigned task.) By way of example, consider the polynomial $3x^3 + x^2 + 4x + 7$, and let us perform repeated synthetic division by a general monomial $x - a$. The conventional calculation then proceeds according to the following tableau, reading it in conventional lexical order (left-to-right and top-to-bottom):

$$\begin{array}{ccccccc}
 3 & & 1 & & 4 & & 7 \\
 \downarrow & & \downarrow & & \downarrow & & \downarrow \\
 3 & \xrightarrow{a} & 3a+1 & \xrightarrow{a} & 3a^2+a+4 & \xrightarrow{a} & 3a^3+a^2+4a+7 \\
 \downarrow & & \downarrow & & \downarrow & & \downarrow \\
 3 & \xrightarrow{a} & 6a+1 & \xrightarrow{a} & 9a^2+2a+4 & & \\
 \downarrow & & \downarrow & & & & \\
 3 & \xrightarrow{a} & 9a+1 & & & & \\
 \downarrow & & & & & & \\
 3 & & & & & & \\
 \end{array} \tag{22.3.7}$$

Here, each row (after the first) shows a synthetic division or, equivalently, evaluation of the cumulants of the polynomial whose coefficients are the preceding row. The results at the right edge of the rows are the values of the polynomial and (up to integer factorials) its three nonzero derivatives, or (equivalently, without factorials) coefficients of the shifted polynomial.

We could parallelize the calculation of each row of tableau (22.3.7) by recursive doubling. That is a lot of recursion, which incurs a nonnegligible overhead. A much better way of doing the calculation is to deform tableau (22.3.7) into the following equivalent tableau,

$$\begin{array}{ccccccc}
 3 \longrightarrow & & 3 & & & & \\
 & a \downarrow & & \searrow & & & \\
 1 \longrightarrow & 3a+1 & & 3 & & & \\
 & a \downarrow & \searrow & a \downarrow & \searrow & & \\
 4 \longrightarrow & 3a^2+a+4 & & 6a+1 & & 3 & \\
 & a \downarrow & \searrow & a \downarrow & \searrow & a \downarrow & \searrow \\
 7 \longrightarrow & 3a^3+a^2+4a+7 & & 9a^2+2a+4 & & 9a+1 & 3
 \end{array} \tag{22.3.8}$$

Now each row explicitly depends on only the previous row (and the given first column), so the rows can be calculated in turn by an explicit parallel expression, with no recursive calls needed. An example of coding (22.3.8) in Fortran 90 can be found in the routine `pcshft` in Chapter B5. (It is also possible to eliminate most of the multiplications in (22.3.8), at the expense of a much smaller number of divisions. We have not done this because of the necessity for then treating all possible divisions by zero as special cases. See [1] for details and references.)

Actually, the deformation of (22.3.7) into (22.3.8) is the same trick as was used in Volume 1, p. 167, for evaluating a polynomial and its derivative simultaneously, also generalized in the Fortran 77 implementation of the routine `ddpoly` (Chapter 5). In the Fortran 90 implementation of `ddpoly` (Chapter B5) we *don't* use this trick, but instead use `poly_term`, because, there, we want to parallelize over the length of the polynomial, not over the number of desired derivatives.

Don't confuse the cases of *iterated* synthetic division, discussed here, with the simpler case of doing many simultaneous synthetic divisions. In the latter case, you can simply implement equation (22.3.3) serially, exactly as written, but with each operation being data-parallel across your problem set. (This case occurs in our routine `polcoe` in Chapter B3.)

Polynomial Coefficients from Roots

A parallel calculation algorithmically very similar to (22.3.7) or (22.3.8) occurs when we want to find the coefficients of a polynomial $P(x)$ from its roots r_1, \dots, r_N . For this, the tableau is

$$\begin{array}{c}
 r_1 \\
 \downarrow \\
 r_2 : \\
 \downarrow \\
 r_1 + r_2 \\
 \downarrow \\
 r_3 : \\
 \downarrow \\
 r_1 + r_2 + r_3 \quad r_1r_2 + r_3(r_1 + r_2) \quad r_1r_2r_3
 \end{array} \tag{22.3.9}$$

As before, the rows are computed consecutively, from top to bottom. Each row is computed via a single parallel expression. Note that values moving on vertical arrows are simply added in, while values moving on diagonal arrows are multiplied by a new root before adding. Examples of coding (22.3.9) in Fortran 90 can be found in the routines `vander` (Chapter B2) and `polcoe` (Chapter B3).

An equivalent deformation of (22.3.9) is

$$\begin{array}{c}
 r_1 \\
 \downarrow \\
 r_2 : \\
 \downarrow \\
 r_1r_2 \quad r_1 + r_2 \\
 \downarrow \quad \downarrow \\
 r_3 : \\
 \downarrow \\
 r_1r_2r_3 \quad r_1r_2 + r_3(r_1 + r_2) \quad r_1 + r_2 + r_3
 \end{array} \tag{22.3.10}$$

Here the diagonal arrows are simple additions, while the vertical arrows represent multiplication by a root value. Note that the coefficient answers in (22.3.10) come out in the opposite order from (22.3.9). An example of coding (22.3.10) in Fortran 90 can be found in the routine `fixrts` in Chapter B13.

22.4 Fast Fourier Transforms

Fast Fourier transforms are beloved by computer scientists, especially those who are interested in parallel algorithms, because the FFT's hierarchical structure generates a complicated, but analyzable, set of requirements for interprocessor communication on MMPs. Thus, almost all books on parallel algorithms (e.g., [1–3]) have a chapter on FFTs.

Unfortunately, the resulting algorithms are highly specific to particular parallel architectures, and therefore of little use to us in writing general purpose code in an architecture-independent parallel language like Fortran 90.

Luckily there is a good alternative that covers almost all cases of both serial and parallel machines. If, for a one-dimensional FFT of size N , one is satisfied with parallelism of order \sqrt{N} , then there is a good, general way of achieving a parallel FFT with *quite minimal* interprocessor communication; and the communication required is simply the matrix transpose operation, which Fortran 90 implements as an intrinsic. That is the approach that we discuss in this section, and implement in Chapter B12.

For a machine with M processors, this approach will saturate the processors (the desirable condition where none are idle) when the size of a one-dimensional Fourier transform, N , is large enough: $N > M^2$. Smaller N 's will not achieve maximum parallelism. But such N 's are in fact so small for one-dimensional problems that they are unlikely to be the rate-determining step in scientific calculations. If they are, it is usually because you are doing many such transforms independently, and you should recover “outer parallelism” by doing them all at once.

For two or more dimensions, the adopted approach will saturate M processors when *each* dimension of the problem is larger than M .

Column- and Row-Parallel FFTs

The basic building block that we assume (and implement in Chapter B12) is a routine for simultaneously taking the FFT of each *row* of a two-dimensional matrix. The method is exactly that of Volume 1's four1 routine, but with array sections like `data(:,j)` replacing scalars like `data(j)`. Chapter B12's implementation of this is a routine called `fourrow`. If all the data for one column (that is, all the values `data(i,:)`, for some `i`) are local to a single processor, then the parallelism involves no interprocessor communication at all: The independent FFTs simply proceed, data parallel and in lockstep. This is architecture-independent parallelism with a vengeance.

We will also need to take the FFT of each *column* of a two-dimensional matrix. One way to do this is to take the transpose (a Fortran 90 intrinsic that hides a lot of interprocessor communication), then take the FFT of the rows using `fourrow`, then take the transpose again. An alternative method is to recode the `four1` routine with array sections in the other dimension (`data(j,:)`) replacing `four1`'s scalars (`data(j)`). This scheme, in Chapter B12, is a routine called `fourcol`. In this case, good parallelism will be achieved only if the values `data(:,i)`, for some `i`, are local to a single processor. Of course, Fortran 90 does not give the user direct control over how data are distributed over the machine; but extensions such as HPF are designed to give just such control.

On a serial machine, you might think that `fourrow` and `fourcol` should have identical timings (acting on a square matrix, say). The two routines do exactly the same operations, after all. Not so! On modern serial computers, `fourrow` and `fourcol` can have timings that differ by a factor of 2 or more, even when their detailed arithmetic is made identical (by giving to one a data array that is the transpose of the data array given to the other). This effect is due to the multilevel cache architecture of most computer memories, and the fact that serial Fortran always stores matrices by columns (first index changing most rapidly). On our workstations, `fourrow` is significantly faster than `fourcol`, and this is likely the generic behavior. However, we do not exclude the possibility that some machines, and some sizes of matrices, are the other way around.

One-Dimensional FFTs

Turn now to the problem of how to do a single, one-dimensional, FFT. We are given a complex array f of length N , an integer power of 2. The basic idea is to address the input array as if it were a two-dimensional array of size $m \times M$, where m and M are each integer powers of 2. Then the components of f can be addressed as

$$f(Jm + j), \quad 0 \leq j < m, \quad 0 \leq J < M \quad (22.4.1)$$

where the j index changes more rapidly, the J index more slowly, and parentheses denote Fortran-style subscripts.

Now, suppose we had some magical (parallel) method to compute the discrete Fourier transform

$$F(kM + K) \equiv \sum_{j,J} e^{2\pi i(kM+K)(Jm+j)/(Mm)} f(Jm + j), \\ 0 \leq k < m, \quad 0 \leq K < M \quad (22.4.2)$$

Then, you can see that the indices k and K would address the desired result (FFT of the original array), with K varying more rapidly.

Starting with equation (22.4.2) it is easy to verify the following identity,

$$F(kM + K) = \sum_j \left[e^{2\pi ijk/m} \left(e^{2\pi ijK/(Mm)} \left[\sum_J e^{2\pi iJK/M} f(Jm + j) \right] \right) \right] \quad (22.4.3)$$

But this, reading it from the innermost operation outward, is just the magical method that we need:

- Reshape the original array to $m \times M$ in Fortran normal order (storage by columns).
- FFT on the second (column) index for all values of the first (row) index, using the routine `fourrow`.
- Multiply each component by a phase factor $\exp[2\pi ijK/(Mm)]$.
- Transpose.

- Again FFT on the second (column) index for all values of the first (row) index, using the routine `fourrow`.
- Reshape the two-dimensional array back into one-dimensional output.

The above scheme uses `fourrow` exclusively, on the assumption that it is faster than its sibling `fourcol`. When that is the case (as we typically find), it is likely that the above method, implemented as `four1` in Chapter B12, is faster, even on scalar machines, than Volume 1's scalar version of `four1` (Chapter 12). The reason, as already mentioned, is that `fourrow`'s parallelism is taking better advantage of cache memory locality.

If `fourrow` is *not* faster than `fourcol` on your machine, then you should instead try the following alternative scheme, using `fourcol` only:

- Reshape the original array to $m \times M$ in Fortran normal order (storage by columns).
- Transpose.
- FFT on the first (row) index for all values of the second (column) index, using the routine `fourcol`.
- Multiply each component by a phase factor $\exp[2\pi ijK/(Mm)]$.
- Transpose.
- Again FFT on the first (row) index for all values of the second (column) index, using the routine `fourcol`.
- Transpose.
- Reshape the two-dimensional array back into one-dimensional output.

In Chapter B12, this scheme is implemented as `four1_alt`. You might wonder why `four1_alt` has three transpose operations, while `four1` had only one. Shouldn't there be a symmetry here? No. Fortran makes the arbitrary, but consistent, choice of storing two-dimensional arrays by columns, and this choice favors `four1` in terms of transposes. Luckily, at least on our serial workstations, `fourrow` (used by `four1`) is faster than `fourcol` (used by `four1_alt`), so it is a double win.

For further discussion and references on the ideas behind `four1` and `four1_alt` see [4], where these algorithms are called the four-step and six-step frameworks, respectively.

22.5 Missing Language Features

A few facilities that are fairly important to parallel programming are missing from the Fortran 90 language standard. On scalar machines this lack is not a

problem, since one can readily program the missing features by using do-loops. On parallel machines, both SSP machines and MMP machines, one must hope that hardware manufacturers provide library routines, callable from Fortran 90, that provide access to the necessary facilities, or use extensions of Fortran 90, such as High Performance Fortran (HPF).

Scatter-with-Combine Functions

Fortran 90 allows the use of *vector subscripts* for so-called *gather* and *scatter* operations. For example, with the setup

```
REAL(SP), DIMENSION(6) :: arr,barr,carr
INTEGER(I4B), DIMENSION(6) :: iarr,jarr
...
iarr = (/ 1,3,5,2,4,6 /)
jarr = (/ 3,2,3,2,1,1 /)
```

Fortran 90 allows both the *one-to-one* gather and the *one-to-many* gather,

```
barr=arr(iarr)
carr=arr(jarr)
```

It also allows the one-to-one scatter,

```
barr(iarr)=carr
```

where the elements of *carr* are “scattered” into *barr* under the direction of the vector subscript *iarr*.

Fortran 90 does *not* allow the *many-to-one* scatter

```
barr(jarr)=carr           ! illegal for this jarr
```

because the repeated values in *jarr* try to assign different components of *carr* to the same location in *barr*. The result would not be deterministic.

Sometimes, however, one would in fact like a many-to-one construction, where the colliding elements get combined by a (commutative and associative) operation, like *+* or ***, or *max()*. These so-called *scatter-with-combine* functions are readily implemented on serial machines by a do-loop, for example,

```
barr=0.
do j=1,size(carr)
    barr(jarr(j))=barr(jarr(j))+carr(j)
end do
```

Fortran 90 unfortunately provides no means for effecting scatter-with-combine functions in parallel. Luckily, almost all parallel machines do provide such a facility as a library program, as does HPF, where the above facility is called **SUM_SCATTER**. In Chapter 23 we will define utility routines **scatter_add** and **scatter_max** for scatter-with-combine functionalities, but the implementation given in Fortran 90 will be strictly serial, with a do-loop.

Skew Sections

Fortran 90 provides no good, parallel way to access the diagonal elements of a matrix, either to read them or to set them. Do-loops will obviously serve this need on serial machines. In principle, a construction like the following bizarre fragment could also be utilized,

```
REAL(SP), DIMENSION(n,n) :: mat
REAL(SP), DIMENSION(n*n) :: arr
REAL(SP), DIMENSION(n) :: diag
...
arr = reshape(mat,shape(arr))
diag = arr(1:n*n:n+1)
```

which extracts every $(n + 1)$ st element from a one-dimensional array derived by reshaping the input matrix. However, it is unlikely that any foreseeable parallel compiler will implement the above fragment without a prohibitive amount of unnecessary data movement; and code like the above is also exceedingly slow on all serial machines that we have tried.

In Chapter 23 we will define utility routines `get_diag`, `put_diag`, `diagadd`, `diagmult`, and `unit_matrix` to manipulate diagonal elements, but the implementation given in Fortran 90 will again be strictly serial, with do-loops.

Fortran 95 (see §21.6) will essentially fix Fortran 90's skew sections deficiency. For example, using its `forall` construction, the diagonal elements of an array can be accessed by a statement like

```
forall (j=1:20) diag(j) = arr(j,j)
```

SIMD vs. MIMD

Recall that we use “SIMD” (single-instruction, multiple data) and “data parallel” as interchangeable terms, and that “MIMD” (multiple-instruction, multiple data) is a more general programming model. (See §22.1.)

You should not be too quick to jump to the conclusion that Fortran 90’s data parallel or SIMD model is “bad,” and that MIMD features, absent in Fortran 90, are therefore “good.” On the contrary, Fortran 90’s basic data-parallel paradigm has a lot going for it. As we discussed in §22.1, most scientific problems naturally have a “data dimension” across which the time ordering of the calculation is irrelevant. Parallelism across this dimension, which is by nature most often SIMD, frees the mind to think clearly about the computational steps in an algorithm that actually need to be sequential. SIMD code has advantages of clarity and predictability that should not be taken lightly. The general MIMD model of “lots of different things all going on at the same time and communicating data with each other” is a programming and debugging nightmare.

Having said this, we must at the same time admit that a few MIMD features — most notably the ability to go through different logical branches for calculating different data elements in a data-parallel computation — are badly needed in certain programming situations. Fortran 90 is quite weak in this area.

Note that the `where...elsewhere...end where` construction is *not* a MIMD construction. Fortran 90 requires that the `where` clause be executed completely before the `elsewhere` is started. (This allows the results of any calculations in the former

clause to be available for use in the latter.) So, this construction cannot be used to allow two logical branches to be calculated in parallel.

Special functions, where one would like to calculate function values for an array of input quantities, are a particularly compelling example of the need for some MIMD access. Indeed, you will find that Chapter B6 contains a number of intricate, and in a few cases truly bizarre, workarounds, using allowed combinations of `merge`, `where`, and `CONTAINS` (the latter, for separating different logical branches into formally different subprograms).

Fortran 95's ELEMENTAL and PURE constructions, and to some extent also `forall` (whose body will be able to include PURE function calls), will go a long way towards providing exactly the kind of MIMD constructions that are most needed. Once Fortran 95 becomes available and widespread, you can expect to see a new version of this volume, with a much-improved Chapter B6.

Conversely, the number of routines outside of Chapter B6 that can be significantly improved by the use of MIMD features is relatively small; this illustrates the underlying viability of the basic data-parallel SIMD model, even in a future language version with useful MIMD features.

Chapter 23. Numerical Recipes Utility Functions for Fortran 90

23.0 *Introduction and Summary Listing*

This chapter describes and summarizes the Numerical Recipes utility routines that are used throughout the rest of this volume. A complete implementation of these routines in Fortran 90 is listed in Appendix C1.

Why do we need utility routines? Aren't there already enough of them built into the language as Fortran 90 intrinsics? The answers lie in this volume's dual purpose: to implement the Numerical Recipes routines in Fortran 90 code that runs efficiently on fast serial machines, *and* to implement them, wherever possible, with efficient parallel code for multiprocessor machines that will become increasingly common in the future. We have found three kinds of situations where additional utility routines seem desirable:

1. Fortran 90 is a big language, with many high-level constructs — single statements that actually result in a lot of computing. We like this; it gives the language the potential for expressing algorithms very readably, getting them “out of the mud” of microscopic coding. In coding the 350+ Recipes for this volume, we kept a systematic watch for bits of microscopic coding that were repeated in many routines, and that seemed to be at a lower level of coding than that aspired to by good Fortran 90 style. Once these bits were identified, we pulled them out and substituted calls to new utility routines. These are the utilities that arguably ought to be new language intrinsics, equally useful for serial and parallel machines. (A prime example is `swap`.)

2. Fortran 90 contains many highly parallelizable language constructions. But, as we have seen in §22.5, it is also missing a few important constructions. Most parallel machines will provide these missing elements as machine-coded library subroutines. Some of our utility routines are provided simply as a standard interface to these common, but nonstandard, functionalities. Note that it is the nature of these routines that our specific implementation, in Appendix C1, will be serial, and therefore inefficient on parallel machines. If you have a parallel machine, you will need to recode these; this often involves no more than substituting a one-line library function call for the body of our implementation. Utilities in this category will likely become unnecessary over time, either as machine-dependent libraries converge to standard interfaces, or as the utilities get added to future Fortran versions. (Indeed,

some routines in this category will be unnecessary in Fortran 95, once it is available; see §23.7.)

3. Some tasks should just be done differently in serial, versus parallel, implementation. Linear recurrence relations are a good example (§22.2). These are trivially coded with a do-loop on serial machines, but require a fairly elaborate recursive construction for good parallelization. Rather than provide separate serial and parallel versions of the Numerical Recipes, we have chosen to pull out of the Recipes, and into utility routines, some identifiable tasks of this kind. These are cases where some recoding of our implementation in Appendix C1 might result in improved performance on your particular hardware. Unfortunately, it is not so simple as providing a single “serial implementation” and another single “parallel implementation,” because even the seemingly simple word “serial” hides, at the hardware level, a variety of different degrees of pipelining, wide instructions, and so on. Appendix C1 therefore provides only a single implementation, although with some adjustable parameters that you can customize (by experiment) to maximize performance on your hardware.

The above three cases are not really completely distinct, and it is therefore not possible to assign any single utility routine to exactly one situation. Instead, we organize the rest of this chapter as follows: first, an alphabetical list, with short summary, of all the new utility routines; next, a series of short sections, grouped by functionality, that contain the detailed descriptions of the routines.

Alphabetical Listing

The following list gives an abbreviated mnemonic for the type, rank, and/or shape of the returned values (as in §21.4), the routine’s calling sequence (optional arguments shown in italics), and a brief, often incomplete, description. The complete description of the routine is given in the later section shown in square brackets.

For each entry, the number shown in parentheses is the approximate number of distinct Recipes in this book that make use of that particular utility function, and is thus a rough guide to that utility’s importance. (There may be multiple invocations of the utility in each such Recipe.) Where this number is small or zero, it is usually because the utility routine is a member of a related family of routines whose total usage was deemed significant enough to include, and we did not want users to have to “guess” which family members were instantiated.

```
call array_copy(src,dest,n_copied,n_not_copied)
    Copy one-dimensional array (whose size is not necessarily known).
    [23.1] (9)

[Arr]   arth(first,increment,n)
        Return an arithmetic progression as an array. [23.4] (55)

call assert(n1,n2,...,string)
    Exit with error message if any logical arguments are false. [23.3] (50)

[Int]   assert_eq(n1,n2,...,string)
        Exit with error message if all integer arguments are not equal; otherwise
        return common value. [23.3] (133)

[argTS] cumprod(arr,seed)
```

Cumulative products of one-dimensional array, with optional seed value. [23.4] (3)

[argTS] `cumsum(arr,seed)`

Cumulative sums of one-dimensional array, with optional seed value. [23.4] (9)

call `diagadd(mat,diag)`

Adds vector to diagonal of a matrix. [23.7] (4)

call `diagmult(mat,diag)`

Multiplies vector into diagonal of a matrix. [23.7] (2)

[Arr] `geop(first,factor,n)`

Return a geometrical progression as an array. [23.4] (7)

[Arr] `get_diag(mat)`

Gets diagonal of a matrix. [23.7] (2)

[Int] `ifirstloc(arr)`

Location of first true value in a logical array, returned as an integer. [23.2] (3)

[Int] `imaxloc(arr)`

Location of array maximum, returned as an integer. [23.2] (11)

[Int] `iminloc(arr)`

Location of array minimum, returned as an integer. [23.2] (8)

[Mat] `lower_triangle(j,k,extra)`

Returns a lower triangular logical mask. [23.7] (1)

call `nrerror(string)`

Exit with error message. [23.3] (96)

[Mat] `outerand(a,b)`

Returns the outer logical and of two vectors. [23.5] (1)

[Mat] `outerdiff(a,b)`

Returns the outer difference of two vectors. [23.5] (4)

[Mat] `outerdiv(a,b)`

Returns the outer quotient of two vectors. [23.5] (0)

[Mat] `outerprod(a,b)`

Returns the outer product of two vectors. [23.5] (14)

[Mat] `outersum(a,b)`

Returns the outer sum of two vectors. [23.5] (0)

[argTS] `poly(x,coeffs,mask)`

Evaluate a polynomial $P(x)$ for one or more values x , with optional mask. [23.4] (15)

[argTS] `poly_term(a,x)`

Returns partial cumulants of a polynomial, equivalent to synthetic

	division. [23.4] (4)
	call <code>put_diag(diag,mat)</code> Sets diagonal of a matrix. [23.7] (0)
[Ptr]	call <code>reallocate(p,n,m,...)</code> Reallocate pointer to new size, preserving its contents. [23.1] (5)
	call <code>scatter_add(dest,source,dest_index)</code> Scatter-adds source vector to specified components of destination vector. [23.6] (2)
	call <code>scatter_max(dest,source,dest_index)</code> Scatter-max source vector to specified components of destination vector. [23.6] (0)
	call <code>swap(a,b,<i>mask</i>)</code> Swap corresponding elements of a and b. [23.1] (24)
	call <code>unit_matrix(mat)</code> Sets matrix to be a unit matrix. [23.7] (6)
[Mat]	call <code>upper_triangle(j,k,<i>extra</i>)</code> Returns an upper triangular logical mask. [23.7] (4)
[Real]	call <code>vabs(v)</code> Length of a vector in L_2 norm. [23.8] (6)
[CArr]	call <code>zroots.Unity(n,nn)</code> Returns nn consecutive powers of the complex nth root of unity. [23.4] (4)

Comment on Relative Frequencies of Use

We find it interesting to compare our frequency of using the `nrutil` utility routines, with our most used language intrinsics (see §21.4). On this basis, the following routines are as useful to us as the *top 10* language intrinsics: `arth`, `assert`, `assert_eq`, `outerprod`, `poly`, and `swap`. We strongly recommend that the X3J3 standards committee, as well as individual compiler library implementors, consider the inclusion of new language intrinsics (or library routines) that subsume the capabilities of at least these routines. In the next tier of importance, we would put some further cumulative operations (`geop`, `cumsum`), some other “outer” operations on vectors (e.g., `outerdiff`), basic operations on the diagonals of matrices (`get_diag`, `put_diag`, `diag_add`), and some means of access to an array of unknown size (`array_copy`).

23.1 Routines That Move Data

To describe our utility routines, we introduce two items of Fortran 90 pseudocode: We use the symbol **T** to denote some type and rank declaration (including

scalar rank, i.e., zero); and when we append a colon to a type specification, as in `INTEGER(I4B)(:)`, for example, we denote an array of the given type.

The routines `swap`, `array_copy`, and `reallocate` simply move data around in useful ways.

* * *

swap (swaps corresponding elements)

User interface (or, “USE nrutil”):

```
SUBROUTINE swap(a,b,mask)
T, INTENT(INOUT) :: a,b
LOGICAL(LGT), INTENT(IN), OPTIONAL :: mask
END SUBROUTINE swap
```

Applicable types and ranks:

$\mathbf{T} \equiv$ any type, any rank

Types and ranks implemented (overloaded) in nrutil:

```
 $\mathbf{T} \equiv$  INTEGER(I4B), REAL(SP), REAL(SP)(:), REAL(DP),
      COMPLEX(SPC), COMPLEX(SPC)(:), COMPLEX(SPC)(:, :),
      COMPLEX(DPC), COMPLEX(DPC)(:), COMPLEX(DPC)(:, :)
```

Action:

Swaps the corresponding elements of `a` and `b`. If `mask` is present, performs the swap only where `mask` is true. (Following code is the unmasked case. For speed at run time, the masked case is implemented by overloading, not by testing for the optional argument.)

Reference implementation:

```
T :: dum
dum=a
a=b
b=dum
```

* * *

array_copy (copy one-dimensional array)

User interface (or, “USE nrutil”):

```
SUBROUTINE array_copy(src,dest,n_copied,n_not_copied)
T, INTENT(IN) :: src
T, INTENT(OUT) :: dest
INTEGER(I4B), INTENT(OUT) :: n_copied, n_not_copied
END SUBROUTINE array_copy
```

Applicable types and ranks:

$\mathbf{T} \equiv$ any type, rank 1

Types and ranks implemented (overloaded) in nrutil:

```
 $\mathbf{T} \equiv$  INTEGER(I4B)(:), REAL(SP)(:), REAL(DP)(:)
```

Action:

Copies to a destination array `dest` the one-dimensional array `src`, or as much of `src` as will fit in `dest`. Returns the number of components copied as `n_copied`, and the number of components not copied as `n_not_copied`.

The main use of this utility is where `src` is an expression that returns an array whose size is not known in advance, for example, the value returned by the `pack` intrinsic.

Reference implementation:

```
n_copied=min(size(src),size(dest))
n_not_copied=size(src)-n_copied
dest(1:n_copied)=src(1:n_copied)
```

★ ★ ★

realloc (reallocate a pointer, preserving contents)

User interface (or, “USE nrutil”):

```
FUNCTION realloc(p,n[,m,...])
T, POINTER :: p, realloc
INTEGER(I4B), INTENT(IN) :: n[,m,...]
END FUNCTION realloc
```

Applicable types and ranks:

$T \equiv$ any type, rank 1 or greater

Types and ranks implemented (overloaded) in nrutil:

$T \equiv$ INTEGER(I4B)(:), INTEGER(I4B)(:, :), REAL(SP)(:),
REAL(SP)(:, :), CHARACTER(1)(:)

Action:

Allocates storage for a new array with shape specified by the integer(s) n , m , ... (equal in number to the rank of pointer p). Then, copies the contents of p 's target (or as much as will fit) into the new storage. Then, deallocates p and returns a pointer to the new storage.

The typical use is $p=realloc(p,n[,m,...])$, which has the effect of changing the allocated size of p while preserving the contents.

The reference implementation, below, shows only the case of rank 1.

Reference implementation:

```
INTEGER(I4B) :: nold,ierr
allocate(realloc(n),stat=ierr)
if (ierr /= 0) call &
    nrerror('realloc: problem in attempt to allocate memory')
if (.not. associated(p)) RETURN
nold=size(p)
realloc(1:min(nold,n))=p(1:min(nold,n))
deallocate(p)
```

23.2 Routines Returning a Location

Fortran 90's intrinsics `maxloc` and `minloc` return rank-one arrays. When, in the most frequent usage, their argument is a one-dimensional array, the answer comes back in the inconvenient form of an array containing a single component, which cannot be itself used in a subscript calculation. While there are workaround tricks (e.g., use of the `sum` intrinsic to convert the array to a scalar), it seems clearer to define routines `imaxloc` and `iminloc` that return integers directly.

The routine `ifirstloc` adds a related facility missing among the intrinsics: Return the first true location in a logical array.

★ ★ ★

imaxloc (location of array maximum as an integer)*User interface (or, “USE nrutil”):*

```
FUNCTION imaxloc(arr)
T, INTENT(IN) :: arr
INTEGER(I4B) :: imaxloc
END FUNCTION imaxloc
```

Applicable types and ranks: $T \equiv$ any integer or real type, rank 1*Types and ranks implemented (overloaded) in nrutil:* $T \equiv$ INTEGER(I4B)(:) , REAL(SP)(:)*Action:*

For one-dimensional arrays, identical to the `maxloc` intrinsic, except returns its answer as an integer rather than as `maxloc`'s somewhat awkward rank-one array containing a single component.

Reference implementation:

```
INTEGER(I4B), DIMENSION(1) :: imax
imax=maxloc(arr(:))
imaxloc=imax(1)
```

★ ★ ★

iminloc (location of array minimum as an integer)*User interface (or, “USE nrutil”):*

```
FUNCTION iminloc(arr)
T, INTENT(IN) :: arr
INTEGER(I4B) :: iminloc
END FUNCTION iminloc
```

Applicable types and ranks: $T \equiv$ any integer or real type, rank 1*Types and ranks implemented (overloaded) in nrutil:* $T \equiv$ REAL(SP)(:)*Action:*

For one-dimensional arrays, identical to the `minloc` intrinsic, except returns its answer as an integer rather than as `minloc`'s somewhat awkward rank-one array containing a single component.

Reference implementation:

```
INTEGER(I4B), DIMENSION(1) :: imin
imin=minloc(arr(:))
iminloc=imin(1)
```

★ ★ ★

ifirstloc (returns location of first “true” in a logical vector)*User interface (or, “USE nrutil”):*

```
FUNCTION ifirstloc(mask)
T, INTENT(IN) :: mask
INTEGER(I4B) :: ifirstloc
END FUNCTION ifirstloc
```

Applicable types and ranks:

$\mathbf{T} \equiv$ any logical type, rank 1

Types and ranks implemented (overloaded) in nrutil:

$\mathbf{T} \equiv$ LOGICAL(LGT)

Action:

Returns the index (subscript value) of the first location, in a one-dimensional logical mask, that has the value .TRUE., or returns size(mask)+1 if all components of mask are .FALSE.

Note that while the reference implementation uses a do-loop, the function is parallelized in nrutil by instead using the merge and maxloc intrinsics.

Reference implementation:

```
INTEGER(I4B) :: i
do i=1,size(mask)
    if (mask(i)) then
        ifirstloc=i
        return
    end if
end do
ifirstloc=i
```

23.3 Argument Checking and Error Handling

It is good programming practice for a routine to check the assumptions (“assertions”) that it makes about the sizes of input arrays, allowed range of numerical arguments, and so forth. The routines assert and assert_eq are meant for this kind of use. The routine nrerror is our default error reporting routine.

* * *

assert (exit with error message if any assertion is false)

User interface (or, “USE nrutil”):

```
SUBROUTINE assert(n1,n2,...,string)
CHARACTER(LEN=*) , INTENT(IN) :: string
LOGICAL, INTENT(IN) :: n1,n2, ...
END SUBROUTINE assert
```

Action:

Embedding program dies gracefully with an error message if any of the logical arguments are false. Typical use is with logical expressions as the actual arguments. nrutil implements and overloads forms with 1, 2, 3, and 4 logical arguments, plus a form with a vector logical argument, LOGICAL, DIMENSION(:), INTENT(IN) :: n that is checked by the all(n) intrinsic.

Reference implementation:

```
if (.not. (n1.and.n2.and...)) then
    write (*,*) 'nrerror: an assertion failed with this tag:', string
    STOP 'program terminated by assert'
end if
```

★ ★ ★

assert_eq (exit with error message if integer arguments not all equal)

User interface (or, “USE nrutil”):

```
FUNCTION assert_eq(n1,n2,n3,...,string)
CHARACTER(LEN=*, INTENT(IN) :: string
INTEGER, INTENT(IN) :: n1,n2,n3, ...
INTEGER :: assert_eq
END FUNCTION assert_eq
```

Action:

Embedding program dies gracefully with an error message if any of the integer arguments are not equal to the first. Otherwise, return the value of the first argument. Typical use is for enforcing equality on the sizes of arrays passed to a subprogram. `nrutil` implements and overloads forms with 1, 2, 3, and 4 integer arguments, plus a form with a vector integer argument, `INTEGER, DIMENSION(:), INTENT(IN) :: n` that is checked by the conditional `if (all(nn(2:)==nn(1)))`.

Reference implementation:

```
if (n1==n2.and.n2==n3.and...) then
    assert_eq=n1
else
    write (*,*) 'nrerror: an assert_eq failed with this tag:', string
    STOP 'program terminated by assert_eq'
end if
```

★ ★ ★

nrerror (report error message and stop)

User interface (or, “USE nrutil”):

```
SUBROUTINE nrerror(string)
CHARACTER(LEN=*, INTENT(IN) :: string
END SUBROUTINE nrerror
```

Action:

This is the minimal error handler used in this book. In applications of any complexity, it is intended only as a placeholder for a user’s more complicated error handling strategy.

Reference implementation:

```
write (*,*) 'nrerror: ',string
STOP 'program terminated by nrerror'
```

23.4 Routines for Polynomials and Recurrences

Apart from programming convenience, these routines are designed to allow for nontrivial parallel implementations, as discussed in §22.2 and §22.3.

★ ★ ★

arth (returns arithmetic progression as an array)

User interface (or, “USE nrutil”):

```
FUNCTION arth(first,increment,n)
T, INTENT(IN) :: first,increment
INTEGER(I4B), INTENT(IN) :: n
T, DIMENSION(n) {or, 1 rank higher than T}:: arth
END FUNCTION arth
```

Applicable types and ranks:

$T \equiv$ any numerical type, any rank

Types and ranks implemented (overloaded) in nrutil:

$T \equiv$ INTEGER(I4B), REAL(SP), REAL(DP)

Action:

Returns an array of length n containing an arithmetic progression whose first value is first and whose increment is increment . If first and increment have rank greater than zero, returns an array of one larger rank, with the last subscript having size n and indexing the progressions. Note that the following reference implementation (for the scalar case) is definitional only, and neither parallelized nor optimized for roundoff error. See §22.2 and Appendix C1 for implementation by subvector scaling.

Reference implementation:

```
INTEGER(I4B) :: k
if (n > 0) arth(1)=first
do k=2,n
    arth(k)=arth(k-1)+increment
end do
```

★ ★ ★

geop (returns geometric progression as an array)

User interface (or, “USE nrutil”):

```
FUNCTION geop(first,factor,n)
T, INTENT(IN) :: first,factor
INTEGER(I4B), INTENT(IN) :: n
T, DIMENSION(n) {or, 1 rank higher than T}:: geop
END FUNCTION geop
```

Applicable types and ranks:

$T \equiv$ any numerical type, any rank

Types and ranks implemented (overloaded) in nrutil:

$T \equiv$ INTEGER(I4B), REAL(SP), REAL(DP), REAL(DP)(:),
COMPLEX(SPC)

Action:

Returns an array of length n containing a geometric progression whose first value is `first` and whose multiplier is `factor`. If `first` and `factor` have rank greater than zero, returns an array of one larger rank, with the last subscript having size n and indexing the progression. Note that the following reference implementation (for the scalar case) is definitional only, and neither parallelized nor optimized for roundoff error. See §22.2 and Appendix C1 for implementation by subvector scaling.

Reference implementation:

```
INTEGER(I4B) :: k
if (n > 0) geop(1)=first
do k=2,n
    geop(k)=geop(k-1)*factor
end do
```

★ ★ ★

cumsum (cumulative sum on an array, with optional additive seed)*User interface (or, “USE nrutil”):*

```
FUNCTION cumsum(arr,seed)
T, DIMENSION(:, INTENT(IN) :: arr
T, OPTIONAL, INTENT(IN) :: seed
T, DIMENSION(size(arr)), INTENT(OUT) :: cumsum
END FUNCTION cumsum
```

Applicable types and ranks:

$T \equiv$ any numerical type

Types and ranks implemented (overloaded) in nrutil:

$T \equiv$ INTEGER(I4B), REAL(SP)

Action:

Given the rank 1 array `arr` of type `T`, returns an array of identical type and size containing the cumulative sums of `arr`. If the optional argument `seed` is present, it is added to the first component (and therefore, by cumulation, all components) of the result. See §22.2 for parallelization ideas.

Reference implementation:

```
INTEGER(I4B) :: n,j
T :: sd
n=size(arr)
if (n == 0) return
sd=0.0
if (present(seed)) sd=seed
cumsum(1)=arr(1)+sd
do j=2,n
    cumsum(j)=cumsum(j-1)+arr(j)
end do
```

★ ★ ★

cumprod (cumulative prod on an array, with optional multiplicative seed)*User interface (or, “USE nrutil”):*

```
FUNCTION cumprod(arr,seed)
T, DIMENSION(:, INTENT(IN) :: arr
T, OPTIONAL, INTENT(IN) :: seed
T, DIMENSION(size(arr)), INTENT(OUT) :: cumprod
END FUNCTION cumprod
```

Applicable types and ranks:

T \equiv any numerical type

Types and ranks implemented (overloaded) in nrutil:

T \equiv REAL(SP)

Action:

Given the rank 1 array **arr** of type **T**, returns an array of identical type and size containing the cumulative products of **arr**. If the optional argument **seed** is present, it is multiplied into the first component (and therefore, by cumulation, into all components) of the result. See §22.2 for parallelization ideas.

Reference implementation:

```
INTEGER(I4B) :: n,j
T :: sd
n=size(arr)
if (n == 0) return
sd=1.0
if (present(seed)) sd=seed
cumprod(1)=arr(1)*sd
do j=2,n
    cumprod(j)=cumprod(j-1)*arr(j)
end do
```

★ ★ ★

poly (polynomial evaluation)

User interface (or, “USE nrutil”):

```
FUNCTION poly(x,coeffs,mask)
T,, DIMENSION(:,...), INTENT(IN) :: x
T, DIMENSION(:), INTENT(IN) :: coeffs
LOGICAL(LGT), DIMENSION(:,...), OPTIONAL, INTENT(IN) :: mask
T :: poly
END FUNCTION poly
```

Applicable types and ranks:

T \equiv any numerical type (**x** may be scalar or have any rank; **x** and **coeffs** may have different numerical types)

Types and ranks implemented (overloaded) in nrutil:

T \equiv various combinations of REAL(SP), REAL(SP)(:), REAL(DP),
REAL(DP)(:), COMPLEX(SPC) (see Appendix C1 for details)

Action:

Returns a scalar value or array with the same type and shape as **x**, containing the result of evaluating the polynomial with one-dimensional coefficient vector **coeffs** on each component of **x**. The optional argument **mask**, if present, has the same shape as **x**, and suppresses evaluation of the polynomial where its components are .false.. The following reference code shows the case where **mask** is not present. (The other case can be included by overloading.)

Reference implementation:

```
INTEGER(I4B) :: i,n
n=size(coeffs)
if (n <= 0) then
    poly=0.0
else
    poly=coeffs(n)
    do i=n-1,1,-1
        poly=x*poly+coeffs(i)
    end do
end if
```

★ ★ ★

poly-term (partial cumulants of a polynomial)

User interface (or, “USE nrutil”):

```
FUNCTION poly_term(a,x)
T, DIMENSION(:), INTENT(IN) :: a
T, INTENT(IN) :: x
T, DIMENSION(size(a)) :: poly_term
END FUNCTION poly_term
```

Applicable types and ranks:

T ≡ any numerical type

Types and ranks implemented (overloaded) in nrutil:

T ≡ REAL(SP), COMPLEX(SPC)

Action:

Returns an array of type and size the same as the one-dimensional array **a**, containing the partial cumulants of the polynomial with coefficients **a** (arranged from highest-order to lowest-order coefficients, n.b.) evaluated at **x**. This is equivalent to synthetic division, and can be parallelized. See §22.3. Note that the order of arguments is reversed in **poly** and **poly-term** — each routine returns a value with the size and shape of the *first* argument, the usual Fortran 90 convention.

Reference implementation:

```
INTEGER(I4B) :: n,j
n=size(a)
if (n <= 0) return
poly_term(1)=a(1)
do j=2,n
    poly_term(j)=a(j)+x*poly_term(j-1)
end do
```

★ ★ ★

zroots_unity (returns powers of complex *n*th root of unity)

User interface (or, “USE nrutil”):

```
FUNCTION zroots_unity(n,nn)
INTEGER(I4B), INTENT(IN) :: n,nn
COMPLEX(SPC), DIMENSION(nn) :: zroots_unity
END FUNCTION zroots_unity
```

Action:

Returns a complex array containing nn consecutive powers of the n th complex root of unity. Note that the following reference implementation is definitional only, and neither parallelized nor optimized for roundoff error. See Appendix C1 for implementation by subvector scaling.

Reference implementation:

```
INTEGER(I4B) :: k
REAL(SP) :: theta
if (nn==0) return
zroots_unity(1)=1.0
if (nn==1) return
theta=TWOPi/n
zroots_unity(2)=cmplx(cos(theta),sin(theta))
do k=3,nn
    zroots_unity(k)=zroots_unity(k-1)*zroots_unity(2)
end do
```

23.5 Routines for Outer Operations on Vectors

Outer operations on vectors take two vectors as input, and return a matrix as output. One dimension of the matrix is the size of the first vector, the other is the size of the second vector. Our convention is always the standard one,

$$\text{result}(i,j) = \text{first_operand}(i) (op) \text{second_operand}(j)$$

where (*op*) is any of addition, subtraction, multiplication, division, and logical and. The reason for coding these as utility routines is that Fortran 90's native construction, with two spreads (cf. §22.1), is difficult to read and thus prone to programmer errors.

★ ★ ★

outerprod (outer product)

User interface (or, “USE nrutil”):

```
FUNCTION outerprod(a,b)
T, DIMENSION(:), INTENT(IN) :: a,b
T, DIMENSION(size(a),size(b)) :: outerprod
END FUNCTION outerprod
```

Applicable types and ranks:

$T \equiv$ any numerical type

Types and ranks implemented (overloaded) in nrutil:

$T \equiv \text{REAL(SP)}, \text{REAL(DP)}$

Action:

Returns a matrix that is the outer product of two vectors.

Reference implementation:

```
outerprod = spread(a,dim=2,ncopies=size(b)) * &
            spread(b,dim=1,ncopies=size(a))
```

★ ★ ★

outerdiv (outer quotient)*User interface (or, “USE nrutil”):*

```
FUNCTION outerdiv(a,b)
T, DIMENSION(:, INTENT(IN) :: a,b
T, DIMENSION(size(a),size(b)) :: outerdiv
END FUNCTION outerdiv
```

Applicable types and ranks: $T \equiv \text{any numerical type}$ *Types and ranks implemented (overloaded) in nrutil:* $T \equiv \text{REAL(SP)}$ *Action:*

Returns a matrix that is the outer quotient of two vectors.

Reference implementation:

```
outerdiv = spread(a,dim=2,ncopies=size(b)) / &
           spread(b,dim=1,ncopies=size(a))
```

★ ★ ★

outersum (outer sum)*User interface (or, “USE nrutil”):*

```
FUNCTIONoutersum(a,b)
T, DIMENSION(:, INTENT(IN) :: a,b
T, DIMENSION(size(a),size(b)) ::outersum
END FUNCTIONoutersum
```

Applicable types and ranks: $T \equiv \text{any numerical type}$ *Types and ranks implemented (overloaded) in nrutil:* $T \equiv \text{REAL(SP)}$ *Action:*

Returns a matrix that is the outer sum of two vectors.

Reference implementation:

```
outersum = spread(a,dim=2,ncopies=size(b)) + &
            spread(b,dim=1,ncopies=size(a))
```

★ ★ ★

outerdiff (outer difference)*User interface (or, “USE nrutil”):*

```
FUNCTIONouterdiff(a,b)
T, DIMENSION(:, INTENT(IN) :: a,b
T, DIMENSION(size(a),size(b)) ::outerdiff
END FUNCTIONouterdiff
```

Applicable types and ranks: $T \equiv \text{any numerical type}$ *Types and ranks implemented (overloaded) in nrutil:* $T \equiv \text{INTEGER(I4B), REAL(SP), REAL(DP)}$ *Action:*

Returns a matrix that is the outer difference of two vectors.

Reference implementation:

```
outerdiff = spread(a,dim=2,ncopies=size(b)) - &
           spread(b,dim=1,ncopies=size(a))
```

★ ★ ★

outerand (outer logical and)

User interface (or, “USE nrutil”):

```
FUNCTION outerand(a,b)
LOGICAL(LGT), DIMENSION(:), INTENT(IN) :: a,b
LOGICAL(LGT), DIMENSION(size(a),size(b)) :: outerand
END FUNCTION outerand
```

Applicable types and ranks:

$\mathbf{T} \equiv$ any logical type

Types and ranks implemented (overloaded) in nrutil:

$\mathbf{T} \equiv$ LOGICAL(LGT)

Action:

Returns a matrix that is the outer logical and of two vectors.

Reference implementation:

```
outerand = spread(a,dim=2,ncopies=size(b)) .and. &
           spread(b,dim=1,ncopies=size(a))
```

23.6 Routines for Scatter with Combine

These are common parallel functions that Fortran 90 simply doesn’t provide a means for implementing. If you have a parallel machine, you should substitute library routines specific to your hardware.

★ ★ ★

scatter_add (scatter-add source to specified components of destination)

User interface (or, “USE nrutil”):

```
SUBROUTINE scatter_add(dest,source,dest_index)
T, DIMENSION(:), INTENT(OUT) :: dest
T, DIMENSION(:), INTENT(IN) :: source
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: dest_index
END SUBROUTINE scatter_add
```

Applicable types and ranks:

$\mathbf{T} \equiv$ any numerical type

Types and ranks implemented (overloaded) in nrutil:

$\mathbf{T} \equiv$ REAL(SP), REAL(DP)

Action:

Adds each component of the array source into a component of dest specified by the index array dest_index. (The user will usually have zeroed dest before the call to this routine.) Note that dest_index has the size of source, but must contain values in the range from 1 to size(dest), inclusive. Out-of-range values are ignored. There is no parallel implementation of this routine accessible from Fortran 90; most parallel machines supply an implementation as a library routine.

Reference implementation:

```
INTEGER(I4B) :: m,n,j,i
n=assert_eq(size(source),size(dest_index),'scatter_add')
m=size(dest)
do j=1,n
    i=dest_index(j)
    if (i > 0 .and. i <= m) dest(i)=dest(i)+source(j)
end do
```

★ ★ ★

scatter_max (scatter-max source to specified components of destination)*User interface (or, “USE nrutil”):*

```
SUBROUTINE scatter_max(dest,source,dest_index)
T, DIMENSION(:), INTENT(OUT) :: dest
T, DIMENSION(:), INTENT(IN) :: source
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: dest_index
END SUBROUTINE scatter_max
```

Applicable types and ranks:

T ≡ any integer or real type

Types and ranks implemented (overloaded) in nrutil:

T ≡ REAL(SP), REAL(DP)

Action:

Takes the max operation between each component of the array source and a component of dest specified by the index array dest_index, replacing that component of dest with the value obtained (“maxing into” operation). (The user will often want to fill the array dest with the value –huge before the call to this routine.) Note that dest_index has the size of source, but must contain values in the range from 1 to size(dest), inclusive. Out-of-range values are ignored. There is no parallel implementation of this routine accessible from Fortran 90; most parallel machines supply an implementation as a library routine.

Reference implementation:

```
INTEGER(I4B) :: m,n,j,i
n=assert_eq(size(source),size(dest_index),'scatter_max')
m=size(dest)
do j=1,n
    i=dest_index(j)
    if (i > 0 .and. i <= m) dest(i)=max(dest(i),source(j))
end do
```

23.7 Routines for Skew Operations on Matrices

These are also missing parallel capabilities in Fortran 90. In Appendix C1 they are coded serially, with one or more do-loops.

★ ★ ★

diagadd (adds vector to diagonal of a matrix)

User interface (or, “USE nrutil”):

```
SUBROUTINE diagadd(mat,diag)
  T, DIMENSION(:, :), INTENT(INOUT) :: mat
  T, DIMENSION(:), INTENT(IN) :: diag
END SUBROUTINE diagadd
```

Applicable types and ranks:

$T \equiv$ any numerical type

Types and ranks implemented (overloaded) in nrutil:

$T \equiv$ REAL(SP)

Action:

The argument `diag`, either a scalar or else a vector whose size must be the smaller of the two dimensions of matrix `mat`, is added to the diagonal of the matrix `mat`. The following shows an implementation where `diag` is a vector; the scalar case can be overloaded (see Appendix C1).

Reference implementation:

```
INTEGER(I4B) :: j,n
n = assert_eq(size(diag),min(size(mat,1),size(mat,2)),’diagadd’)
do j=1,n
    mat(j,j)=mat(j,j)+diag(j)
end do
```

★ ★ ★

diagmult (multiplies vector into diagonal of a matrix)

User interface (or, “USE nrutil”):

```
SUBROUTINE diagmult(mat,diag)
  T, DIMENSION(:, :), INTENT(INOUT) :: mat
  T, DIMENSION(:), INTENT(IN) :: diag
END SUBROUTINE diagmult
```

Applicable types and ranks:

$T \equiv$ any numerical type

Types and ranks implemented (overloaded) in nrutil:

$T \equiv$ REAL(SP)

Action:

The argument `diag`, either a scalar or else a vector whose size must be the smaller of the two dimensions of matrix `mat`, is multiplied onto the diagonal of the matrix `mat`. The following shows an implementation where `diag` is a vector; the scalar case can be overloaded (see Appendix C1).

Reference implementation:

```
INTEGER(I4B) :: j,n
n = assert_eq(size(diag),min(size(mat,1),size(mat,2)),’diagmult’)
do j=1,n
    mat(j,j)=mat(j,j)*diag(j)
end do
```

★ ★ ★

get_diag (gets diagonal of matrix)

User interface (or, “USE nrutil”):

```
FUNCTION get_diag(mat)
T, DIMENSION(:, :), INTENT(IN) :: mat
T, DIMENSION(min(size(mat,1),size(mat,2))) :: get_diag
END FUNCTION get_diag
```

Applicable types and ranks:

T ≡ any type

Types and ranks implemented (overloaded) in nrutil:

T ≡ REAL(SP), REAL(DP)

Action:

Returns a vector containing the diagonal values of the matrix **mat**.

Reference implementation:

```
INTEGER(I4B) :: j
do j=1,min(size(mat,1),size(mat,2))
    get_diag(j)=mat(j,j)
end do
```

★ ★ ★

put_diag (sets the diagonal elements of a matrix)

User interface (or, “USE nrutil”):

```
SUBROUTINE put_diag(diag,mat)
T, DIMENSION(:, :), INTENT(IN) :: diag
T, DIMENSION(:, :), INTENT(INOUT) :: mat
END SUBROUTINE put_diag
```

Applicable types and ranks:

T ≡ any type

Types and ranks implemented (overloaded) in nrutil:

T ≡ REAL(SP)

Action:

Sets the diagonal of matrix **mat** equal to the argument **diag**, either a scalar or else a vector whose size must be the smaller of the two dimensions of matrix **mat**. The following shows an implementation where **diag** is a vector; the scalar case can be overloaded (see Appendix C1).

Reference implementation:

```
INTEGER(I4B) :: j,n
n=assert_eq(size(diag),min(size(mat,1),size(mat,2)),’put_diag’)
do j=1,n
    mat(j,j)=diag(j)
end do
```

★ ★ ★

unit_matrix (returns a unit matrix)*User interface (or, “USE nrutil”):*

```
SUBROUTINE unit_matrix(mat)
  T, DIMENSION(:, :), INTENT(OUT) :: mat
END SUBROUTINE unit_matrix
```

Applicable types and ranks: $T \equiv$ any numerical type*Types and ranks implemented (overloaded) in nrutil:* $T \equiv$ REAL(SP)*Action:*

Sets the diagonal components of `mat` to unity, all other components to zero. When `mat` is square, this will be the unit matrix; otherwise, a unit matrix with appended rows or columns of zeros.

Reference implementation:

```
INTEGER(I4B) :: i,n
n=min(size(mat,1),size(mat,2))
mat(:,:)=0.0
do i=1,n
  mat(i,i)=1.0
end do
```

★ ★ ★

upper_triangle (returns an upper triangular mask)*User interface (or, “USE nrutil”):*

```
FUNCTION upper_triangle(j,k,extra)
INTEGER(I4B), INTENT(IN) :: j,k
INTEGER(I4B), OPTIONAL, INTENT(IN) :: extra
LOGICAL(LGT), DIMENSION(j,k) :: upper_triangle
END FUNCTION upper_triangle
```

Action:

When the optional argument `extra` is zero or absent, returns a logical mask of shape (j, k) whose values are true above and to the right of the diagonal, false elsewhere (including on the diagonal). When `extra` is present and positive, a corresponding number of additional (sub-)diagonals are returned as true. (`extra = 1` makes the main diagonal return true.) When `extra` is present and negative, it suppresses a corresponding number of superdiagonals.

Reference implementation:

```
INTEGER(I4B) :: n,jj,kk
n=0
if (present(extra)) n=extra
do jj=1,j
  do kk=1,k
    upper_triangle(jj,kk)= (jj-kk < n)
  end do
end do
```

★ ★ ★

lower_triangle (returns a lower triangular mask)

User interface (or, “USE nrutil”):

```
FUNCTION lower_triangle(j,k,extra)
INTEGER(I4B), INTENT(IN) :: j,k
INTEGER(I4B), OPTIONAL, INTENT(IN) :: extra
LOGICAL(LGT), DIMENSION(j,k) :: lower_triangle
END FUNCTION lower_triangle
```

Action:

When the optional argument `extra` is zero or absent, returns a logical mask of shape (j, k) whose values are true below and to the left of the diagonal, false elsewhere (including on the diagonal). When `extra` is present and positive, a corresponding number of additional (super-)diagonals are returned as true. (`extra = 1` makes the main diagonal return true.) When `extra` is present and negative, it suppresses a corresponding number of subdiagonals.

Reference implementation:

```
INTEGER(I4B) :: n,jj,kk
n=0
if (present(extra)) n=extra
do jj=1,j
  do kk=1,k
    lower_triangle(jj,kk)= (kk-jj < n)
  end do
end do
```

Fortran 95’s `forall` construction will make the parallel implementation of all our skew operations utilities extremely simple. For example, the do-loop in `diagadd` will collapse to

```
forall (j=1:n) mat(j,j)=mat(j,j)+diag(j)
```

In fact, this implementation is so simple as to raise the question of whether a separate utility like `diagadd` will be needed at all. There are valid arguments on both sides of this question: The “con” argument, against a routine like `diagadd`, is that it is just another reserved name that you have to remember (if you want to use it). The “pro” argument is that a separate routine avoids the “index pollution” (the opposite disease from “index loss” discussed in §22.1) of introducing a superfluous variable `j`, and that a separate utility allows for additional error checking on the sizes and compatibility of its arguments. We expect that different programmers will have differing tastes.

The argument for keeping a routine like `upper_triangle` or `lower_triangle`, once Fortran 95’s *masked* `forall` constructions become available, is less persuasive. We recommend that you consider these two routines as placeholders for “remember to recode this in Fortran 95, someday.”

23.8 Other Routine(s)

You might argue that we don’t really need a routine for the idiom

```
sqrt(dot_product(v,v))
```

You might be right. The ability to overload the complex case, with its additional complex conjugate, is an argument in its favor, however.

★ ★ ★

vabs (L_2 norm of a vector)

User interface (or, “USE nrutil”):

```
FUNCTION vabs(v)
T, DIMENSION(:), INTENT(IN) :: v
T :: vabs
END FUNCTION vabs
```

Applicable types and ranks:

$\mathbf{T} \equiv$ any real or complex type

Types and ranks implemented (overloaded) in nrutil:

$\mathbf{T} \equiv$ REAL(SP)

Action:

Returns the length of a vector \mathbf{v} in L_2 norm, that is, the square root of the sum of the squares of the components. (For complex types, the `dot_product` should be between the vector and its complex conjugate.)

Reference implementation:

```
vabs=sqrt(dot_product(v,v))
```

Fortran 90 Code Chapters B1–B20

Fortran 90 versions of all the Numerical Recipes routines appear in the following Chapters B1 through B20, numbered in correspondence with Chapters 1 through 20 in Volume 1. Within each chapter, the routines appear in the same order as in Volume 1, but not broken out separately by section number within Volume 1’s chapters.

There are commentaries accompanying many of the routines, generally following the printed listing of the routine to which they apply. These are of two kinds: issues related to parallelizing the algorithm in question, and issues related to the Fortran 90 implementation. To distinguish between these two, rather different, kinds of discussions, we use the two icons,

the left icon (above) indicating a “parallel note,” and the right icon denoting a “Fortran 90 tip.” Specific code segments of the routine that are discussed in these commentaries are singled out by reproducing some of the code as an “index line” next to the icon, or at the beginning of subsequent paragraphs if there are several items that are commented on.

`d=merge(FPMIN,d,abs(d)<FPMIN)` This would be the start of a discussion of code that begins at the line in the listing containing the indicated code fragment.

★ ★ ★

A row of stars, like the above, is used between unrelated routines, or at the beginning and end of related groups of routines.

Some chapters contain discussions that are more general than commentary on individual routines, but that were deemed too specific for inclusion in Chapters 21 through 23. Here are some highlights of this additional material:

- Approximations to roots of orthogonal polynomials for parallel computation of Gaussian quadrature formulas (Chapter B4)
- Difficulty of, and tricks for, parallel calculation of special function values in a SIMD model of computation (Chapter B6)
- Parallel random number generation (Chapter B7)
- Fortran 90 tricks for dealing with ties in sorted arrays, counting things in boxes, etc. (Chapter B14)
- Use of recursion in implementing multigrid elliptic PDE solvers (Chapter B19)

Chapter B1. Preliminaries

```
SUBROUTINE flmoon(n,nph,jd,frac)
USE nrtype; USE nrutil, ONLY : nrerror
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: n,nph
INTEGER(I4B), INTENT(OUT) :: jd
REAL(SP), INTENT(OUT) :: frac
Our programs begin with an introductory comment summarizing their purpose and explaining their calling sequence. This routine calculates the phases of the moon. Given an integer n and a code nph for the phase desired (nph = 0 for new moon, 1 for first quarter, 2 for full, 3 for last quarter), the routine returns the Julian Day Number jd, and the fractional part of a day frac to be added to it, of the nth such phase since January, 1900. Greenwich Mean Time is assumed.
REAL(SP), PARAMETER :: RAD=PI/180.0_sp
INTEGER(I4B) :: i
REAL(SP) :: am,as,c,t,t2,xtra
c=n+nph/4.0_sp                                         This is how we comment an individual line.
t=c/1236.85_sp
t2=t**2
as=359.2242_sp+29.105356_sp*c                         You aren't really intended to understand this algorithm, but it does work!
am=306.0253_sp+385.816918_sp*c+0.010730_sp*t2
jd=2415020+28*n+7*nph
xtra=0.75933_sp+1.53058868_sp*c+(1.178e-4_sp-1.55e-7_sp*t)*t2
select case(nph)
  case(0,2)
    xtra=xtra+(0.1734_sp-3.93e-4_sp*t)*sin(RAD*as)-0.4068_sp*sin(RAD*am)
  case(1,3)
    xtra=xtra+(0.1721_sp-4.0e-4_sp*t)*sin(RAD*as)-0.6280_sp*sin(RAD*am)
  case default
    call nrerror('flmoon: nph is unknown')               This is how we will indicate error
  end select                                               conditions.
i=int(merge(xtra,xtra-1.0_sp, xtra >= 0.0))
jd=jd+i
frac=xtra-i
END SUBROUTINE flmoon
```

f90 `select case(nph)...case(0,2)...end select` Fortran 90 includes a case construction that executes at most one of several blocks of code, depending on the value of an integer, logical, or character expression. Ideally, the case construction will execute more efficiently than a long sequence of cascaded `if...else if...else if...` constructions. C programmers should note that the Fortran 90 construction, perhaps mercifully, does not have C's "drop-through" feature.

`merge(xtra,xtra-1.0_sp, xtra >= 0.0)` The `merge` construction in Fortran 90, while intended primarily for use with vector arguments, is also a convenient way of generating conditional scalar expressions, that is, expressions with one value, or another, depending on the result of a logical test.

When the arguments of a `merge` are vectors, parallelization by the compiler is straightforward as an array parallel operation (see p. 964).

Less obvious is how the scalar case, as above, is handled. For small-scale parallel (SSP) machines, the natural gain is via speculative evaluation of both of the first two arguments simultaneously with evaluation of the test.

A good compiler should not penalize a scalar machine for use of either the scalar or vector `merge` construction. The Fortran 90 standard states that “it is not necessary for a processor to evaluate all of the operands of an expression, or to evaluate entirely each operand, if the value of the expression can be determined otherwise.” Therefore, for each test on a scalar machine, only one or the other of the first two argument components need be evaluated.

    icon=ic
    n=n+ic
  end if
end do
end if
end do
end do
END PROGRAM badluk

```

f90 ...IGREG=15+31*(10+12*1582) (in julday), ...TIMZON=-5.0_sp/24.0_sp
 (in badluk) These are two examples of initialization expressions for
 "named constants" (that is, PARAMETERS). Because the initialization
 expressions will generally be evaluated at compile time, Fortran 90 puts some
 restrictions on what kinds of intrinsic functions they can contain. Although the
 evaluation of a real expression like -5.0_sp/24.0_sp *ought* to give identical results
 at compile time and at execution time, all the way down to the least significant
 bit, in our opinion the conservative programmer shouldn't count on strict identity
 at the level of floating-point roundoff error. (In the special case of *cross-compilers*,
 such roundoff-level discrepancies between compile time and run time are almost
 inevitable.)

* * *

```
SUBROUTINE caldat(julian,mm,id,iyyy)
USE nrtype

Chapter B2. Solution of Linear Algebraic Equations

```

SUBROUTINE gaussj(a,b)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror,outerand,outerprod,swap
IMPLICIT NONE
REAL(SP), DIMENSION(:,:), INTENT(INOUT) :: a,b
    Linear equation solution by Gauss-Jordan elimination, equation (2.1.1). a is an  $N \times N$  input coefficient matrix. b is an  $N \times M$  input matrix containing  $M$  right-hand-side vectors. On output, a is replaced by its matrix inverse, and b is replaced by the corresponding set of solution vectors.
INTEGER(I4B), DIMENSION(size(a,1)) :: ipiv,indxr,indxc
    These arrays are used for bookkeeping on the pivoting.
LOGICAL(LGT), DIMENSION(size(a,1)) :: lpiiv
REAL(SP) :: pivinv
REAL(SP), DIMENSION(size(a,1)) :: dumc
INTEGER(I4B), TARGET :: irc(2)
INTEGER(I4B) :: i,l,n
INTEGER(I4B), POINTER :: irow,icol
n(assert_eq(size(a,1),size(a,2),size(b,1),'gaussj'))
irow => irc(1)
icol => irc(2)
ipiv=0
do i=1,n                                Main loop over columns to be reduced.
    ipiv = (ipiv == 0)                  Begin search for a pivot element.
    irc=maxloc(abs(a),outerand(lpiiv,lpiiv))
    ipiv(icol)=ipiv(icol)+1
    if (ipiv(icol) > 1) call nrerror('gaussj: singular matrix (1)')
        We now have the pivot element, so we interchange rows, if needed, to put the pivot element on the diagonal. The columns are not physically interchanged, only relabeled: indxc(i), the column of the i-th pivot element, is the i-th column that is reduced, while indxr(i) is the row in which that pivot element was originally located. If indxr(i) ≠ indxc(i) there is an implied column interchange. With this form of bookkeeping, the solution b's will end up in the correct order, and the inverse matrix will be scrambled by columns.
    if (irow /= icol) then
        call swap(a(irow,:),a(icol,:))
        call swap(b(irow,:),b(icol,:))
    end if
    indxr(i)=irow                         We are now ready to divide the pivot row by the pivot
    indxc(i)=icol                         element, located at irow and icol.
    if (a(icol,icol) == 0.0) &
        call nrerror('gaussj: singular matrix (2)')
    pivinv=1.0_sp/a(icol,icol)
    a(icol,icol)=1.0
    a(icol,:)=a(icol,:)*pivinv
    b(icol,:)=b(icol,:)*pivinv
    dumc=a(:,icol)
    a(:,icol)=0.0                           Next, we reduce the rows, except for the pivot one, of
                                            course.

```

```

a(icol,icol)=pivinv
a(1:icol-1,:)=a(1:icol-1,:)-outerprod(dumc(1:icol-1),a(icol,:))
b(1:icol-1,:)=b(1:icol-1,:)-outerprod(dumc(1:icol-1),b(icol,:))
a(icol+1,:,:)=a(icol+1,:,:)-outerprod(dumc(icol+1:),a(icol,:))
b(icol+1,:,:)=b(icol+1,:,:)-outerprod(dumc(icol+1:),b(icol,:))
end do
It only remains to unscramble the solution in view of the column interchanges. We do this
by interchanging pairs of columns in the reverse order that the permutation was built up.
do l=n,1,-1
  call swap(a(:,indxr(l)),a(:,indxc(l)))
end do
END SUBROUTINE gaussj

```

f90 $i_{\text{row}} \Rightarrow \text{irc}(1) \dots i_{\text{col}} \Rightarrow \text{irc}(2)$ The `maxloc` intrinsic returns the location of the maximum value of an array as an integer array, in this case of size 2. Pre-pointing pointer variables to components of the array that will be thus set makes possible convenient references to the desired row and column positions.

$\text{irc}=\text{maxloc}(\text{abs}(\text{a}),\text{outerand}(\text{lpivot},\text{lpivot}))$ The combination of `maxloc` and one of the `outer...routines` from `nrutil` allows for a very concise formulation. If this task is done with loops, it becomes the ungainly “flying vee,”

```

aa=0.0
do i=1,n
  if (lpiv(i)) then
    do j=1,n
      if (lpiv(j)) then
        if (abs(a(i,j)) > aa) then
          aa=abs(a(i,j))
          irow=i
          icol=j
        endif
      endif
    end do
  end do
end do

```

`call swap(a(irow,:),a(icol,:))` The `swap` routine (in `nrutil`) is concise and convenient. Fortran 90’s ability to overload multiple routines onto a single name is vital here: Much of the convenience would vanish if we had to remember variant routine names for each variable type and rank of object that might be swapped.

Even better, here, than overloading would be if Fortran 90 allowed user-written *elemental* procedures (procedures with unspecified or arbitrary rank and shape), like the intrinsic elemental procedures built into the language. Fortran 95 will, but Fortran 90 doesn’t.

 One quick (if superficial) test for how much parallelism is achieved in a Fortran 90 routine is to count its do-loops, and compare that number to the number of do-loops in the Fortran 77 version of the same routine. Here, in `gaussj`, 13 do-loops are reduced to 2.

```

a(1:icol-1,:)=... b(1:icol-1,:)=...
a(icol+1,:,:)=... b(icol+1,:,:)=...

```

Here the same operation is applied to every row of \mathbf{a} , and to every row of \mathbf{b} , *except* row number icol . On a massively multiprocessor (MMP) machine it would be better to use a logical mask and do all of \mathbf{a} in a single statement, all of \mathbf{b} in another one. For a small-scale parallel (SSP) machine, the lines as written should saturate the machine's concurrency, and they avoid the additional overhead of testing the mask.

This would be a good place to point out, however, that linear algebra routines written in Fortran 90 are likely *never* to be competitive with the hand-coded library routines that are generally supplied as part of MMP programming environments. If you are using our routines instead of library routines written specifically for your architecture, you are wasting cycles!

```
SUBROUTINE ludcmp(a,indx,d)
USE nrtype; USE nrutil, ONLY : assert_eq,imaxloc,nrerror,outerprod,swap
IMPLICIT NONE
REAL(SP), DIMENSION(:, :, ), INTENT(INOUT) :: a
INTEGER(I4B), DIMENSION(:, ), INTENT(OUT) :: indx
REAL(SP), INTENT(OUT) :: d
      Given an  $N \times N$  input matrix  $\mathbf{a}$ , this routine replaces it by the LU decomposition of a
      rowwise permutation of itself. On output,  $\mathbf{a}$  is arranged as in equation (2.3.14);  $\text{indx}$  is an
      output vector of length  $N$  that records the row permutation effected by the partial pivoting;
       $d$  is output as  $\pm 1$  depending on whether the number of row interchanges was even or odd,
      respectively. This routine is used in combination with lubksb to solve linear equations or
      invert a matrix.
REAL(SP), DIMENSION(size(a,1)) :: vv           vv stores the implicit scaling of each row.
REAL(SP), PARAMETER :: TINY=1.0e-20_sp          A small number.
INTEGER(I4B) :: j,n,imax
n(assert_eq(size(a,1),size(a,2),size(indx),'ludcmp'))
d=1.0           No row interchanges yet.
vv=maxval(abs(a),dim=2)           Loop over rows to get the implicit scaling
if (any(vv == 0.0)) call nrerror('singular matrix in ludcmp')   information.
      There is a row of zeros.
vv=1.0_sp/vv           Save the scaling.
do j=1,n
      imax=(j-1)+imaxloc(vv(j:n)*abs(a(j:n,j)))           Find the pivot row.
      if (j /= imax) then
          call swap(a(imax,:),a(j,:))           Do we need to interchange rows?
          d=-d           Yes, do so...
          vv(imax)=vv(j)           ...and change the parity of  $d$ .
      end if           Also interchange the scale factor.
      indx(j)=imax
      if (a(j,j) == 0.0) a(j,j)=TINY
      If the pivot element is zero the matrix is singular (at least to the precision of the al-
      gorithm). For some applications on singular matrices, it is desirable to substitute TINY
      for zero.
      a(j+1:n,j)=a(j+1:n,j)/a(j,j)           Divide by the pivot element.
      a(j+1:n,j+1:n)=(j+1:n,j+1:n)-outerprod(a(j+1:n,j),a(j,j+1:n))
      Reduce remaining submatrix.
end do
END SUBROUTINE ludcmp
```

f90 $\text{vv}=\maxval(\text{abs}(\mathbf{a}),\text{dim}=2)$ A single statement finds the maximum absolute value in each row. Fortran 90 intrinsics like `maxval` generally “do their thing” in the dimension specified by `dim` and return a result with a shape corresponding to the *other* dimensions. Thus, here, `vv`’s size is that of the *first* dimension of \mathbf{a} .

`imax=(j-1)+imaxloc(vv(j:n)*abs(a(j:n,j)))` Here we see why the `nrutil` routine `imaxloc` is handy: We want the index, in the range `1:n` of a quantity to be searched for only in the limited range `j:n`. Using `imaxloc`, we just add back the proper offset of `j-1`. (Using only Fortran 90 intrinsics, we could write `imax=(j-1)+sum(maxloc(vv(j:n)*abs(a(j:n,j))))`), but the use of `sum` just to turn an array of length 1 into a scalar seems sufficiently confusing as to be avoided.)

`a(j+1:n,j+1:n)=a(j+1:n,j+1:n)-outerprod(a(j+1:n,j),a(j,j+1:n))`

The Fortran 77 version of `ludcmp`, using Crout's algorithm for the reduction, does not parallelize well: The elements are updated by $O(N^2)$ separate dot product operations in a particular order. Here we use a slightly different reduction, termed "outer product Gaussian elimination" by Golub and Van Loan [1], that requires just N steps of matrix-parallel reduction. (See their §3.2.3 and §3.2.9 for the algorithm, and their §3.4.1 to understand how the pivoting is performed.)

We use `nrutil`'s routine `outerprod` instead of the more cumbersome pure Fortran 90 construction:

```
spread(a(j+1:n,j),dim=2,ncopies=n-j)*spread(a(j,j+1:n),dim=1,ncopies=n-j)
```

```
SUBROUTINE lubksb(a,indx,b)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:, :, ), INTENT(IN) :: a
INTEGER(I4B), DIMENSION(:, ), INTENT(IN) :: indx
REAL(SP), DIMENSION(:, ), INTENT(INOUT) :: b
      Solves the set of  $N$  linear equations  $A \cdot X = B$ . Here the  $N \times N$  matrix a is input, not as the original matrix A, but rather as its LU decomposition, determined by the routine ludcmp. indx is input as the permutation vector of length  $N$  returned by ludcmp. b is input as the right-hand-side vector B, also of length  $N$ , and returns with the solution vector X. a and indx are not modified by this routine and can be left in place for successive calls with different right-hand sides b. This routine takes into account the possibility that b will begin with many zero elements, so it is efficient for use in matrix inversion.
INTEGER(I4B) :: i,n,ii,11
REAL(SP) :: summ
n(assert_eq(size(a,1),size(a,2),size(indx),'lubksb'))
ii=0
do i=1,n
  ll=indx(i)
  summ=b(ll)
  b(ll)=b(i)
  if (ii /= 0) then
    summ=summ-dot_product(a(i,ii:i-1),b(ii:i-1))
  else if (summ /= 0.0) then
    ii=i
    A nonzero element was encountered, so from now on we will
    have to do the dot product above.
    b(i)=summ
  end if
end do
do i=n,1,-1
  Now we do the backsubstitution, equation (2.3.7).
  b(i) = (b(i)-dot_product(a(i,i+1:n),b(i+1:n)))/a(i,i)
end do
END SUBROUTINE lubksb
```

Conceptually, the search for the first nonvanishing element of `b` (index `ii`) should be moved out of the first do-loop. However, in practice, the need to unscramble the permutation, and also considerations of performance

on scalar machines, cause us to write this very scalar-looking code. The performance penalty on parallel machines should be minimal.

★ ★ ★

Serial and parallel algorithms for tridiagonal problems are quite different. We therefore provide separate routines `tridag_ser` and `tridag_par`. In the MODULE `nr` interface file, one or the other of these (your choice) is given the generic name `tridag`. Of course, *either* version will work correctly on any computer; it is only a question of efficiency. See §22.2 for the numbering of the equation coefficients, and for a description of the parallel algorithm.

```
SUBROUTINE tridag_ser(a,b,c,r,u)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: a,b,c,r
REAL(SP), DIMENSION(:), INTENT(OUT) :: u
      Solves for a vector u of size N the tridiagonal linear set given by equation (2.4.1) using a
      serial algorithm. Input vectors b (diagonal elements) and r (right-hand sides) have size N,
      while a and c (off-diagonal elements) are size N - 1.
REAL(SP), DIMENSION(size(b)) :: gam      One vector of workspace, gam is needed.
INTEGER(I4B) :: n,j
REAL(SP) :: bet
n=assert_eq(/size(a)+1,size(b),size(c)+1,size(r),size(u)/,'tridag_ser')
bet=b(1)
if (bet == 0.0) call nrerror('tridag_ser: Error at code stage 1')
      If this happens then you should rewrite your equations as a set of order N - 1, with  $u_2$ 
      trivially eliminated.
u(1)=r(1)/bet
do j=2,n                                Decomposition and forward substitution.
      gam(j)=c(j-1)/bet
      bet=b(j)-a(j-1)*gam(j)
      if (bet == 0.0) &                      Algorithm fails; see below routine in Vol. 1.
          call nrerror('tridag_ser: Error at code stage 2')
      u(j)=(r(j)-a(j-1)*u(j-1))/bet
end do
do j=n-1,1,-1                            Backsubstitution.
      u(j)=u(j)-gam(j+1)*u(j+1)
end do
END SUBROUTINE tridag_ser
```

```

if (n < NPAR_TRIDAG) then
      call tridag_ser(a,b,c,r,u)
else
      if (maxval(abs(b(1:n))) == 0.0) &          Algorithm fails; see below routine in Vol. 1.

```

```

    call nrerror('tridag_par: possible singular matrix')
n2=size(y)
nm=size(pivc)
nx=size(x)
piva = a(1:n-1:2)/b(1:n-1:2)                                Zero the odd a's and even c's, giving x,
pivc = c(2:n-1:2)/b(3:n:2)                                     y, z, q.
y(1:nm) = b(2:n-1:2)-piva(1:nm)*c(1:n-2:2)-pivc*a(2:n-1:2)
q(1:nm) = r(2:n-1:2)-piva(1:nm)*r(1:n-2:2)-pivc*r(3:n:2)
if (nm < n2) then
    y(n2) = b(n)-piva(n2)*c(n-1)
    q(n2) = r(n)-piva(n2)*r(n-1)
end if
x = -piva(2:n2)*a(2:n-2:2)
z = -pivc(1:nx)*c(3:n-1:2)
call tridag_par(x,y,z,q,u(2:n:2))      Recurse and get even u's.
u(1) = (r(1)-c(1)*u(2))/b(1)           Substitute and get odd u's.
u(3:n-1:2) = (r(3:n-1:2)-a(2:n-2:2)*u(2:n-2:2) &
              -c(3:n-1:2)*u(4:n:2))/b(3:n-1:2)
if (nm == n2) u(n)=(r(n)-a(n-1)*u(n-1))/b(n)
end if
END SUBROUTINE tridag_par

```

f90 The serial version `tridag_ser` is called when the routine has recursed its way down to sufficiently small subproblems. The point at which this occurs is determined by the parameter `NPAR_TRIDAG` whose optimal value is likely machine-dependent. Notice that `tridag_ser` must here be called by its specific name, not by the generic `tridag` (which might itself be overloaded with either `tridag_ser` or `tridag_par`).

★ ★ ★

```

SUBROUTINE banmul(a,m1,m2,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,arth
IMPLICIT NONE
REAL(SP), DIMENSION(:, :, ), INTENT(IN) :: a
INTEGER(I4B), INTENT(IN) :: m1,m2
REAL(SP), DIMENSION(:, ), INTENT(IN) :: x
REAL(SP), DIMENSION(:, ), INTENT(OUT) :: b
Matrix multiply b = A · x, where A is band diagonal with m1 rows below the diagonal and m2 rows above. If the input vector x and output vector b are of length N, then the array a(1:N,1:m1+m2+1) stores A as follows: The diagonal elements are in a(1:N,m1+1). Subdiagonal elements are in a(j:N,1:m1) (with j > 1 appropriate to the number of elements on each subdiagonal). Superdiagonal elements are in a(1:j,m1+2:m1+m2+1) with j < N appropriate to the number of elements on each superdiagonal.
INTEGER(I4B) :: m,n
n(assert_eq(size(a,1),size(b),size(x),'banmul: n'))
m(assert_eq(size(a,2),m1+m2+1,'banmul: m'))
b=sum(a*eoshift(spread(x,dim=2,ncopies=m), &
                 dim=1,shift=arth(-m1,1,m)),dim=2)
END SUBROUTINE banmul

```

f90 `b=sum(a*eoshift(spread(x,dim=2,ncopies=m), &`

This is a good example of Fortran 90 at both its best and its worst: best, because it allows quite subtle combinations of fully parallel operations to be built up; worst, because the resulting code is virtually incomprehensible!

What is going on becomes clearer if we imagine a temporary array y with a declaration like `REAL(SP), DIMENSION(size(a,1),size(a,2)) :: y`. Then, the above single line decomposes into

<code>y=spread(x,dim=2,ncopies=m)</code>	[Duplicate x into columns of y .]
<code>y=eoshift(y,dim=1,shift=arth(-m1,1,m))</code>	[Shift columns by a linear progression.]
<code>b=sum(a*y,dim=2)</code>	[Multiply by the band-diagonal elements, and sum.]

We use here a relatively rare subcase of the `eoshift` intrinsic, using a vector value for the `shift` argument to accomplish the simultaneous shifting of a bunch of columns, by different amounts (here specified by the linear progression returned by `arth`).

If you still don't see how this accomplishes the multiplication of a band diagonal matrix by a vector, work through a simple example by hand.

```
SUBROUTINE bandec(a,m1,m2,al,indx,d)
USE nrtype; USE nrutil, ONLY : assert_eq,imaxloc,swap,arth
IMPLICIT NONE
REAL(SP), DIMENSION(:, :, ), INTENT(INOUT) :: a
INTEGER(I4B), INTENT(IN) :: m1,m2
REAL(SP), DIMENSION(:, :, ), INTENT(OUT) :: al
INTEGER(I4B), DIMENSION(:, ), INTENT(OUT) :: indx
REAL(SP), INTENT(OUT) :: d
REAL(SP), PARAMETER :: TINY=1.0e-20_sp
Given an  $N \times N$  band diagonal matrix  $A$  with  $m1$  subdiagonal rows and  $m2$  superdiagonal rows, compactly stored in the array  $a(1:N, 1:m1+m2+1)$  as described in the comment for routine bandmul, this routine constructs an  $LU$  decomposition of a rowwise permutation of  $A$ . The upper triangular matrix replaces  $a$ , while the lower triangular matrix is returned in  $al(1:N, 1:m1)$ .  $indx$  is an output vector of length  $N$  that records the row permutation effected by the partial pivoting;  $d$  is output as  $\pm 1$  depending on whether the number of row interchanges was even or odd, respectively. This routine is used in combination with banbks to solve band-diagonal sets of equations.
INTEGER(I4B) :: i,k,l,mdum,mm,n

mdum(assert_eq(size(al,2),m1,'bandec: mdum'))
a(1:m1,:)=eoshift(a(1:m1,:),dim=2,shift=arth(m1,-1,m1))      Rearrange the storage a
d=1.0                                         bit.
do k=1,n                                     For each row...
    l=min(m1+k,n)
    i=imaxloc(abs(a(k:l,1)))+k-1           Find the pivot element.
    dum=a(i,1)
    if (dum == 0.0) a(k,1)=TINY
        Matrix is algorithmically singular, but proceed anyway with TINY pivot (desirable in some
        applications).
    indx(k)=i
    if (i /= k) then                         Interchange rows.
        d=-d
        call swap(a(k,1:mm),a(i,1:mm))
    end if
    do i=k+1,1                               Do the elimination.
        dum=a(i,1)/a(k,1)
        al(k,i-k)=dum
        a(i,1:mm-1)=a(i,2:mm)-dum*a(k,2:mm)
        a(i,mm)=0.0
    end do
end do
END SUBROUTINE bandec
```

f90 $a(1:m1,:)=eoshift(a(1:m1,:), \dots)$ See similar discussion of `eoshift` for `banmul`, just above.

$i=\text{imaxloc}(\text{abs}(a(k:1,1)))+k-1$ See discussion of `imaxloc` on p. 1017.

 Notice that the above is *not* well parallelized for MMP machines: the outer do-loop is done N times, where N , the diagonal length, is potentially the largest dimension in the problem. Small-scale parallel (SSP) machines, and scalar machines, are not disadvantaged, because the parallelism of order $\text{mm}=m1+m2+1$ in the inner loops can be enough to saturate their concurrency.

We don't know of an N -parallel algorithm for decomposing band diagonal matrices, at least one that has any reasonably concise expression in Fortran 90. Conceptually, one can view a band diagonal matrix as a *block tridiagonal* matrix, and then apply the same recursive strategy as was used in `tridag_par`. However, the implementation details of this are daunting. (We would welcome a user-contributed routine, clear, concise, and with parallelism of order N .)

```
SUBROUTINE banbks(a,m1,m2,al,indx,b)
USE nrtype; USE nrutil, ONLY : assert_eq,swap
IMPLICIT NONE
REAL(SP), DIMENSION(:, :, ), INTENT(IN) :: a,al
INTEGER(I4B), INTENT(IN) :: m1,m2
INTEGER(I4B), DIMENSION(:, ), INTENT(IN) :: indx
REAL(SP), DIMENSION(:, ), INTENT(INOUT) :: b
Given the arrays a, al, and indx as returned from bandec, and given a right-hand-side
vector b, solves the band diagonal linear equations  $A \cdot x = b$ . The solution vector x overwrites
b. The other input arrays are not modified, and can be left in place for successive calls with
different right-hand sides.
INTEGER(I4B) :: i,k,l,mdum,mm,n
n(assert_eq(size(a,1),size(al,1),size(b),size(indx),'banbks: n'))
mm=assert_eq(size(a,2),m1+m2+1,'banbks: mm')
mdum=assert_eq(size(al,2),m1,'banbks: mdum')
do k=1,n                         Forward substitution, unscrambling the permuted rows as we
    l=min(n,m1+k)                  go.
    i=indx(k)
    if (i /= k) call swap(b(i),b(k))
    b(k+1:l)=b(k+1:l)-al(k,1:l-k)*b(k)
end do
do i=n,1,-1                        Backsubstitution.
    l=min(mm,n-i+1)
    b(i)=(b(i)-dot_product(a(i,2:l),b(i+1:i+l-1)))/a(i,1)
end do
END SUBROUTINE banbks
```

 As for `bandec`, the routine `banbks` is not parallelized on the large dimension N , though it does give the compiler the opportunity for ample small-scale parallelization inside the loops.

```
SUBROUTINE mprove(a,alud,indx,b,x)
USE nrtype; USE nrutil, ONLY : assert_eq
USE nr, ONLY : lubksb
IMPLICIT NONE

INTEGER(I4B), DIMENSION(:), INTENT(IN) :: indx
REAL(SP), DIMENSION(:), INTENT(IN) :: b
REAL(SP), DIMENSION(:), INTENT(INOUT) :: x
    Improves a solution vector x of the linear set of equations  $A \cdot X = B$ . The  $N \times N$  matrix a and the  $N$ -dimensional vectors b and x are input. Also input is alud, the LU decomposition of a as returned by ludcmp, and the  $N$ -dimensional vector indx also returned by that routine. On output, only x is modified, to an improved set of values.
INTEGER(I4B) :: ndum
REAL(SP), DIMENSION(size(a,1)) :: r
ndum=assert_eq((/size(a,1),size(a,2),size(alud,1),size(alud,2),size(b),&
    size(x),size(indx)/),'mprove')
r=matmul(real(a,dp),real(x,dp))-real(b,dp)
    Calculate the right-hand side, accumulating the residual in double precision.
call lubksb(alud,indx,r)           Solve for the error term,
x=x-r                           and subtract it from the old solution.
END SUBROUTINE mprove
```

f90 assert_eq((...), 'mprove') This overloaded version of the nrutil routine assert_eq makes use of a trick for passing a variable number of scalar arguments to a routine: Put them into an array constructor, (/.../), and pass the array. The receiving routine can use the size intrinsic to count them. The technique has some obvious limitations: All the arguments in the array must be of the same type; and the arguments are passed, in effect, by *value*, not by address, so they must be, in effect, INTENT(IN).

r=matmul(real(a,dp),real(x,dp))-real(b,dp) Since Fortran 90's elemental intrinsics operate with the type of their arguments, we can use the real(...,dp)'s to force the matmul matrix multiplication to be done in double precision, which is what we want. In Fortran 77, we would have to do the matrix multiplication with temporary double precision variables, both inconvenient and (since Fortran 77 has no dynamic memory allocation) a waste of memory.

    tmp=0.0                     but replace 1/wj by zero if wj = 0.
end where
```

```
x=matmul(v,tmp)           Matrix multiply by V to get answer.
END SUBROUTINE svbksb_sp
```

f90 where ($w \neq 0.0$)...tmp=...elsewhere...tmp= Normally, when a where ...elsewhere construction is used to set a variable (here tmp) to one or another value, we like to replace it with a merge expression. Here, however, the where is required to guarantee that a division by zero doesn't occur. The rule is that where will *never* evaluate expressions that are excluded by the mask in the where line, but other constructions, like merge, *might* perform speculative evaluation of more than one possible outcome before selecting the applicable one.

Because singular value decomposition is something that one often wants to do in double precision, we include a double-precision version. In nr, the single- and double-precision versions are overloaded onto the name svbksb.

```

The SVD algorithm implemented above does not parallelize very well.

There are two parts to the algorithm. The first, reduction to bidiagonal form, can be parallelized. The second, the iterative diagonalization of the bidiagonal form, uses QR transformations that are intrinsically serial. There have been proposals for parallel SVD algorithms [2], but we do not have sufficient experience with them yet to recommend them over the well-established serial algorithm.

tempn(1:n)=matmul...a(i:m,1:n)=...outerprod... Here is an example of an update as in equation (22.1.6). In this case b_i is independent of i : It is simply $1/h$. The lines beginning `tempn(1:m)=matmul` about 16 lines down are of a similar form, but with the terms in the opposite order in the `matmul`.

f90 As with `svbksb`, single- and double-precision versions of the routines are overloaded onto the name `svdcmp` in `nr`.

SUBROUTINE cyclic(a,b,c,alpha,beta,r,x)
USE nrtype; USE nrutil, ONLY : assert,assert_eq
USE nr, ONLY : tridag
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN):: a,b,c,r
REAL(SP), INTENT(IN) :: alpha,beta
REAL(SP), DIMENSION(:), INTENT(OUT):: x
      Solves the "cyclic" set of linear equations given by equation (2.7.9). a, b, c, and r are
      input vectors, while x is the output solution vector, all of the same size. alpha and beta
      are the corner entries in the matrix. The input is not modified.
INTEGER(I4B) :: n
REAL(SP) :: fact,gamma
REAL(SP), DIMENSION(size(x)) :: bb,u,z
n=assert_eq((/size(a),size(b),size(c),size(r),size(x)/),'cyclic')
call assert(n > 2, 'cyclic arg')
gamma=-b(1)                                Avoid subtraction error in forming bb(1).
bb(1)=b(1)-gamma                           Set up the diagonal of the modified tridiag-
bb(n)=b(n)-alpha*beta/gamma                 onal system.
bb(2:n-1)=b(2:n-1)                         Solve A · x = r.
call tridag(a(2:n),bb,c(1:n-1),r,x)       Set up the vector u.
u(1)=gamma
u(n)=alpha
u(2:n-1)=0.0
call tridag(a(2:n),bb,c(1:n-1),u,z)        Solve A · z = u.
fact=(x(1)+beta*x(n)/gamma)/(1.0_sp+z(1)+beta*z(n)/gamma)   Form v·x/(1+v·z).
x=x-fact*z                                     Now get the solution vector x.
END SUBROUTINE cyclic

```

The parallelism in `cyclic` is in `tridag`. Users with multiprocessor machines will want to be sure that, in `nrutil`, they have set the name `tridag` to be overloaded with `tridag_par` instead of `tridag_ser`.

* * *

The routines `sprsin`, `sprsinx`, `sprstx`, `sprstp`, and `sprsdia` give roughly equivalent functionality to the corresponding Fortran 77 routines, but they are *not* plug compatible. Instead, they take advantage of (and illustrate) several Fortran 90 features that are not present in Fortran 77.

In the module `nrtype` we define a TYPE `sprs2_sp` for two-dimensional sparse, square, matrices, in single precision, as follows

```

TYPE sprs2_sp
  INTEGER(I4B) :: n,len
  REAL(SP), DIMENSION(:), POINTER :: val
  INTEGER(I4B), DIMENSION(:), POINTER :: irow
  INTEGER(I4B), DIMENSION(:), POINTER :: jcol
END TYPE sprs2_sp

```

This has much less structure to it than the “row-indexed sparse storage mode” used in Volume 1. Here, a sparse matrix is just a list of values, and corresponding lists giving the row and column number that each value is in. Two integers `n` and `len` give, respectively, the underlying size (number of rows or columns) in the full matrix, and the number of stored nonzero values. While the previously used row-indexed scheme can be somewhat more efficient for serial machines, it does not parallelize conveniently, while this one does (though with some caveats; see below).

```

SUBROUTINE sprsin_sp(a,thresh,sa)
USE nrtype; USE nrutil, ONLY : arth,assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:,,:), INTENT(IN) :: a
REAL(SP), INTENT(IN) :: thresh
TYPE(sprs2_sp), INTENT(OUT) :: sa
    Converts a square matrix a to sparse storage format as sa. Only elements of a with mag-
    nitude  $\geq$  thresh are retained.
INTEGER(I4B) :: n,len
LOGICAL(LGT), DIMENSION(size(a,1),size(a,2)) :: mask

sa%jcol=pack(spread(arth(1,1,n),1,n),mask)
END SUBROUTINE sprsin_dp

```

Note that the routines `sprsin_sp` and `sprsin_dp` — single and double precision versions of the same algorithm — are overloaded onto the name `sprsin` in module `nr`. We supply both forms because the routine `linbcg`, below, works in double precision.

The trick here is to use the same mask, $\text{abs}(a) > \text{thresh}$, in three consecutive pack expressions, thus guaranteeing that the corresponding elements of the array argument get selected for packing. The first time, we get the desired matrix element values. The second time (above code fragment), we construct a matrix with each element having the value of its *row* number. The third time, we construct a matrix with each element having the value of its *column* number.

```

SUBROUTINE sprsax_sp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_sp), INTENT(IN) :: sa
REAL(SP), DIMENSION (:), INTENT(IN) :: x
REAL(SP), DIMENSION (:), INTENT(OUT) :: b
    Multiply a matrix sa in sparse matrix format by a vector x, giving a vector b.
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprsax_sp')
b=0.0_sp
call scatter_add(b,sa%val*x(sa%jcol),sa%irow)
    Each sparse matrix entry adds a term to some component of b.
END SUBROUTINE sprsax_sp

```

```

SUBROUTINE sprsax_dp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_dp), INTENT(IN) :: sa
REAL(DP), DIMENSION (:), INTENT(IN) :: x
REAL(DP), DIMENSION (:), INTENT(OUT) :: b
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprsax_dp')
b=0.0_dp
call scatter_add(b,sa%val*x(sa%jcol),sa%irow)
END SUBROUTINE sprsax_dp

```

 Since more than one component of the middle vector argument will, in general, need to be added into the same component of b, we must resort to a call to the nrutil routine `scatter_add` to achieve parallelism. However, this parallelism is achieved only if a parallel version of `scatter_add` is available! As we have discussed previously (p. 984), Fortran 90 does not provide any scatter-with-combine (here, scatter-with-add) facility, insisting instead that indexed operations yield non-colliding addresses. Luckily, almost all parallel machines do provide such a facility as a library program. In HPF, for example, the equivalent of `scatter_add` is `SUM_SCATTER`.

The call to `scatter_add` above is equivalent to the do-loop

```

b=0.0
do k=1,sa%len
    b(sa%irow(k))=b(sa%irow(k))+sa%val(k)*x(sa%jcol(k))
end do

```

```

SUBROUTINE sprstx_sp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_sp), INTENT(IN) :: sa
REAL(SP), DIMENSION (:), INTENT(IN) :: x
REAL(SP), DIMENSION (:), INTENT(OUT) :: b
    Multiply the transpose of a matrix sa in sparse matrix format by a vector x, giving a vector b.
INTEGER(I4B) :: ndum
ndum=assert_eq(sa%n,size(x),size(b),'sprstx_sp')
b=0.0_sp
call scatter_add(b,sa%val*x(sa%irow),sa%jcol)
    Each sparse matrix entry adds a term to some component of b.
END SUBROUTINE sprstx_sp

```

```
SUBROUTINE sprstx_dp(sa,x,b)
USE nrtype; USE nrutil, ONLY : assert_eq,scatter_add
IMPLICIT NONE
TYPE(sprs2_dp), INTENT(IN) :: sa
REAL(DP), DIMENSION (:), INTENT(IN) :: x
REAL(DP), DIMENSION (:), INTENT(OUT) :: b

i(1:k)=pack(sa%irow(1:l),mask)
deallocate(mask)
b=0.0
b(i(1:k))=val(1:k)
END SUBROUTINE sprsdiag_dp
```

We use the `nrutil` routine `array_copy` because we don't know in advance how many nonzero diagonal elements will be selected by `mask`. Of course we could count them with a `count(mask)`, but this is an extra step, and inefficient on scalar machines.

`i(1:k)=pack(sa%irow(1:l),mask)` Using the same `mask`, we pick out the corresponding locations of the diagonal elements. No need to use `array_copy` now, since we know the value of `k`.

`b(i(1:k))=val(1:k)` Finally, we can put each element in the right place. Notice that if the sparse matrix is ill-formed, with more than one value stored for the same diagonal element (which should not happen!) then the vector subscript `i(1:k)` is a “many-one section” and its use on the left-hand side is illegal.

```
SUBROUTINE linbcg(b,x,itol,tol,itmax,iter,err)
USE nrtype; USE nrutil, ONLY : assert_eq,nrerror
USE nr, ONLY : atimes,asolve,snrm
IMPLICIT NONE
REAL(DP), DIMENSION(:, ), INTENT(IN) :: b      Double precision is a good idea in this
REAL(DP), DIMENSION(:, ), INTENT(INOUT) :: x      routine.
INTEGER(I4B), INTENT(IN) :: itol,itmax
REAL(DP), INTENT(IN) :: tol
INTEGER(I4B), INTENT(OUT) :: iter
REAL(DP), INTENT(OUT) :: err
REAL(DP), PARAMETER :: EPS=1.0e-14_dp
```

Solves $\mathbf{A} \cdot \mathbf{x} = \mathbf{b}$ for \mathbf{x} , given \mathbf{b} of the same length, by the iterative biconjugate gradient method. On input \mathbf{x} should be set to an initial guess of the solution (or all zeros); `itol` is 1,2,3, or 4, specifying which convergence test is applied (see text); `itmax` is the maximum number of allowed iterations; and `tol` is the desired convergence tolerance. On output, \mathbf{x} is reset to the improved solution, `iter` is the number of iterations actually taken, and `err` is the estimated error. The matrix \mathbf{A} is referenced only through the user-supplied routines `atimes`, which computes the product of either \mathbf{A} or its transpose on a vector; and `asolve`,

which solves $\tilde{\mathbf{A}} \cdot \mathbf{x} = \mathbf{b}$ or $\tilde{\mathbf{A}}^T \cdot \mathbf{x} = \mathbf{b}$ for some preconditioner matrix $\tilde{\mathbf{A}}$ (possibly the trivial diagonal part of \mathbf{A}).

f90 The routines `atimes` and `asolve` are examples of user-supplied routines that interface `linbcg` to a user-supplied method for multiplying the user's sparse matrix by a vector, and for solving the preconditioner matrix equation. Here, we have used these routines to connect `linbcg` to the sparse matrix machinery developed above. If we were instead using the different sparse matrix machinery of Volume 1, we would modify `atimes` and `asolve` accordingly.

USE xlinbcg_data This user-supplied module is assumed to have sa (the sparse matrix) in it.

IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: xa,ya
REAL(SP), INTENT(IN) :: x
REAL(SP), INTENT(OUT) :: y,dy
Given arrays xa and ya of length N, and given a value x, this routine returns a value y,
and an error estimate dy. If P(x) is the polynomial of degree N - 1 such that P(xai) =
yai, i = 1, ..., N, then the returned value y = P(x).
INTEGER(I4B) :: m,n,ns
REAL(SP), DIMENSION(size(xa)) :: c,d,den,ho
n=assert_eq(size(xa),size(ya),'polint')
c=ya                                         Initialize the tableau of c's and d's.
d=ya
ho=xa-x
ns=iminloc(abs(x-xa))                      Find index ns of closest table entry.
y=ya(ns)                                      This is the initial approximation to y.
ns=ns-1
do m=1,n-1                                     For each column of the tableau,
    den(1:n-m)=ho(1:n-m)-ho(1+m:n)           we loop over the current c's and d's and up-
    if (any(den(1:n-m) == 0.0)) &             date them.
        call nrerror('polint: calculation failure')
        This error can occur only if two input xa's are (to within roundoff) identical.
    den(1:n-m)=(c(2:n-m+1)-d(1:n-m))/den(1:n-m)
    d(1:n-m)=ho(1+m:n)*den(1:n-m)            Here the c's and d's are updated.
    c(1:n-m)=ho(1:n-m)*den(1:n-m)
    if (2*ns < n-m) then                     After each column in the tableau is completed, we decide
        dy=c(ns+1)                           which correction, c or d, we want to add to our accu-
    else                                       mulating value of y, i.e., which path to take through
        dy=d(ns)                            the tableau—forking up or down. We do this in such a
        ns=ns-1                            way as to take the most “straight line” route through the
    end if                                      tableau to its apex, updating ns accordingly to keep track
    y=y+dy                                    of where we are. This route keeps the partial approximations
end do                                         centered (insofar as possible) on the target x. The
END SUBROUTINE polint                         last dy added is thus the error indication.

```

```

SUBROUTINE ratint(xa,ya,x,y,dy)

USE nrtype; USE nrutil, ONLY : assert_eq,nrerror
USE nr, ONLY: locate
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: xa,ya,y2a
REAL(SP), INTENT(IN) :: x
REAL(SP) :: spline

```

Given the arrays *xa* and *ya*, which tabulate a function (with the *xa*'s in increasing or decreasing order), and given the array *y2a*, which is the output from *spline* above, and given a value of *x*, this routine returns a cubic-spline interpolated value. The arrays *xa*, *ya* and *y2a* are all of the same size.

```

INTEGER(I4B) :: khi,klo,n
REAL(SP) :: a,b,h
n=assert_eq(size(xa),size(ya),size(y2a),'spline')
klo=max(min(locate(xa,x),n-1),1)
We will find the right place in the table by means of locate's bisection algorithm. This is
optimal if sequential calls to this routine are at random values of x. If sequential calls are in
order, and closely spaced, one would do better to store previous values of klo and khi and
test if they remain appropriate on the next call.
khi=klo+1                      klo and khi now bracket the input value of x.
h=xa(khi)-xa(klo)
if (h == 0.0) call nrerror('bad xa input in spline')   The xa's must be distinct.
a=(xa(khi)-x)/h                  Cubic spline polynomial is now evaluated.
b=(x-xa(klo))/h
spline=a*ya(klo)+b*ya(khi)+((a**3-a)*y2a(klo)+(b**3-b)*y2a(khi))*(h**2)/6.0_sp
END FUNCTION spline

```

f90 *klo=max(min(locate(xa,x),n-1),1)* In the Fortran 77 version of *spline*, there is in-line code to find the location in the table by bisection. Here we prefer an explicit call to *locate*, which performs the bisection. On some massively multiprocessor (MMP) machines, one might substitute a different, more parallel algorithm (see next note).

★ ★ ★

```

FUNCTION locate(xx,x)
USE nrtype
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: xx
REAL(SP), INTENT(IN) :: x
INTEGER(I4B) :: locate

```

Given an array *xx*(1:*N*), and given a value *x*, returns a value *j* such that *x* is between *xx(j)* and *xx(j + 1)*. *xx* must be monotonic, either increasing or decreasing. *j* = 0 or *j* = *N* is returned to indicate that *x* is out of range.

```

INTEGER(I4B) :: n,jl,jm,ju
LOGICAL :: ascnd

```

```

n=size(xx)
ascnd = (xx(n) >= xx(1))           True if ascending order of table, false otherwise.
jl=0                                Initialize lower
ju=n+1                             and upper limits.
do
    if (ju-jl <= 1) exit            Repeat until this condition is satisfied.
    jm=(ju+jl)/2                  Compute a midpoint,
    if (ascnd .eqv. (x >= xx(jm))) then
        jl=jm                      and replace either the lower limit
    else
        ju=jm                      or the upper limit, as appropriate.
    end if
end do
if (x == xx(1)) then                Then set the output, being careful with the endpoints.
    locate=1
else if (x == xx(n)) then
    locate=n-1
else
    locate=jl
end if
END FUNCTION locate

```

The use of bisection is perhaps a sin on a genuinely parallel machine, but (since the process takes only logarithmically many sequential steps) it is at most a *small* sin. One can imagine a “fully parallel” implementation like,

```

k=iminloc(abs(x-xx))
if ((x < xx(k)) .eqv. (xx(1) < xx(n))) then
    locate=k-1
else
    locate=k
end if

```

Problem is, unless the number of *physical* (not logical) processors participating in the `iminloc` is larger than N , the length of the array, this “parallel” code turns a $\log N$ algorithm into one scaling as N , quite an unacceptable inefficiency. So we prefer to be small sinners and bisect.

```

end do
s=y/polcoe
polcoe=matmul(s,a)           Solve linear system.
END FUNCTION polcoe
```

 For a description of the coding here, see §22.3, especially equation (22.3.9). You might also want to compare the coding here with the Fortran 77 version, and also look at the description of the method on p. 84 in Volume 1. The Fortran 90 implementation here is in fact much closer to that description than is the Fortran 77 method, which goes through some acrobatics to roll the synthetic division and matrix multiplication into a single set of two nested loops. The price we pay, here, is storage for the matrix a . Since the degree of any useful polynomial is not a very large number, this is essentially no penalty.

Also worth noting is the way that parallelism is brought to the required synthetic division. For a *single* such synthetic division (e.g., as accomplished by the `nrutil` routine `poly_term`), parallelism can be obtained only by recursion. Here things are much simpler, because we need a whole bunch of simultaneous and independent synthetic divisions; so we can just do them in the obvious, data-parallel, way.

END SUBROUTINE bcucof

```

f90 $x=\text{matmul}(wt,x) \dots c=\text{reshape}(x,(/4,4/),\text{order}=(/2,1/))$ It is a powerful technique to combine the `matmul` intrinsic with `reshape`'s of the input or output. The idea is to use `matmul` whenever the calculation can be cast into the form of a linear mapping between input and output objects. Here the `order=(/2,1/)` parameter specifies that we want the packing to be by rows, not by Fortran's default of columns. (In this two-dimensional case, it's the equivalent of applying `transpose`.)

Chapter B4. Integration of Functions

```
SUBROUTINE trapzd(func,a,b,s,n)
USE nrtype; USE nrutil, ONLY : arth
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), INTENT(INOUT) :: s
INTEGER(I4B), INTENT(IN) :: n
INTERFACE
    FUNCTION func(x)
    USE nrtype
    REAL(SP), DIMENSION(:), INTENT(IN) :: x
    REAL(SP), DIMENSION(size(x)) :: func
    END FUNCTION func
END INTERFACE
This routine computes the nth stage of refinement of an extended trapezoidal rule. func is
input as the name of the function to be integrated between limits a and b, also input. When
called with n=1, the routine returns as s the crudest estimate of  $\int_a^b f(x)dx$ . Subsequent
calls with n=2,3,... (in that sequential order) will improve the accuracy of s by adding  $2^{n-2}$ 
additional interior points. s should not be modified between sequential calls.
REAL(SP) :: del,fsum
INTEGER(I4B) :: it
if (n == 1) then
    s=0.5_sp*(b-a)*sum(func( (/ a,b /) ))
else
    it=2**n-2
    del=(b-a)/it
    fsum=sum(func(arth(a+0.5_sp*del,del,it))) This is the spacing of the points to be added.
    s=0.5_sp*(s+del*fsum) This replaces s by its refined value.
end if
END SUBROUTINE trapzd
```

f90 While most of the quadrature routines in this chapter are coded as functions, `trapzd` is a subroutine because the argument `s` that returns the function value must also be supplied as an input parameter. We could change the subroutine into a function by declaring `s` to be a local variable with the `SAVE` attribute. However, this would prevent us from being able to use the routine recursively to do multidimensional quadrature (see `quad3d` on p. 1065). When `s` is left as an argument, a fresh copy is created on each recursive call. As a `SAVE`'d variable, by contrast, its value would get overwritten on each call, and the code would not be properly “re-entrant.”

`s=0.5_sp*(b-a)*sum(func((/ a,b /)))` Note how we use the `(/.../)` construct to supply a set of scalar arguments to a vector function.

IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP) :: qromb
INTERFACE
    FUNCTION func(x)
    USE nrtype
    REAL(SP), DIMENSION(:, ), INTENT(IN) :: x
    REAL(SP), DIMENSION(size(x)) :: func
    END FUNCTION func
END INTERFACE
INTEGER(I4B), PARAMETER :: JMAX=20,JMAXP=JMAX+1,K=5,KM=K-1
REAL(SP), PARAMETER :: EPS=1.0e-6_sp
    Returns the integral of the function func from a to b. Integration is performed by Romberg's
    method of order 2K, where, e.g., K=2 is Simpson's rule.
    Parameters: EPS is the fractional accuracy desired, as determined by the extrapolation er-
    ror estimate; JMAX limits the total number of steps; K is the number of points used in the
    extrapolation.
REAL(SP), DIMENSION(JMAXP) :: h,s           These store the successive trapezoidal ap-
REAL(SP) :: dqromb                         proximations and their relative stepsizes.
INTEGER(I4B) :: j
h(1)=1.0
do j=1,JMAX
    call trapzd(func,a,b,s(j),j)
    if (j >= K) then
        call polint(h(j-KM:j),s(j-KM:j),0.0_sp,qromb,dqromb)
        if (abs(dqromb) <= EPS*abs(qromb)) RETURN
    end if
    s(j+1)=s(j)
    h(j+1)=0.25_sp*h(j)
end do
call nrerror('qromb: too many steps')
END FUNCTION qromb

```

This is a key step: The factor is 0.25 even
though the stepsize is decreased by only
0.5. This makes the extrapolation a poly-
nomial in h^2 as allowed by equation (4.2.1),
not just a polynomial in h .

REAL(SP), PARAMETER :: EPS=1.0e-6

```

Romberg integration on an open interval. Returns the integral of the function `func` from a to b , using any specified integrating subroutine `choose` and Romberg's method. Normally `choose` will be an open formula, not evaluating the function at the endpoints. It is assumed that `choose` triples the number of steps on each call, and that its error series contains only

even powers of the number of steps. The routines `midpnt`, `midinf`, `midsql`, `midsqu`, and `midexp` are possible choices for choose. The parameters have the same meaning as in `qromb`.

```

REAL(SP), DIMENSION(JMAXP) :: h,s
REAL(SP) :: dqromo
INTEGER(I4B) :: j
h(1)=1.0
do j=1,JMAX
    call choose(func,a,b,s(j),j)
    if (j >= K) then
        call polint(h(j-KM:j),s(j-KM:j),0.0_sp,qromo,dqromo)
        if (abs(dqromo) <= EPS*abs(qromo)) RETURN
    end if
    s(j+1)=s(j)
    h(j+1)=h(j)/9.0_sp           This is where the assumption of step tripling and an even
end do                                error series is used.
call nrerror('qromo: too many steps')
END FUNCTION qromo

f90 FUNCTION func(x) The change of variable could have been effected by a statement function in midinf itself. However, the statement function is a Fortran 77 feature that is deprecated in Fortran 90 because it does not allow the benefits of having an explicit interface, i.e., a complete set of specification statements. Statement functions can always be coded as internal subprograms instead.

The roots are symmetric in the interval,
so we only have to find half of them.

Initial approximations to the roots.

Newton's method carried out simultaneously on the roots.

Loop up the recurrence relation to get
the Legendre polynomials evaluated
at z.

Newton's method.

Scale the root to the desired interval,
and put in its symmetric counterpart.

Compute the weight
and its symmetric counterpart.

f90 Often we have an iterative procedure that has to be applied until all components of a vector have satisfied a convergence criterion. Some components of the vector might converge sooner than others, and it is inefficient on a small-scale parallel (SSP) machine to continue iterating on those components. The general structure we use for such an iteration is exemplified by the following lines from `gauleg`:

```

LOGICAL(LGT), DIMENSION((size(x)+1)/2) :: unfinished
...
unfinished=.true.
do its=1,MAXIT

```

```

        where (unfinished)
        ...
        unfinished=(abs(z-z1) > EPS)
    end where
    if (.not. any(unfinished)) exit
end do
if (its == MAXIT+1) call nrerror('too many iterations in gauleg')

```

We use the logical mask `unfinished` to control which vector components are processed inside the `where`. The mask gets updated on each iteration by testing whether any further vector components have converged. When all have converged, we exit the iteration loop. Finally, we check the value of `its` to see whether the maximum allowed number of iterations was exceeded before all components converged.

The logical expression controlling the `where` block (in this case `unfinished`) gets evaluated completely on entry into the `where`, and it is then perfectly fine to modify it inside the block. The modification affects only the *next* execution of the `where`.

On a strictly *serial* machine, there is of course some penalty associated with the above scheme: after a vector component converges, its corresponding component in `unfinished` is redundantly tested on each further iteration, until the slowest-converging component is done. If the number of iterations required does not vary too greatly from component to component, this is a minor, often negligible, penalty. However, one should be on the alert against algorithms whose worst-case convergence could differ from typical convergence by orders of magnitude. For these, one would need to implement a more complicated packing-unpacking scheme. (See discussion in Chapter B6, especially introduction, p. 1083, and notes for `factrl`, p. 1087.)

END SUBROUTINE gaulag

```

 The key difficulty in parallelizing this routine starting from the Fortran 77 version is that the initial guesses for the roots of the Laguerre polynomials were given in terms of previously determined roots. This prevents one from finding all the roots simultaneously. The solution is to come up with a new approximation to the roots that is a simple explicit formula, like the formula we used for the Legendre roots in `gauleg`.

We start with the approximation to $L_n^\alpha(x)$ given in equation (10.15.8) of [1]. We keep only the first term and ask when it is zero. This gives the following prescription for the k th root x_k of $L_n^\alpha(x)$: Solve for θ the equation

$$2\theta - \sin 2\theta = \frac{4n - 4k + 3}{4n + 2\alpha + 2}\pi \quad (\text{B4.1})$$

Since $1 \leq k \leq n$ and $\alpha > -1$, we can always find a value such that $0 < \theta < \pi/2$. Then the approximation to the root is

$$x_k = (4n + 2\alpha + 2) \cos^2 \theta \quad (\text{B4.2})$$

This typically gives 3-digit accuracy, more than enough for the Newton iteration to be able to refine the root. Unfortunately equation (B4.1) is not an explicit formula for θ . (You may recognize it as being of the same form as Kepler's equation in mechanics.) If we call the right-hand side of (B4.1) y , then we can get an explicit formula by working out the power series for $y^{1/3}$ near $\theta = 0$ (using a computer algebra program). Next invert the series to give θ as a function of $y^{1/3}$. Finally, economize the series (see §5.11). The result is the concise approximation

$$\begin{aligned} \theta = 0.9084064y^{1/3} + 5.214976 \times 10^{-2}y + 2.579930 \times 10^{-3}y^{5/3} \\ + 3.986126 \times 10^{-3}y^{7/3} \end{aligned} \quad (\text{B4.3})$$

```

  END SUBROUTINE gauher

```

Once again we need an explicit approximation for the polynomial roots, this time for $H_n(x)$. We can use the same approximation scheme as for $L_n^\alpha(x)$, since

$$H_{2m}(x) \propto L_m^{-1/2}(x^2), \quad H_{2m+1}(x) \propto x L_m^{1/2}(x^2) \quad (\text{B4.4})$$

Equations (B4.1) and (B4.2) become

$$2\theta - \sin 2\theta = \frac{4k-1}{2n+1}\pi$$

$$x_k = \sqrt{2n+1} \cos \theta \quad (\text{B4.5})$$

Here $k = 1, 2, \dots, m$ where $m = [(n+1)/2]$, and $k = 1$ is the largest root. The negative roots follow from symmetry. The root at $x = 0$ for odd n is included in this approximation.

```

END SUBROUTINE gaujac
```

Now we need an explicit approximation for the roots of the Jacobi polynomials $P_n^{(\alpha,\beta)}(x)$. We start with the asymptotic expansion (10.14.10) of [1]. Setting this to zero gives the formula

$$x = \cos \left[\frac{k - 1/4 + \alpha/2}{n + (\alpha + \beta + 1)/2} \pi \right] \quad (\text{B4.6})$$

This is better than the formula (22.16.1) in [2], especially at small and moderate n .

f90

As discussed in Volume 1, multidimensional quadrature can be performed by calling a one-dimensional quadrature routine along each dimension.

If the same routine is used for all such calls, then the calls are recursive. The file `quad3d.f90` contains two modules, `quad3d_qgaus_mod` and `quad3d_qromb_mod`. In the first, the basic one-dimensional quadrature routine is a 10-point Gaussian quadrature routine called `qgaus` and three-dimensional quadrature is performed by calling `quad3d_qgaus`. In the second, the basic one-dimensional routine is `qromb` of §4.3 and the three-dimensional routine is `quad3d_qromb`. The Gaussian quadrature is simpler but its accuracy is not controllable. The Romberg integration lets you specify an accuracy, but is apt to be very slow if you try for too much accuracy. The only difference between the stand-alone version of `trapzd` and the version included here is that we have to add the keyword `RECURSIVE`. The only changes from the stand-alone version of `qromb` are: We have to add `RECURSIVE`; we remove `trapzd` from the list of routines in `USE nr`; we increase `EPS` to 3×10^{-6} . Even this value could be too ambitious for difficult functions. You may want to set `JMAX` to a smaller value than 20 to avoid burning up a lot of computer time. Some people advocate using a smaller `EPS` on the inner quadrature (over z in our routine) than on the outer quadratures (over x or y). That strategy would require separate copies of `qromb`.

```

END MODULE quad3d_qgaus_mod

```

f90 PRIVATE...PUBLIC quad3d_qgaus By default, all module entities are accessible by a routine that uses the module (unless we restrict the USE statement with ONLY). In this module, the user needs access only to the routine quad3d_qgaus; the variables xsav, ysav and the procedures f, g, h, and qgaus are purely internal. It is good programming practice to prevent duplicate name conflicts or data overwriting by limiting access to only the desired entities. Here the PRIVATE statement with no variable names resets the default from PUBLIC. Then we include in the PUBLIC statement only the function name we want to be accessible.

REAL(SP) :: xsav,ysav In Fortran 90, we generally avoid declaring global variables in COMMON blocks. Instead, we give them complete specifications in a module. A deficiency of Fortran 90 is that it does not allow pointers to functions. So here we have to use the fixed-name function func for the function to be integrated over. If we could have a pointer to a function as a global variable, then we would just set the pointer to point to the user function (of any name) in the calling program. Similarly the functions y1, y2, z1, and z2 could also have any name.

CONTAINS Here follow the internal subprograms f, g, h, qgaus, and quad3d_qgaus. Note that such internal subprograms are all “visible” to each other, i.e., their interfaces are mutually explicit, and do not require INTERFACE statements.

RECURSIVE SUBROUTINE qgaus(func,a,b,ss) The RECURSIVE keyword is required for the compiler to process correctly any procedure that is invoked again in its body before the return from the first call has been completed. While some compilers may let you get away without explicitly informing them that a routine is recursive, don’t count on it!

end if
END SUBROUTINE eulsum
```

f90 This routine uses the function `reallocate` in `nrutil` to define a temporary workspace and then, if necessary, enlarge the workspace without destroying the earlier contents. The pointer `wksp` is declared with the `SAVE` attribute. Since Fortran 90 pointers are born “in limbo,” we cannot immediately test whether they are associated or not. Hence the code `if (init)...nullify(wksp)`. Then the line `wksp=>reallocate(wksp,100)` allocates an array of length 100 and points `wksp` to it. On subsequent calls to `eulsum`, if `nterm` ever gets bigger than the size of `wksp`, the call to `reallocate` doubles the size of `wksp` and copies the old contents into the new storage.

You could achieve the same effect as the code `if (init)...nullify(wksp)...wksp=>reallocate(wksp,100)` with a simple `allocate(wksp,100)`. You would then use

reallocate only for increasing the storage if necessary. Don't! The advantage of the above scheme becomes clear if you consider what happens if `eulsum` is invoked *twice* by the calling program to evaluate two different sums. On the second invocation, when `jterm` = 1 again, you would be allocating an already allocated pointer. This does not generate an error — it simply leaves the original target inaccessible. Using `realloc` instead not only allocates a new array of length 100, but also detects that `wksp` had already been associated. It dutifully (and wastefully) copies the first 100 elements of the old `wksp` into the new storage, and, more importantly, deallocates the old `wksp`, reclaiming its storage. While only two invocations of `eulsum` without intervening deallocation of memory would not cause a problem, many such invocations might well. We believe that, as a general rule, the potential for catastrophe from reckless use of `allocate` is great enough that you should *always deallocate* whenever storage is no longer required.

The unnecessary copying of 100 elements when `eulsum` is invoked a second time could be avoided by making `init` an argument. It hardly seems worth it to us.

For Fortran 90 neophytes, note that unlike in C you have to do nothing special to get the contents of the storage a pointer is addressing. The compiler figures out from the context whether you mean the contents, such as `wksp(1:nterm)`, or the address, such as both occurrences of `wksp` in `wksp=>realloc(wksp,100)`.

`wksp(1:nterm+1)=poly_term(wksp(1:nterm+1),0.5_sp)` The `poly_term` function in `nrutil` tabulates the partial sums of a polynomial, or, equivalently, performs the synthetic division of a polynomial by a monomial.

Small-scale parallelism in `eulsum` is achieved straightforwardly by the use of vector constructions and `poly-term` (which parallelizes recursively).

The routine is not written to take advantage of data parallelism in the (infrequent) case of wanting to sum many different series simultaneously; nor, since `wksp` is a SAVED variable, can it be used in many simultaneous instances on a MIMD machine. (You can easily recode these generalizations if you need them.)

pd(3:nd)=fac(2:nd-1)*pd(3:nd)
      After the first derivative, factorial constants
      come in.
END SUBROUTINE ddpoly

```

f90 `d(nc:1:-1)=poly_term(c(nc:1:-1),x)` The `poly_term` function in `nrutil` tabulates the partial sums of a polynomial, or, equivalently, performs synthetic division. See §22.3 for a discussion of why `ddpoly` is coded this way.

`fac=cumprod(arth(1.0_sp,1.0_sp,nd))` Here the function `arth` from `nrutil` generates the sequence 1, 2, 3.... The function `cumprod` then tabulates the cumulative products, thus making a table of factorials.

Notice that `ddpoly` doesn't need an argument to pass N_d , the number of output terms desired by the user: It gets that information from the length of the array `pd` that the user provides for it to fill. It is a minor curiosity that `pd`, declared as `INTENT(OUT)`, can thus be used, on the sly, to pass some `INTENT(IN)` information. (A Fortran 90 brain teaser could be: A subroutine with only `INTENT(OUT)` arguments can be called to print any specified integer. How is this done?)

```
SUBROUTINE poldiv(u,v,q,r)
USE nrtype; USE nrutil, ONLY : assert_eq

END FUNCTION ratval_s
```

f90 This simple routine uses the function `poly` from `nrutil` to evaluate the numerator and denominator polynomials. Single- and double-precision versions, `ratval_s` and `ratval_v`, are overloaded onto the name `ratval` when the module `nr` is used.

```

FUNCTION ratval_v(x,cof,mm,kk)
USE nrtype; USE nrutil, ONLY : poly
IMPLICIT NONE
REAL(DP), DIMENSION(:), INTENT(IN) :: x
INTEGER(I4B), INTENT(IN) :: mm,kk
REAL(DP), DIMENSION(mm+kk+1), INTENT(IN) :: cof
REAL(DP), DIMENSION(size(x)) :: ratval_v
ratval_v=poly(x,cof(1:mm+1))/(1.0_dp+x*poly(x,cof(mm+2:mm+kk+1)))
END FUNCTION ratval_v

```

★ ★ ★

The routines `recur1` and `recur2` are new in this volume, and do not have Fortran 77 counterparts. First- and second-order linear recurrences are implemented as trivial do-loops on strictly serial machines. On parallel machines, however, they pose different, and quite interesting, programming challenges. Since many calculations can be decomposed into recurrences, it is useful to have general, parallelizable routines available. The algorithms behind `recur1` and `recur2` are discussed in §22.2.

```

RECURSIVE FUNCTION recur1(a,b) RESULT(u)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: a,b
REAL(SP), DIMENSION(size(a)) :: u
INTEGER(I4B), PARAMETER :: NPAR_RECUR1=8
Given vectors a of size n and b of size n - 1, returns a vector u that satisfies the first
order linear recurrence  $u_1 = a_1$ ,  $u_j = a_j + b_{j-1}u_{j-1}$ , for  $j = 2, \dots, n$ . Parallelization is
via a recursive evaluation.
INTEGER(I4B) :: n,j
n=assert_eq(size(a),size(b)+1,'recur1')
u(1)=a(1)
if (n < NPAR_RECUR1) then           Do short vectors as a loop.
  do j=2,n
    u(j)=a(j)+b(j-1)*u(j-1)
  end do
else
  Otherwise, combine coefficients and recurse on the even components, then evaluate all
  the odd components in parallel.
  u(2:n:2)=recur1(a(2:n:2)+a(1:n-1:2)*b(1:n-1:2), &
                  b(3:n-1:2)*b(2:n-2:2))
  u(3:n:2)=a(3:n:2)+b(2:n-1:2)*u(2:n-1:2)
end if
END FUNCTION recur1

```

RECURSIVE FUNCTION `recur1(a,b)` RESULT(`u`) When a recursive function invokes itself only indirectly through a sequence of function calls, then the function name can be used for the result just as in a nonrecursive function. When the function invokes itself directly, however, as in `recur1`, then another name must be used for the result. If you are hazy on the syntax for `RESULT`, see the discussion of recursion in §21.5.

    func(real(cos(theta)*bma+bpa,sp)))*2.0_dp/n
    We evaluate the function at the  $n$  points required by (5.8.7). We accumulate the sum
    in double precision for safety.
END FUNCTION chebft
```

f90 `chebft(:)=matmul(...)` Here again Fortran 90 produces a very concise parallelizable formulation that requires some effort to decode. Equation (5.8.7) is a product of the matrix of cosines, where the rows are indexed by j and the columns by k , with the vector of function values indexed by k . We use the `outerprod` function in `nrutil` to form the matrix of arguments for the cosine, and rely on the element-by-element application of `cos` to produce the matrix of cosines. `matmul` then takes care of the matrix product. A subtlety is that, while the calculation is being done in double precision to minimize roundoff, the function is assumed to be supplied in single precision. Thus `real(...,sp)` is used to convert the double precision argument to single precision.

```
FUNCTION chebev_s(a,b,c,x)
USE nrtype; USE nrutil, ONLY : nrerror
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b,x
REAL(SP), DIMENSION(:), INTENT(IN) :: c

SUBROUTINE pcshft(a,b,d)
USE nrtype; USE nrutil, ONLY : geop
IMPLICIT NONE
REAL(SP), INTENT(IN) :: a,b
REAL(SP), DIMENSION(:), INTENT(INOUT) :: d
    Polynomial coefficient shift. Given a coefficient array d of length N, this routine generates
    a coefficient array g of the same length such that  $\sum_{k=1}^N d_k y^{k-1} = \sum_{k=1}^N g_k x^{k-1}$ , where
    x and y are related by (5.8.10), i.e., the interval  $-1 < y < 1$  is mapped to the interval
    a < x < b. The array g is returned in d.
INTEGER(I4B) :: j,n
REAL(SP), DIMENSION(size(d)) :: dd
REAL(SP) :: x
n=size(d)
dd=d*geop(1.0_sp,2.0_sp/(b-a),n)
x=-0.5_sp*(a+b)
d(1)=dd(n)
d(2:n)=0.0
do j=n-1,1,-1
    d(2:n+1-j)=d(2:n+1-j)*x+d(1:n-j)           We accomplish the shift by synthetic division, that miracle of
    d(1)=d(1)*x+dd(j)                           high-school algebra.
end do
END SUBROUTINE pcshft

```

There is a subtle, but major, distinction between the synthetic division algorithm used in the Fortran 77 version of `pcshft` and that used above.

In the Fortran 77 version, the synthetic division (translated to Fortran 90 notation) is

```

d(1:n)=dd(1:n)
do j=1,n-1
    do k=n-1,j,-1
        d(k)=x*d(k+1)+d(k)
    end do
end do

```

while, in Fortran 90, it is

```

d(1)=dd(n)
d(2:n)=0.0
do j=n-1,1,-1
    d(2:n+1-j)=d(2:n+1-j)*x+d(1:n-j)
    d(1)=d(1)*x+dd(j)
end do

```

As explained in §22.3, these are algebraically — but not algorithmically — equivalent. The inner loop in the Fortran 77 version does not parallelize, because each k value uses the result of the previous one. In fact, the k loop is a synthetic division, which can be parallelized *recursively* (as in the `nrutil` routine `poly_term`), but not simply

vectorized. In the Fortran 90 version, since not one but $n-1$ successive synthetic divisions are to be performed (by the outer loop), it is possible to reorganize the calculation to allow vectorization.

write(*,10) it,devmax
end do
10 format (' ratlsq iteration=',i2,' max error=',1p,e10.3)
END SUBROUTINE ratlsq

```

temp=geop(spread(1.0_dp,1,npt),xs,ncof) The design matrix u_{ij} is de-

fined for $i = 1, \dots, npts$ by

$$u_{ij} = \begin{cases} w_i x_i^{j-1}, & j = 1, \dots, m+1 \\ -b_i x_i^{j-m-2}, & j = m+2, \dots, n \end{cases} \quad (\text{B5.12})$$

The first case in equation (B5.12) is computed in parallel by constructing the matrix temp equal to

$$\begin{bmatrix} 1 & x_1 & x_1^2 & \cdots \\ 1 & x_2 & x_2^2 & \cdots \\ 1 & x_3 & x_3^2 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

and then multiplying by the matrix spread(wt,2,mm+1), which is just

$$\begin{bmatrix} w_1 & w_1 & w_1 & \cdots \\ w_2 & w_2 & w_2 & \cdots \\ w_3 & w_3 & w_3 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{bmatrix}$$

(Remember that multiplication using * means element-by-element multiplication, not matrix multiplication.) A similar construction is used for the second part of the design matrix.

Chapter B6. Special Functions

f90 A Fortran 90 intrinsic function such as `sin(x)` is both *generic* and *elemental*. Generic means that the argument `x` can be any of multiple intrinsic data types and kind values (in the case of `sin`, any real or complex kind). Elemental means that `x` need not be a scalar, but can be an array of any rank and shape, in which case the calculation of `sin` is performed independently for each element.

Ideally, when we implement more complicated special functions in Fortran 90, as we do in this chapter, we would make them, too, both generic and elemental. Unfortunately, the language standard does not completely allow this. User-defined elemental functions are prohibited in Fortran 90, though they will be allowed in Fortran 95. And, there is no fully automatic way of providing for a single routine to allow arguments of multiple data types or kinds — nothing like C++’s “class templates,” for example.

However, don’t give up hope! Fortran 90 does provide a powerful mechanism for overloading, which can be used (perhaps not always with a maximum of convenience) to *simulate* both generic and elemental function features. In most cases, when we implement a special function with a scalar argument, `gammln(x)` say, we will also implement a corresponding vector-valued function of vector argument that evaluates the special function for each component of the vector argument. We will then overload the scalar and vector version of the function onto the same function name. For example, within the `nr` module are the lines

```
INTERFACE gammln
  FUNCTION gammln_s(xx)
    USE nrtype
    REAL(SP), INTENT(IN) :: xx
    REAL(SP) :: gammln_s
  END FUNCTION gammln_s

  FUNCTION gammln_v(xx)
    USE nrtype
    REAL(SP), DIMENSION(:), INTENT(IN) :: xx
    REAL(SP), DIMENSION(size(xx)) :: gammln_v
  END FUNCTION gammln_v
END INTERFACE
```

which can be included by a statement like “`USE nr, ONLY: gammln`,” and then allow you to write `gammln(x)` without caring (or even thinking about) whether `x` is a scalar or a vector. If you want arguments of even higher rank (matrices, and so forth), you can provide these yourself, based on our models, and overload them, too.

That takes care of “elemental”; what about “generic”? Here, too, overloading provides an acceptable, if not perfect, solution. Where double-precision versions of special functions are needed, you can in many cases easily construct them from our provided routines by changing the variable kinds (and any necessary convergence

parameters), and then additionally overload them onto the same generic function names. (In general, in the interest of brevity, we will not ourselves do this for the functions in this chapter.)

At first meeting, Fortran 90's overloading capability may seem trivial, or merely cosmetic, to the Fortran 77 programmer; but one soon comes to rely on it as an important conceptual simplification. Programming at a "higher level of abstraction" is usually more productive than spending time "bogged down in the mud." Furthermore, the use of overloading is generally fail-safe: If you invoke a generic name with arguments of shapes or types for which a specific routine has not been defined, the compiler tells you about it.

We won't reprint the module `nr`'s interface blocks for all the routines in this chapter. When you see routines named `something_s` and `something_v`, below, you can safely assume that the generic name `something` is defined in the module `nr` and overloaded with the two specific routine names. A full alphabetical listing of all the interface blocks in `nr` is given in Appendix C2.

Given our heavy investment, in this chapter, in overloadable vector-valued special function routines, it is worth discussing whether this effort is simply a stopgap measure for Fortran 90, soon to be made obsolete by Fortran 95's provision of user-definable `ELEMENTAL` procedures. The answer is "not necessarily," and takes us into some speculation about the future of SIMD, versus MIMD, computing.

Elemental procedures, while applying the same executable code to each element, do not insist that it be feasible to perform all the parallel calculations in lockstep. That is, elemental procedures can have tests and branches (`if-then-else` constructions) that result in different elements being calculated by totally different pieces of code, in a fashion that can only be determined at run time. For true 100% MIMD (multiple instruction, multiple data) machines, this is not a problem: individual processors do the individual element calculations asynchronously.

However, virtually none of today's (and likely tomorrow's) largest-scale parallel supercomputers are 100% MIMD in this way. While modern parallel supercomputers increasingly have MIMD features, they continue to reward the use of SIMD (single instruction, multiple data) code with greater computational speed, often because of hardware pipelining or vector processing features within the individual processors. The use of Fortran 90 (or, for that matter Fortran 95) in a data-parallel or SIMD mode is thus by no means superfluous, or obviated by Fortran 95's `ELEMENTAL` construction.

The problem we face is that parallel calculation of special function values often doesn't fit well into the SIMD mold: Since the calculation of the value of a special function typically requires the convergence of an iterative process, as well as possible branches for different values of arguments, it cannot *in general* be done efficiently with "lockstep" SIMD programming.

Luckily, in particular cases, including most (but not all) of the functions in this chapter, one can in fact make reasonably good parallel implementations with the SIMD tools provided by the language. We will in fact see a number of different tricks for accomplishing this in the code that follows.

We are interested in demonstrating SIMD techniques, but we are not completely impractical. None of the data-parallel implementations given below are too inefficient on a scalar machine, and some may in fact be faster than Fortran 95's `ELEMENTAL`

alternative, or than do-loops over calls to the scalar version of the function. On a scalar machine, how can this be? We have already, above, hinted at the answer: (i) most modern scalar processors can overlap instructions to some degree, and data-parallel coding often provides compilers with the ability to accomplish this more efficiently; and (ii) data-parallel code can sometimes give better cache utilization.

    ser=ser+coef(i)/y
end do
gammln_v=tmp+log(stp*ser/x)
END FUNCTION gammln_v

```

f90 call assert(xx > 0.0, 'gammln_s arg') We use the `nrutil` routine `assert` for functions that have restrictions on the allowed range of arguments. One could instead have used an `if` statement with a call to `nrerror`; but we think that the uniformity of using `assert`, and the fact that its logical arguments read the “desired” way, not the “erroneous” way, make for a clearer programming style. In the vector version, the `assert` line is:

```
call assert(all(xx > 0.0), 'gammln_v arg')
```

Notice that the scalar and vector versions achieve parallelism in quite different ways, something that we will see many times in this chapter.

In the scalar case, parallelism (at least small-scale) is achieved through constructions like

```
sum(coef(:)/arth(x+1.0_dp,1.0_dp,size(coef)))
```

Here vector utilities construct the series $x + 1, x + 2, \dots$ and then sum a series with these terms in the denominators and a vector of coefficients in the numerators. (This code may seem terse to Fortran 90 novices, but once you get used to it, it is quite clear to read.)

In the vector version, by contrast, parallelism is achieved across the components of the vector argument, and the above series is evaluated sequentially as a do-loop. Obviously the assumption is that the length of the vector argument is much longer than the very modest number (here, 6) of terms in the sum.

end if                                      Actually, this big a value is going to overflow
END FUNCTION factrl_s                      on many computers, but no harm in trying.
```

f90 `cumprod(arth(1.0_sp,1.0_sp,NMAX-1))` By now you should recognize this as an idiom for generating a vector of consecutive factorials. The routines `cumprod` and `arth`, both in `nrutil`, are both capable of being parallelized, e.g., by recursion, so this idiom is potentially faster than an in-line do-loop.

```

FUNCTION factrl_v(n)
USE nrtype; USE nrutil, ONLY : arth,assert,cumprod
USE nr, ONLY : gammln

factrl_v=unpack(exp(gammln(pack(n,mask)+1.0_sp)),mask,0.0_sp)
where (.not. mask) factrl_v=a(n+1)
END FUNCTION factrl_v

```

unpack(exp(gammln(pack(n,mask)+1.0_sp)),mask,0.0_sp) Here we meet the first of several solutions to a common problem: How shall we get answers, from an external vector-valued function, for just a *subset* of vector arguments, those defined by a mask? Here we use what we call the “pack-unpack” solution: Pack up all the arguments using the mask, send them to the function, and unpack the answers that come back. This packing and unpacking is not without cost (highly dependent on machine architecture, to be sure), but we hope to “earn it back” in the parallelism of the external function.

where (.not. mask) factrl_v=a(n+1) In some cases we might take care of the .not. mask case directly within the unpack construction, using its third (“FIELD=”) argument to provide the not-unpacked values. However, there is no guarantee that the compiler won’t evaluate all components of the “FIELD=” array, if it finds it efficient to do so. Here, since the index of a(n+1) would be out of range, we can’t do it this way. Thus the separate where statement.

               1.0_sp-gcf(a,merge(x,0.0_sp,.not. mask)),mask)
END FUNCTION gammp_v

```

f90

call assert(x >= 0.0, a > 0.0, 'gammp_s args') The generic routine assert in nrutil is overloaded with variants for more than one logical assertion, so you can make more than one assertion about argument ranges.

||| gammp_v=merge(gser(a,merge(x,0.0_sp,mask)), &
 1.0_sp-gcf(a,merge(x,0.0_sp,.not. mask)),mask) Here we meet the *second* solution to the problem of getting masked values from an external vector function. (For the first solution, see note to factrl, above.) We call this one “merge with dummy values”: Inappropriate values of the argument x (as determined by mask) are set to zero before gser, and later gcf, are called, and the supernumerary answers returned are discarded by a final merge. The assumption here is that the dummy value sent to the function (here, zero) is a special value that computes extremely fast, so that the overhead of computing and returning the supernumerary function values is outweighed by the parallelism achieved on the nontrivial components of x. Look at gser_v and gcf_v below to judge whether this assumption is realistic in this case.

```

f90 REAL(SP), OPTIONAL, INTENT(OUT) :: gln Normally, an OPTIONAL argument will be INTENT(IN) and be used to provide a less-often-used extra input argument to a function. Here, the OPTIONAL argument is INTENT(OUT), used to provide a useful value that is a byproduct of the main calculation.

Also note that although $x \geq 0$ is required, we omit our usual call assert check for this, because gser is supposed to be called only by gammp or gammq — and these routines supply the argument checking themselves.

do n=1,ITMAX...end do...if (n > ITMAX)... This is typical code in Fortran 90 for a loop with a maximum number of iterations, relying on Fortran 90's guarantee that the index of the do-loop will be available after normal completion of the loop with a predictable value, greater by one than the upper limit of the loop. If the exit statement within the loop is ever taken, the if statement is guaranteed to fail; if the loop goes all the way through ITMAX cycles, the if statement is guaranteed to succeed.

||||| zero=(x == 0.0)...where (zero) gser_v=0.0...converged=zero This is the code that provides for very low overhead calculation of zero arguments, as is assumed by the merge-with-dummy-values strategy in gammp and gammq. Zero arguments are “pre-converged” and are never the holdouts in the convergence test.

```
FUNCTION gcf_s(a,x,gln)

★ ★ ★

```
FUNCTION erf_s(x)
USE nrtype
USE nr, ONLY : gammp
IMPLICIT NONE
REAL(SP), INTENT(IN) :: x
REAL(SP) :: erf_s
    Returns the error function erf(x).
erf_s=gammp(0.5_sp,x**2)
if (x < 0.0) erf_s=-erf_s
END FUNCTION erf_s
```

```
FUNCTION erf_v(x)
USE nrtype
USE nr, ONLY : gammp
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: x
REAL(SP), DIMENSION(size(x)) :: erf_v
erf_v=gammp(spread(0.5_sp,1,size(x)),x**2)
where (x < 0.0) erf_v=-erf_v
END FUNCTION erf_v
```

 `erf_v=gammp(spread(0.5_sp,1,size(x)),x**2)` Yes, we do have an overloaded vector version of `gammp`, but it is vectorized on *both* its arguments.

Thus, in a case where we want to vectorize on only *one* argument, we need a `spread` construction. In many contexts, Fortran 90 automatically makes scalars conformable with arrays (i.e., it automatically spreads them to the shape of the array); but the language does *not* do so when trying to match a generic function or subroutine call to a specific overloaded name. Perhaps this is wise; it is safer to prevent “accidental” invocations of vector-specific functions. Or, perhaps it is an area where the language could be improved.

```
FUNCTION erfc_s(x)
USE nrtype
USE nr, ONLY : gammp,gammq
IMPLICIT NONE
REAL(SP), INTENT(IN) :: x
REAL(SP) :: erfc_s
    Returns the complementary error function erfc(x).
erfc_s=merge(1.0_sp+gammp(0.5_sp,x**2),gammq(0.5_sp,x**2), x < 0.0)
END FUNCTION erfc_s
```

 `erfc_s=merge(1.0_sp+gammp(0.5_sp,x**2),gammq(0.5_sp,x**2), x < 0.0)` An example of our use of `merge` as an idiom for a conditional expression. Once you get used to these, you’ll find them just as clear as the multiline `if...then...else` alternative.

```

FUNCTION erfc_v(x)
USE nrtype
USE nr, ONLY : gammp,gammq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: x
REAL(SP), DIMENSION(size(x)) :: erfc_v
LOGICAL(LGT), DIMENSION(size(x)) :: mask
mask = (x < 0.0)
erfc_v=merge(1.0_sp+gammp(spread(0.5_sp,1,size(x)), &
    merge(x,0.0_sp,mask)**2),gammq(spread(0.5_sp,1,size(x)), &
    merge(x,0.0_sp,.not. mask)**2),mask)
END FUNCTION erfc_v

```

f90 `erfc_v=merge(1.0_sp+...)` Another example of the “merge with dummy values” idiom described on p. 1090. Here positive values of x in the call to `gammp`, and negative values in the call to `gammq`, are first set to the dummy value zero. The value zero is a special argument that computes very fast. The unwanted dummy function values are then discarded by the final outer `merge`.

★ ★ ★

```

FUNCTION erfcc_s(x)
USE nrtype; USE nrutil, ONLY : poly
IMPLICIT NONE
REAL(SP), INTENT(IN) :: x
REAL(SP) :: erfcc_s
    Returns the complementary error function  $\text{erfc}(x)$  with fractional error everywhere less than
     $1.2 \times 10^{-7}$ .
REAL(SP) :: t,z
REAL(SP), DIMENSION(10) :: coef = (/ -1.26551223_sp, 1.00002368_sp, &
    0.37409196_sp, 0.09678418_sp, -0.18628806_sp, 0.27886807_sp, &
    -1.13520398_sp, 1.48851587_sp, -0.82215223_sp, 0.17087277_sp /)

```

FUNCTION erfcc_v(x)
USE nrtype; USE nrutil, ONLY : poly
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: x
REAL(SP), DIMENSION(size(x)) :: erfcc_v,t,z
REAL(SP), DIMENSION(10) :: coef = (/ -1.26551223_sp, 1.00002368_sp, &
    0.37409196_sp, 0.09678418_sp, -0.18628806_sp, 0.27886807_sp, &
    -1.13520398_sp, 1.48851587_sp, -0.82215223_sp, 0.17087277_sp /)
z=abs(x)
t=1.0_sp/(1.0_sp+0.5_sp*z)
erfcc_v=t*exp(-z*z+poly(t,coef))
where (x < 0.0) erfcc_v=2.0_sp-erfcc_v
END FUNCTION erfcc_v

```

f90 `erfcc_v=t*exp(-z*z+poly(t,coef))` The vector code is identical to the scalar, because the `nrutil` routine `poly` has overloaded cases for the evaluation of a polynomial at a single value of the independent variable, and at multiple values. One *could* also overload a version with a matrix of coefficients whose columns could be used for the simultaneous evaluation of different polynomials at different values of independent variable. The point is that as long as there are differences in the shapes of at least one argument, the intended version of `poly` can be discerned by the compiler.

★ ★ ★

```

FUNCTION expint(n,x)
USE nrtype; USE nrutil, ONLY : arth,assert,nrerror
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: n
REAL(SP), INTENT(IN) :: x
REAL(SP) :: expint
INTEGER(I4B), PARAMETER :: MAXIT=100

        if (term < EPS) exit
        if (term < prev) then
            sm=sm+term
        else
            sm=sm-prev
            exit
        end if
    end do
    if (k > MAXIT) call nrerror('asymptotic failed in ei')
    ei=exp(x)*(1.0_sp+sm)/x
end if
END FUNCTION ei

```

Special case: avoid failure of convergence test
because of underflow.
Use power series.

Use asymptotic series.
Start with second term.

Since final sum is greater than one, term itself
approximates the relative error.
Still converging: add new term.
Diverging: subtract previous term and exit.

 ei does not readily parallelize, and we thus don't provide a vector version. For syntactic convenience you could make a vector version with a do-loop over calls to this scalar version; or, in Fortran 95, you can of course make the function ELEMENTAL.

f90 `d=merge(FPMIN,d, abs(d)<FPMIN)` The scalar version does this with an `if`. Why does it become a `merge` here in the vector version, rather than a `where`? Because we are already inside a “`where (.not.converged)`” block, and Fortran 90 doesn’t allow nested `where’s!` (Fortran 95 *will* allow nested `where’s.`)

```

 where (mask)...bessj0_v=poly(y,r,mask)/poly(y,s,mask) Here we meet the *third* solution to the problem of getting masked values from an external vector function. (For the other two solutions, see notes to `factrl`, p. 1087, and `gammp`, p. 1090.) Here we simply evade all responsibility and pass the mask into every routine that is supposed to be masked. Let it be somebody else's problem! That works here because your hardworking authors have overloaded the `nrutil` routine `poly` with a masked vector version. More typically, of course, it becomes *your* problem, and you have to remember to write masked versions of all the vector routines that you call in this way. (We'll meet examples of this later.)

f90 Notice that the vector routine is *exactly* the same as the scalar routine, but operates only on vectors, and that nothing in the routine is specific to any level of precision or kind type of real variable. Cases like this make us wish that Fortran 90 provided for “template” types that could automatically take the type and shape of the actual arguments. (Such facilities are available in other, more object-oriented languages such as C++.)

```

Downwards recurrence from an even m
here computed.

jsum will alternate between 0 and 1; when
it is 1, we accumulate in sum the
even terms in (5.5.16).

The downward recurrence.

Renormalize to prevent overflows.

Accumulate the sum.
Change 0 to 1 or vice versa.
Save the unnormalized answer.

Compute (5.5.16)
and use it to normalize the answer.

The `bessj` routine does not conveniently parallelize with Fortran 90's language constructions, but Bessel functions are of sufficient importance that we feel the need for a parallel version nevertheless. The basic method adopted below is to encapsulate as contained vector functions two separate algorithms, one for the case $x \leq n$, the other for $x > n$. Both of these have masks as input arguments; within each routine, however, they immediately revert to the pack-unpack method. The choice to pack in the subsidiary routines, rather than in the main routine, is arbitrary; the main routine is supposed to be a little clearer this way.

f90

if (exponent(bj) > IEXP) then... In the Fortran 77 version of this routine, we scaled the variables by 10^{-10} whenever bj was bigger than 10^{10} . On a machine with a large exponent range, we could improve efficiency by scaling less often. In order to remain portable, however, we used the conservative value of 10^{10} . An elegant way of handling renormalization is provided by the Fortran 90 intrinsic functions that manipulate real numbers. We test with `if (exponent(bj) > IEXP)` and then if necessary renormalize with `bj=scale(bj,-IEXP)` and similarly for the other variables. Our conservative choice is to set `IEXP=maxexponent(x)/2`. Note that an added benefit of scaling this way is that only the exponent of each variable is modified; no roundoff error is introduced as it can be if we do a floating-point division instead.

Equation (6.7.13).
Evaluate CF2 by modified Lentz's method
(§5.2).

Equations (6.7.6) – (6.7.10).

Scale original J_ν and J'_ν .

Upward recurrence of Y_ν .

 Yes there is a vector version `bessjy_v`. Its general scheme is to have a bunch of contained functions for various cases, and then combine their outputs (somewhat like `bessj_v`, above, but much more complicated). A listing runs to about four printed pages, and we judge it to be of not much interest, so we will not include it here. (It is included on the machine-readable media.)

```

Evaluate CF2 by Steed's algorithm (§5.2),
which is OK because there can be no
zero denominators.

Initializations for recurrence (6.7.35).

First term in equation (6.7.34).

Need only test convergence of sum, since
CF2 itself converges more quickly.

Omit the factor $\exp(-x)$ to scale all the
returned functions by $\exp(x)$ for $x \geq XMIN$.

Get I_μ from Wronskian.
Scale original I_ν and I'_ν .

Upward recurrence of K_ν .

bessik does not readily parallelize, and we thus don't provide a vector version. Since airy, immediately following, requires bessik, we don't have a vector version of it, either.

 All those if's (not where's) may strike you as odd in a vector routine, but it is vectorized only on x , the dependent variable, not on the scalar indices l and m . Much harder to write a routine that is parallel for a vector of arbitrary triplets (l, m, x) . Try it!

f90 $b=\text{cmplx}(1.0_sp, -\text{pix2}, \text{kind}=spc)$ It's a good idea *always* to include the `kind=` parameter when you use the `cmplx` intrinsic. The reason is that, perhaps counterintuitively, the result of `cmplx` is not determined by the kind of its arguments, but is rather the "default complex kind." Since that default may not be what you think it is (or what `spc` is defined to be), the desired kind should be specified explicitly.

`c=real(cs)` And why not specify a `kind=` parameter here, where it is also optionally allowed? Our answer is that the `real` intrinsic actually merges two different usages. When its argument is complex, it is the counterpart of `aimag` and returns a value whose kind is determined by the kind of its argument. In fact `aimag` doesn't even allow an optional kind parameter, so we never put one in the corresponding use of `real`. The other usage of `real` is for "casting," that is, converting one real type to another (e.g., double precision to single precision, or vice versa). Here we *always* include a kind parameter, since otherwise the result is the default real kind, with the same dangers mentioned in the previous paragraph.

```

f90 REAL(SP), DIMENSION(NMAX), SAVE :: c=/((0.0_sp,i=1,NMAX) /) This is one way to give initial values to an array. Actually, we're somewhat nervous about using the “implied do-loop” form of the array constructor, as above, because our parallel compilers might not always be smart enough to execute the constructor in parallel. In this case, with NMAX=6, the damage potential is quite minimal. An alternative way to initialize the array would be with a data statement, “DATA c /NMAX*0.0_sp/”; however, this is not considered good Fortran 90 style, and there is no reason to think that it would be faster.

c(1:NMAX)=exp(-(arth(1,2,NMAX)*H)**2) Another example where the arth function of nrutil comes in handy. Otherwise, this would be

```

do i=1,NMAX
    c(i)=exp(-((2.0_sp*i-1.0_sp)*H)**2)
end do

```

arth(n0+1,2,NMAX)...arth(n0-1,-2,NMAX)...geop(ec,ec**2,NMAX) These are not just notationally convenient for generating the sequences $(n_0 + 1, n_0 + 3, n_0 + 5, \dots)$, $(n_0 - 1, n_0 - 3, n_0 - 5, \dots)$, and (ec, ec^3, ec^5, \dots) . They also may allow parallelization with parallel versions of arth and geop, such as those in nrutil.

```

f90 `unpack(3.0_sp*(rc(pack(rho,mask),pack(tau,mask))...),mask,0.0_sp)` If you're willing to put up with fairly unreadable code, you can use the pack-unpack trick (for getting a masked subset of components out of a vector function) right in-line, as here. Of course the "outer level" that is seen by the enclosing `where` construction has to contain only objects that have the same shape as the `mask` that goes with the `where`. Because it is so hard to read, we don't like to do this very often. An alternative would be to use `CONTAINS` to incorporate short, masked "wrapper functions" for the functions used in this way.

```

f90 Notice that the real array (of length 4) `ry` is immediately mapped into a complex array of length 2, and that the process is reversed at the end of the routine with `rdyds`. In Fortran 77 no such mapping is necessary: the calling program sends real arguments, and the Fortran 77 `hypdrv` simply interprets what is sent as complex. Fortran 90's stronger typing does not encourage (and, practically, does not allow) this convenience; but it is a small price to pay for the vastly increased error-checking capabilities of a strongly typed language.

Chapter B7. Random Numbers

One might think that good random number generators, including those in Volume 1, should last forever. The world of computing changes very rapidly, however:

- When Volume 1 was published, it was unusual, except on the fastest supercomputers, to “exhaust” a 32-bit random number generator, that is, to call for all 2^{32} sequential random values in its periodic sequence. Now, this is feasible, and not uncommon, on fast desktop workstations. A useful generator today must have a minimum of 64 bits of state space, and generally somewhat more.
- Before Fortran 90, the Fortran language had no standardized calling sequence for random numbers. Now, although there is still no standard *algorithm* defined by the language (rightly, we think), there is at least a standard calling sequence, exemplified in the intrinsics `random_number` and `random_seed`.
- The rise of parallel computing places new algorithmic demands on random generators. The classic algorithms, which compute each random value from the previous one, evidently need generalization to a parallel environment.
- New algorithms and techniques have been discovered, in some cases significantly faster than their predecessors.

These are the reasons that we have decided to implement, in Fortran 90, different uniform random number generators from those in Volume 1’s Fortran 77 implementations. We hasten to add that there is nothing wrong with any of the generators in Volume 1. That volume’s `ran0` and `ran1` routines are, to our knowledge, completely adequate as 32-bit generators; `ran2` has a 64-bit state space, and our previous offer of \$1000 for *any* demonstrated failure in the algorithm has never yet been claimed (see [1]).

Before we launch into the discussion of parallelizable generators with Fortran 90 calling conventions, we want to attend to the continuing needs of longtime “`x=ran(idum)`” users with purely serial machines. If you are a satisfied user of Volume 1’s `ran0`, `ran1`, or `ran2` Fortran 77 versions, you are in this group. The following routine, `ran`, preserves those routines’ calling conventions, is considerably faster than `ran2`, and does not suffer from the old `ran0` or `ran1`’s 32-bit period exhaustion limitation. It is completely portable to all Fortran 90 environments. We recommend `ran` as the plug-compatible replacement for the old `ran0`, `ran1`, and `ran2`, and we happily offer exactly the same \$1000 reward terms as were (and are still) offered on the old `ran2`.

```

FUNCTION ran(idum)
IMPLICIT NONE
INTEGER, PARAMETER :: K4B=selected_int_kind(9)
INTEGER(K4B), INTENT(INOUT) :: idum
REAL :: ran
    "Minimal" random number generator of Park and Miller combined with a Marsaglia shift
    sequence. Returns a uniform random deviate between 0.0 and 1.0 (exclusive of the endpoint
    values). This fully portable, scalar generator has the "traditional" (not Fortran 90) calling
    sequence with a random deviate as the returned function value: call with idum a negative
    integer to initialize; thereafter, do not alter idum except to reinitialize. The period of this
    generator is about  $3.1 \times 10^{18}$ .
    INTEGER(K4B), PARAMETER :: IA=16807, IM=2147483647, IQ=127773, IR=2836
    REAL, SAVE :: am
    INTEGER(K4B), SAVE :: ix=-1, iy=-1, k
    if (idum <= 0 .or. iy < 0) then           Initialize.
        am=nearest(1.0,-1.0)/IM
        iy=ieor(ieor(888889999,abs(idum)),1)
        ix=ieor(777755555,abs(idum))
        idum=abs(idum)+1                         Set idum positive.
    end if
    ix=ieor(ix,ishft(ix,13))                  Marsaglia shift sequence with period  $2^{32} - 1$ .
    ix=ieor(ix,ishft(ix,-17))
    ix=ieor(ix,ishft(ix,5))
    k=iy/IQ                                  Park-Miller sequence by Schrage's method,
    iy=IA*(iy-k*IQ)-IR*k                     period  $2^{31} - 2$ .
    if (iy < 0) iy=iy+IM
    ran=am*ieor(iand(IM,ieor(ix,iy)),1)      Combine the two generators with masking to
                                                ensure nonzero value.
END FUNCTION ran

```

This is a good place to discuss a new bit of algorithmics that has crept into `ran`, above, and even more strongly affects all of our new random number generators, below. Consider:

```

ix=ieor(ix,ishft(ix,13))
ix=ieor(ix,ishft(ix,-17))
ix=ieor(ix,ishft(ix,5))

```

These lines update a 32-bit integer `ix`, which cycles pseudo-randomly through a full period of $2^{32} - 1$ values (excluding zero) before repeating. Generators of this type have been extensively explored by Marsaglia (see [2]), who has kindly communicated some additional results to us in advance of publication. For convenience, we will refer to generators of this sort as "Marsaglia shift registers."

Useful properties of Marsaglia shift registers are (i) they are very fast on most machines, since they use only fast logical operations, and (ii) the bit-mixing that they induce is quite different in character from that induced by arithmetic operations such as are used in linear congruential generators (see Volume 1) or lagged Fibonacci generators (see below). Thus, the combination of a Marsaglia shift register with another, algorithmically quite different generator is a powerful way to suppress any residual correlations or other weaknesses in the other generator. Indeed, Marsaglia finds (and we concur) that the above generator (with constants 13, -17, 5, as shown) is *by itself* about as good as any 32-bit random generator.

Here is a very brief outline of the theory behind these generators: Consider the 32 bits of the integer as components in a vector of length 32, in a linear space where addition and multiplication are done modulo 2. Noting that exclusive-or (`ieor`) is the same as addition, each of the three lines in the updating can be written as the action of a 32×32 matrix on a vector, where the matrix is all zeros except for ones on

the diagonal, and on exactly one super- or subdiagonal (corresponding to positive or negative second arguments in `ishft`). Denote this matrix as \mathbf{S}_k , where k is the shift argument. Then, one full step of updating (three lines of code, above) corresponds to multiplication by the matrix $\mathbf{T} \equiv \mathbf{S}_{k_3} \mathbf{S}_{k_2} \mathbf{S}_{k_1}$.

One next needs to find triples of integers (k_1, k_2, k_3) , for example $(13, -17, 5)$, that give the full $M \equiv 2^{32} - 1$ period. Necessary and sufficient conditions are that $\mathbf{T}^M = \mathbf{1}$ (the identity matrix), and that $\mathbf{T}^N \neq \mathbf{1}$ for these five values of N : $N = 3 \times 5 \times 17 \times 257$, $N = 3 \times 5 \times 17 \times 65537$, $N = 3 \times 5 \times 257 \times 65537$, $N = 3 \times 17 \times 257 \times 65537$, $N = 5 \times 17 \times 257 \times 65537$. (Note that each of the five prime factors of M is omitted one at a time to get the five values of N .) The required large powers of \mathbf{T} are readily computed by successive squarings, requiring only on the order of $32^3 \log M$ operations. With this machinery, one can find full-period triples (k_1, k_2, k_3) by exhaustive search, at reasonable cost.

Not all such triples are equally good as generators of random integers, however. Marsaglia subjects candidate values to a battery of tests for randomness, and we have ourselves applied various tests. This stage of winnowing is as much art as science, because all 32-bit generators can be made to exhibit signs of failure due to period exhaustion (if for no other reason). “Good” triples, in order of our preference, are $(13, -17, 5)$, $(5, -13, 6)$, $(5, -9, 7)$, $(13, -17, 15)$, $(16, -7, 11)$. When a full-period triple is good, its reverse is also full-period, and also generally good. A good *quadruple* due to Marsaglia (generalizing the above in the obvious way) is $(-4, 8, -1, 5)$. We would not recommend relying on any single Marsaglia shift generator (nor on any other simple generator) *by itself*. Two or more generators, of quite different types, should be combined [1].

* * *

Let us now discuss explicitly the needs of *parallel* random number generators. The general scheme, from the user’s perspective, is that of Fortran 90’s intrinsic `random_number`: A statement like `call ran1(harvest)` (where `ran1` will be one of our portable replacements for the compiler-dependent `random_number`) should fill the real array `harvest` with pseudo-random real values in the range $(0, 1)$. Of course, we want the underlying machinery to be completely parallel, that is, no do-loops of order $N \equiv \text{size}(\text{harvest})$.

A first design decision is whether to replicate the state-space across the parallel dimension N , i.e., whether to reserve storage for essentially N scalar generators. Although there are various schemes that avoid doing this (e.g., mapping a single, smaller, state space into N different output values on each call), we think that it is a memory cost well worth paying in return for achieving a less exotic (and thus better tested) algorithm. However, this choice dictates that we must keep the state space *per component* quite small. We have settled on five or fewer 32-bit words of state space per component as a reasonable limit. Some otherwise interesting and well tested methods (such as Knuth’s subtractive generator, implemented in Volume 1 as `ran3`) are ruled out by this constraint.

A second design decision is how to initialize the parallel state space, so that different parallel components produce different sequences, and so that there is an acceptable degree of randomness *across* the parallel dimension, as well as *between successive calls* of the generator. Each component starts its life with one and only one unique identifier, its component index n in the range $1 \dots N$. One is

tempted simply to hash the values n into the corresponding components of initial state space. “Random” hashing is a bad idea, however, because different n ’s will produce identical 32-bit hash results by chance when N is no larger than $\sim 2^{16}$. We therefore prefer to use a kind of reversible pseudo-encryption (similar to the routine `psdes` in Volume 1 and below) which guarantees causally that different n ’s produce different state space initializations.

f90 The machinery for allocating, deallocating, and initializing the state space, including provision of a user interface for getting or putting the contents of the state space (as in the intrinsic `random_seed`) is fairly complicated. Rather than duplicate it in each different random generator that we provide, we have consolidated it in a single module, `ran_state`, whose contents we will now discuss. Such a discussion is necessarily technical, if not arcane; on first reading, you may wish to skip ahead to the actual new routines `ran0`, `ran1`, and `ran2`. If you do so, you will need to know only that `ran_state` provides each vector random routine with five 32-bit vectors of state information, denoted `iran`, `jran`, `kran`, `mran`, `nran`. (The overloaded scalar generators have five corresponding 32-bit scalars, denoted `iran0`, etc.)

MODULE ran_state

This module supports the random number routines `ran0`, `ran1`, `ran2`, and `ran3`. It provides each generator with five integers (for vector versions, five vectors of integers), for use as internal state space. The first three integers (`iran`, `jran`, `kran`) are maintained as nonnegative values, while the last two (`mran`, `nran`) have 32-bit nonzero values. Also provided by this module is support for initializing or reinitializing the state space to a desired standard sequence number, hashing the initial values to random values, and allocating and deallocating the internal workspace.

```
USE nrtype
IMPLICIT NONE
INTEGER, PARAMETER :: K4B=selected_int_kind(9)
Independent of the usual integer kind I4B, we need a kind value for (ideally) 32-bit integers.
INTEGER(K4B), PARAMETER :: hg=huge(1_K4B), hgm=-hg, hgng=hgm-1
INTEGER(K4B), SAVE :: lenran=0, seq=0
INTEGER(K4B), SAVE :: iran0,jran0,kran0,nran0,mran0,rans
INTEGER(K4B), DIMENSION(:, :, ), POINTER, SAVE :: ranseeds
INTEGER(K4B), DIMENSION(:, ), POINTER, SAVE :: iran,jran,kran, &
nran,mran,ravn
REAL(SP), SAVE :: amm
INTERFACE ran_hash
    MODULE PROCEDURE ran_hash_s, ran_hash_v
END INTERFACE
CONTAINS
```

Scalar and vector versions of the hashing procedure.

(We here intersperse discussion with the listing of the module.) The module defines `K4B` as an integer `KIND` that is intended to be 32 bits. If your machine doesn’t have 32-bit integers (hard to believe!) this will be caught later, and an error message generated. The definition of the parameters `hg`, `hgm`, and `hgng` makes an assumption about 32-bit integers that goes beyond the strict Fortran 90 integer model, that the magnitude of the most negative representable integer is greater by one than that of the most positive representable integer. This is a property of the *two’s complement arithmetic* that is used on virtually all modern machines (see, e.g., [3]).

The global variables `rans` (for scalar) and `ravn` (for vector) are used by all of our routines to store the *integer* value associated with the most recently returned call. You can access these (with a “`USE ran_state`” statement) if you want `integer`, rather than `real`, random deviates.

The first routine, `ran_init`, is called by routines later in the chapter to initialize their state space. It is *not* intended to be called from a user's program.

```

SUBROUTINE ran_init(length)
USE nrtype; USE nrutil, ONLY : arith,nrerror,reallocate
IMPLICIT NONE
INTEGER(K4B), INTENT(IN) :: length
   Initialize or reinitialize the random generator state space to vectors of size length. The
   saved variable seq is hashed (via calls to the module routine ran_hash) to create unique
   starting seeds, different for each vector component.
INTEGER(K4B) :: new,j,hgt
if (length < lenran) RETURN      Simply return if enough space is already al-
hgt=hg          located.

The following lines check that kind value K4B is in fact a 32-bit integer with the usual properties
that we expect it to have (under negation and wrap-around addition). If all of these tests are
satisfied, then the routines that use this module are portable, even though they go beyond
Fortran 90's integer model.
if (hg /= 2147483647) call nrerror('ran_init: arith assumpt 1 fails')
if (hgng >= 0) call nrerror('ran_init: arith assumpt 2 fails')
if (hgt+1 /= hgng) call nrerror('ran_init: arith assumpt 3 fails')
if (not(hg) >= 0) call nrerror('ran_init: arith assumpt 4 fails')
if (not(hgng) < 0) call nrerror('ran_init: arith assumpt 5 fails')
if (hg+hgng >= 0) call nrerror('ran_init: arith assumpt 6 fails')
if (not(-1_k4b) < 0) call nrerror('ran_init: arith assumpt 7 fails')
if (not(0_k4b) >= 0) call nrerror('ran_init: arith assumpt 8 fails')
if (not(1_k4b) >= 0) call nrerror('ran_init: arith assumpt 9 fails')
if (lenran > 0) then           Reallocate space, or ...
   ranseeds=>reallocate(ranseeds,length,5)
   ranv=>reallocate(ranv,length-1)
   new=lenran+1
else                         allocate space.
   allocate(ranseeds(length,5))
   allocate(ranv(length-1))
   new=1                         Index of first location not yet initialized.
   amm=nearest(1.0_sp,-1.0_sp)/hgng
      Use of nearest is to ensure that returned random deviates are strictly less than 1.0.
      if (amm*hgng >= 1.0 .or. amm*hgng <= 0.0) &
         call nrerror('ran_init: arith assumpt 10 fails')
end if
   Set starting values, unique by seq and vector component.
ranseeds(new:,1)=seq
ranseeds(new:,2:5)=spread(arth(new,1,size(ranseeds(new:,1))),2,4)
do j=1,4                      Hash them.
   call ran_hash(ranseeds(new:,j),ranseeds(new:,j+1))
end do
where (ranseeds(new:,1:3) < 0) &      Enforce nonnegativity.
   ranseeds(new:,1:3)=not(ranseeds(new:,1:3))

   nran0=ranseeds(1,5)
   rans=nran0
end if
if (length > 1) then             Point to vector seeds.
   iran => ranseeds(2:,1)
   jran => ranseeds(2:,2)
   kran => ranseeds(2:,3)
   mran => ranseeds(2:,4)
   nran => ranseeds(2:,5)
   ranv = nran

```

```

end if
lenran=length
END SUBROUTINE ran_init

```

f90 `hgt=hg ... if (hgt+1 /= hgng)` Bit of dirty laundry here! We are testing whether the most positive integer `hg` wraps around to the most negative integer `hgng` when 1 is added to it. We can't just write `hg+1`, since some compilers will evaluate this at compile time and return an overflow error message. If your compiler sees through the charade of the temporary variable `hgt`, you'll have to find another way to trick it.

`amm=nearest(1.0_sp,-1.0_sp)/hgng...` Logically, `amm` should be a parameter; but the `nearest` intrinsic is trouble-prone in the initialization expression for a parameter (named constant), so we compute this at run time. We then check that `amm`, when multiplied by the largest possible negative integer, does not equal or exceed unity. (Our random deviates are guaranteed never to equal zero or unity exactly.)

You might wonder why `amm` is negative, and why we multiply it by negative integers to get positive random deviates. The answer, which will become manifest in the random generators given below, is that we want to use the fast `not` operation on integers to convert them to nonzero values of all one sign. This is possible if the conversion is to negative values, since `not(i)` is negative for all nonnegative `i`. If the conversion were to positive values, we would have problems both with zero (its sign bit is already positive) and `hgng` (since `not(hgng)` is generally zero).

```

iran0=ranseeds(1,1) ...
iran => ranseeds(2:,1)...

```

The initial state information is stored in `ranseeds`, a two-dimensional array whose column (second) index ranges from 1 to 5 over the state variables. `ranseeds(1, :)` is reserved for scalar random generators, while `ranseeds(2: , :)` is for vector-parallel generators. The `ranseeds` array is made available to vector generators through the pointers `iran`, `jran`, `kran`, `mran`, and `nran`. The corresponding scalar values, `iran0`, ..., `nran0` are simply global variables, not pointers, because the overhead of addressing a scalar through a pointer is often too great. (We will have to copy these scalar values back into `ranseeds` when it, rarely, needs to be addressed as an array.)

```

call ran_hash(...) Unique, and random, initial state information is obtained
by putting a user-settable "sequence number" into iran, a component number into
jran, and hashing this pair. Then jran and kran are hashed, kran and mran
are hashed, and so forth.

```

```

SUBROUTINE ran_deallocate
  User interface to release the workspace used by the random number routines.
if (lenran > 0) then
  deallocate(ranseeds,ranv)
  nullify(ranseeds,ranv,iran,jran,kran,mran,nran)
  lenran = 0
end if
END SUBROUTINE ran_deallocate

```

The above routine is supplied as a user interface for deallocating all the state space storage.

```

SUBROUTINE ran_seed(sequence,size,put,get)
IMPLICIT NONE
INTEGER, OPTIONAL, INTENT(IN) :: sequence
INTEGER, OPTIONAL, INTENT(OUT) :: size
INTEGER, DIMENSION(:), OPTIONAL, INTENT(IN) :: put
INTEGER, DIMENSION(:), OPTIONAL, INTENT(OUT) :: get
    User interface for seeding the random number routines. Syntax is exactly like Fortran 90's
    random_seed routine, with one additional argument keyword: sequence, set to any integer
    value, causes an immediate new initialization, seeded by that integer.
if (present(size)) then
    size=5*lenran
else if (present(put)) then
    if (lenran == 0) RETURN
    ranseeds=reshape(put,shape(ranseeds))
    where (ranseeds(:,1:3) < 0) ranseeds(:,1:3)=not(ranseeds(:,1:3))
        Enforce nonnegativity and nonzero conditions on any user-supplied seeds.
    where (ranseeds(:,4:5) == 0) ranseeds(:,4:5)=1
    iran0=ranseeds(1,1)
    jran0=ranseeds(1,2)
    kran0=ranseeds(1,3)
    mran0=ranseeds(1,4)
    nran0=ranseeds(1,5)
else if (present(get)) then
    if (lenran == 0) RETURN
    ranseeds(1,1:5)=(/ iran0,jran0,kran0,mran0,nran0 /)
    get=reshape(ranseeds,shape(get))
else if (present(sequence)) then
    call ran_deallocate
    seq=sequence
end if
END SUBROUTINE ran_seed

```

ranseeds=reshape(put,shape(ranseeds)) ...
 get=reshape(ranseeds,shape(get))

Fortran 90's convention is that random state space is a one-dimensional array, so we map to this on both the get and put keywords.

```

iran0=...jran0=...kran0=...
ranseeds(1,1:5)=(/ iran0,jran0,kran0,mran0,nran0 /)

```

It's much more convenient to set a vector from a bunch of scalars then the other way around.

```

SUBROUTINE ran_hash_s(il,ir)

The lines

```
ir=ieor(ir,ishft(ir,5))+1422217823  
ir=ieor(ir,ishft(ir,-16))+1842055030  
ir=ieor(ir,ishft(ir,9))+80567781
```

are *not* a Marsaglia shift sequence, though they resemble one. Instead, they implement a fast, nonlinear function on `ir` that we use as the “S-box” in a DES-like hashing algorithm. (See Volume 1, §7.5.) The triplet $(5, -16, 9)$ is *not* chosen to give a full period Marsaglia sequence — it doesn’t. Instead it is chosen as being particularly good at separating in Hamming distance (i.e., number of nonidentical bits) two initially close values of `ir` (e.g., differing by only one bit). The large integer constants are chosen by a similar criterion. Note that the wrap-around of addition without generating an overflow error condition, which was tested in `ran_init`, is relied upon here.

```

This is the simplest, and fastest, of the generators provided. It combines a subtractive Fibonacci generator (Number 6 in ref. [1], and one of the generators in Marsaglia and Zaman's *mzran*) with a Marsaglia shift sequence. On typical machines it is only 20% or so faster than *ran1*, however; so we recommend the latter preferentially. While we know of no weakness in *ran0*, we are not offering a prize for finding a weakness. *ran0* does have the feature, useful if you have a machine with nonstandard arithmetic, that it does not go beyond Fortran 90's assumed integer model.

Note that *ran0_s* and *ran0_v* are overloaded by the module *nr* onto the single name *ran0* (and similarly for the routines below).

The routine `ran1` combines *three* fast generators: the two used in `ran0`, plus an additional (different) Marsaglia shift sequence. The last generator is combined via an addition that can wrap-around.

We think that, within the limits of its floating-point precision, `ran1` provides perfect random numbers. We will pay \$1000 to the first reader who convinces us otherwise (by exhibiting a statistical test that `ran1` fails in a nontrivial way, excluding the ordinary limitations of a floating-point representation).

ran2, for use by readers whose caution is extreme, also combines three generators. The difference from ran1 is that each generator is based on a completely different method from the other two. The third generator, in this case, is a linear congruential generator, modulo 2^{32} . This generator relies extensively on wrap-around addition (which is automatically tested at initialization). On machines with fast arithmetic, ran2 is on the order of only 20% slower than ran1. We offer a \$1000 bounty on ran2, with the same terms as for ran1, above.

★ ★ ★

```

SUBROUTINE expdev_s(harvest)
USE nrtype
USE nr, ONLY : ran1
IMPLICIT NONE
REAL(SP), INTENT(OUT) :: harvest
      Returns in harvest an exponentially distributed, positive, random deviate of unit mean,
      using ran1 as the source of uniform deviates.
REAL(SP) :: dum
call ran1(dum)
harvest=-log(dum)           We use the fact that ran1 never returns exactly 0 or 1.
END SUBROUTINE expdev_s

```

if (n /= last_allocated) ... We make the assumption that, in most cases, the size of harvest will not change between successive calls.

Therefore, if it *does* change, we don't try to save the previously generated deviates that, half the time, will be around. If your use has rapidly varying sizes (or, even worse, calls alternating between two different sizes), you should remedy this inefficiency in the obvious way.

call array_copy(pack(v1(ng:n),mask(ng:n)),v1(ng:),nn,m) This is a variant of the pack-unpack method (see note to factrl, p. 1087). Different here is that we don't care which random deviates end up in which component. Thus, we can simply keep packing successful returns into v1 and v2 until they are full.

Note also the use of `array_copy`, since we don't know in advance the length of the array returned by `pack`.

★ ★ ★

f90 The routines `psdes` and `psdes-safe` both perform *exactly* the same hashing as was done by the Fortran 77 routine `psdes`. The difference is that `psdes` makes assumptions about arithmetic that go beyond the strict Fortran 90 model, while `psdes-safe` makes no such assumptions. The disadvantage of `psdes-safe` is that it is significantly slower, performing most of its arithmetic in double-precision reals that are then converted to integers with Fortran 90's `modulo` intrinsic.

In fact the nonsafe version, `psdes`, works fine on almost all machines and compilers that we have tried. There is a reason for this: Our assumed integer model is the same as the C language `unsigned int`, and virtually all modern computers and compilers have a lot of C hidden inside. If `psdes` and `psdes-safe` produce identical output on your system for any hundred or so different input values, you can be quite confident about using the faster version exclusively.

At the other end of things, note that in the very unlikely case that your system fails on the `ran_hash` routine in the `ran_state` module (you will have learned this from error messages generated by `ran_init`), you can substitute `psdes-safe` for `ran_hash`: They are plug-compatible.

```

SUBROUTINE psdes_s(lword,rword)
USE nrtype
IMPLICIT NONE
INTEGER(I4B), INTENT(INOUT) :: lword,rword
INTEGER(I4B), PARAMETER :: NITER=4
          "Pseudo-DES" hashing of the 64-bit word (lword,irword). Both 32-bit arguments are
          returned hashed on all bits. Note that this version of the routine assumes properties of
          integer arithmetic that go beyond the Fortran 90 model, though they are compatible with
          unsigned integers in C.
INTEGER(I4B), DIMENSION(4), SAVE :: C1,C2

```

As given, ran3 uses the ran_hash function in the module ran_state as its DES surrogate. That function is sufficiently fast to make ran3 only about a factor of 2 slower than our baseline recommended generator ran1. The slower routine psdes and (even slower) psdes_safe are plug-compatible with ran_hash, and could be substituted for it in this routine.

    END FUNCTION func
END INTERFACE
REAL(SP), PARAMETER :: ALPH=1.5_sp,TINY=1.0e-30_sp
INTEGER(I4B), PARAMETER :: MXDIM=10,NDMX=50
    Performs Monte Carlo integration of a user-supplied d-dimensional function func over a
    rectangular volume specified by region, a vector of length  $2d$  consisting of d "lower left"
    coordinates of the region followed by d "upper right" coordinates. The integration consists of
    itmx iterations, each with approximately ncall calls to the function. After each iteration
    the grid is refined; more than 5 or 10 iterations are rarely useful. The input flag init
    signals whether this call is a new start, or a subsequent call for additional iterations (see
    comments below). The input flag nprn (normally 0) controls the amount of diagnostic
    output. Returned answers are tgral (the best estimate of the integral), sd (its standard
    deviation), and chi2a ( $\chi^2$  per degree of freedom, an indicator of whether consistent results
    are being obtained). See text for further details.

REAL(SP), PARAMETER :: PFAC=0.1_sp,TINY=1.0e-30_sp,BIG=1.0e30_sp
INTEGER(I4B), PARAMETER :: MNPT=15,MNBS=60
Monte Carlo samples a user-supplied ndim-dimensional function func in a rectangular
volume specified by region, a  $2 \times \text{ndim}$  vector consisting of ndim "lower-left" coordinates
of the region followed by ndim "upper-right" coordinates. The function is sampled a total
of npts times, at locations determined by the method of recursive stratified sampling. The
mean value of the function in the region is returned as ave; an estimate of the statistical
uncertainty of ave (square of standard deviation) is returned as var. The input parameter
dith should normally be set to zero, but can be set to (e.g.) 0.1 if func's active region
falls on the boundary of a power-of-2 subdivision of region.
Parameters: PFAC is the fraction of remaining function evaluations used at each stage to
explore the variance of func. At least MNPT function evaluations are performed in any
terminal subregion; a subregion is further bisected only if at least MNBS function evaluations
are available.

Chapter B8. Sorting

Caution! If you are expecting to sort efficiently on a parallel machine, whether its parallelism is small-scale or massive, you almost certainly want to use library routines that are specific to your hardware.

We include in this chapter translations into Fortran 90 of the general purpose *serial* sorting routines that are in Volume 1, augmented by several new routines that give pedagogical demonstrations of how parallel sorts can be achieved with Fortran 90 parallel constructions and intrinsics. However, we intend the above word “pedagogical” to be taken seriously: these new, supposedly parallel, routines are *not* likely to be competitive with machine-specific library routines. Neither do they compete successfully on serial machines with the all-serial routines provided (namely `sort`, `sort2`, `sort3`, `indexx`, and `select`).

★ ★ ★

```
SUBROUTINE sort_pick(arr)
USE nrtype
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sorts an array arr into ascending numerical order, by straight insertion. arr is replaced
    on output by its sorted rearrangement.
INTEGER(I4B) :: i,j,n
REAL(SP) :: a
n=size(arr)
do j=2,n                Pick out each element in turn.
    a=arr(j)
    do i=j-1,1,-1          Look for the place to insert it.
        if (arr(i) <= a) exit
        arr(i+1)=arr(i)
    end do
    arr(i+1)=a            Insert it.
end do
END SUBROUTINE sort_pick
```

Not only is `sort_pick` (renamed from Volume 1’s `piksrt`) *not parallelizable*, but also, even worse, it is an N^2 routine. It is meant to be invoked only for the most trivial sorting jobs, say, $N < 20$.

★ ★ ★

```

SUBROUTINE sort_shell(arr)
USE nrtype
IMPLICIT NONE
REAL(SP), DIMENSION(:, ), INTENT(INOUT) :: arr
    Sorts an array arr into ascending numerical order by Shell's method (diminishing increment
    sort). arr is replaced on output by its sorted rearrangement.
INTEGER(I4B) :: i,j,inc,n
REAL(SP) :: v
n=size(arr)
inc=1
do                                Determine the starting increment.
    inc=3*inc+1
    if (inc > n) exit
end do
do                                Loop over the partial sorts.
    inc=inc/3
    do i=inc+1,n                  Outer loop of straight insertion.
        v=arr(i)
        j=i
        do                         Inner loop of straight insertion.
            if (arr(j-inc) <= v) exit
            arr(j)=arr(j-inc)
            j=j-inc
            if (j <= inc) exit
        end do
        arr(j)=v
    end do
    if (inc <= 1) exit
end do
END SUBROUTINE sort_shell

```

The routine `sort_shell` is renamed from Volume 1's `shell`. Shell's Method, a diminishing increment sort, is not directly parallelizable. However, one can write a fully parallel routine (though not an especially fast one — see remarks at beginning of this chapter) in much the same spirit:

```

SUBROUTINE sort_byreshape(arr)
USE nrtype; USE nrutil, ONLY : swap
IMPLICIT NONE
REAL(SP), DIMENSION(:, ), INTENT(INOUT) :: arr
    Sort an array arr by bubble sorting a succession of reshapings into array slices. The method
    is similar to Shell sort, but allows parallelization within the vectorized masked swap calls.
REAL(SP), DIMENSION(:, :, ), ALLOCATABLE :: tab
REAL(SP), PARAMETER :: big=huge(arr)
INTEGER(I4B) :: inc,n,m
n=size(arr)
inc=1
do                                Find the largest increment that fits.
    inc=2*inc+1
    if (inc > n) exit
end do
do                                Loop over the different shapes for the reshaped
    inc=inc/2
    m=(n+inc-1)/inc
    allocate(tab(inc,m))           Allocate space and reshape the array. big en-
    tab=reshape(arr, (/inc,m/) , (/big/) )   sures that fill elements stay at the
    do                                end.
        Bubble sort all the rows in parallel.
        call swap(tab(:,1:m-1:2),tab(:,2:m:2), &
                   tab(:,1:m-1:2)>tab(:,2:m:2))
        call swap(tab(:,2:m-1:2),tab(:,3:m:2), &
                   tab(:,2:m-1:2)>tab(:,3:m:2))
    end do
end do

```

```

        if (all(tab(:,1:m-1) <= tab(:,2:m))) exit
    end do
    arr=reshape(tab,shape(arr))           Put the array back together for the next shape.
    deallocate(tab)
    if (inc <= 1) exit
end do
END SUBROUTINE sort_byreshape

```

 The basic idea is to reshape the given one-dimensional array into a succession of two-dimensional arrays, starting with “tall and narrow” (many rows, few columns), and ending up with “short and wide” (many columns, few rows). At each stage we sort all the rows in parallel by a bubble sort, giving something close to Shell’s diminishing increments.

★ ★ ★

We now arrive at those routines, based on the Quicksort algorithm, that we actually intend for use with general N on serial machines:

```

SUBROUTINE sort(arr)
USE nrtype; USE nrutil, ONLY : swap,nrerror
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
INTEGER(I4B), PARAMETER :: NN=15, NSTACK=50
Sorts an array arr into ascending numerical order using the Quicksort algorithm. arr is
replaced on output by its sorted rearrangement.
Parameters: NN is the size of subarrays sorted by straight insertion and NSTACK is the
required auxiliary storage.
REAL(SP) :: a
INTEGER(I4B) :: n,k,i,j,jstack,l,r
INTEGER(I4B), DIMENSION(NSTACK) :: istack
n=size(arr)
jstack=0
l=1
r=n
do
    if (r-l < NN) then           Insertion sort when subarray small enough.
        do j=l+1,r
            a=arr(j)
            do i=j-1,l,-1
                if (arr(i) <= a) exit
                arr(i+1)=arr(i)
            end do
            arr(i+1)=a
        end do
        if (jstack == 0) RETURN
        r=istack(jstack)           Pop stack and begin a new round of partition-
        l=istack(jstack-1)         ing.
        jstack=jstack-2
    else
        k=(l+r)/2                 Choose median of left, center, and right elements
        call swap(arr(k),arr(l+1))   as partitioning element a. Also rearrange so
        call swap(arr(1),arr(r),arr(1)>arr(r))      that a(l) ≤ a(l+1) ≤ a(r).
        call swap(arr(1+1),arr(r),arr(1+1)>arr(r))
        call swap(arr(1),arr(l+1),arr(1)>arr(l+1))
        i=l+1                      Initialize pointers for partitioning.
        j=r
        a=arr(l+1)                  Partitioning element.
        do                           Here is the meat.
            do                         Scan up to find element >= a.
                i=i+1
            end do
        end do
    end if
end do

```

```

        if (arr(i) >= a) exit
    end do
    do                                Scan down to find element <= a.
        j=j-1
        if (arr(j) <= a) exit
    end do
    if (j < i) exit                  Pointers crossed. Exit with partitioning complete.
    call swap(arr(i),arr(j))          Exchange elements.
end do
arr(l+1)=arr(j)                   Insert partitioning element.
arr(j)=a
jstack=jstack+2
Push pointers to larger subarray on stack; process smaller subarray immediately.
if (jstack > NSTACK) call nrerror('sort: NSTACK too small')
if (r-i+1 >= j-l) then
    istack(jstack)=r
    istack(jstack-1)=i
    r=j-1
else
    istack(jstack)=j-1
    istack(jstack-1)=l
    l=i
end if
end if
end do
END SUBROUTINE sort

```

f90 call swap(...) ... call swap(...) One might think twice about putting all these external function calls (to nrutil routines) in the inner loop of something as streamlined as a sort routine, but here they are executed only once for each partitioning.

call swap(arr(i),arr(j)) This call *is* in a loop, but not the innermost loop. Most modern machines are very fast at the “context changes” implied by subroutine calls and returns; but in a time-critical context you might code this swap in-line and see if there is any timing difference.

```

SUBROUTINE sort2(arr,slave)
USE nrtype; USE nrutil, ONLY : assert_eq
USE nr, ONLY : indexx
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr,slave
Sorts an array arr into ascending order using Quicksort, while making the corresponding
rearrangement of the same-size array slave. The sorting and rearrangement are performed
by means of an index array.
INTEGER(I4B) :: ndum
INTEGER(I4B), DIMENSION(size(arr)) :: index
ndum=assert_eq(size(arr),size(slave),'sort2')
call indexx(arr,index)           Make the index array.
arr=arr(index)                 Sort arr.
slave=slave(index)             Rearrange slave.
END SUBROUTINE sort2

```

* * *

 A close surrogate for the Quicksort partition-exchange algorithm can be coded, parallelizable, by using Fortran 90’s pack intrinsic. On real compilers, unfortunately, the resulting code is not very efficient as compared with (on serial machines) the tightness of sort’s inner loop, above, or (on parallel machines) supplied library sort routines. We illustrate the principle nevertheless in the following routine.

```

RECURSIVE SUBROUTINE sort_bypack(arr)
USE nrtype; USE nrutil, ONLY : array_copy, swap
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sort an array arr by recursively applying the Fortran 90 pack intrinsic. The method is
    similar to Quicksort, but this variant allows parallelization by the Fortran 90 compiler.
REAL(SP) :: a
INTEGER(I4B) :: n,k,nl,nerr
INTEGER(I4B), SAVE :: level=0
LOGICAL, DIMENSION(:), ALLOCATABLE, SAVE :: mask
REAL(SP), DIMENSION(:), ALLOCATABLE, SAVE :: temp
n=size(arr)
if (n <= 1) RETURN
k=(1+n)/2
call swap(arr(1),arr(k),arr(1)>arr(k))      Pivot element is median of first, middle,
call swap(arr(k),arr(n),arr(k)>arr(n))          and last.
call swap(arr(1),arr(k),arr(1)>arr(k))
if (n <= 3) RETURN
level=level+1
if (level == 1) allocate(mask(n),temp(n))      Keep track of recursion level to avoid al-
a=arr(k)                                         location overhead.
mask(1:n) = (arr <= a)                          Which elements move to left?
mask(k) = .false.
call array_copy(pack(arr,mask(1:n)),temp,nl,nerr)      Move them.
mask(k) = .true.
temp(nl+2:n)=pack(arr,.not. mask(1:n))           Move others to right.
temp(nl+1)=a
arr=temp(1:n)
call sort_bypack(arr(1:nl))                      And recurse.
call sort_bypack(arr(nl+2:n))
if (level == 1) deallocate(mask,temp)
level=level-1
END SUBROUTINE sort_bypack

```

* * *

The following routine, `sort_heap`, is renamed from Volume 1's `hpsort`.

```

SUBROUTINE sort_heap(arr)
USE nrtype
USE nrutil, ONLY : swap
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
    Sorts an array arr into ascending numerical order using the Heapsort algorithm. arr is
    replaced on output by its sorted rearrangement.
INTEGER(I4B) :: i,n
n=size(arr)
do i=n/2,1,-1
    The index i, which here determines the "left" range of the sift-down, i.e., the element to
    be sifted down, is decremented from n/2 down to 1 during the "hiring" (heap creation)
    phase.
    call sift_down(i,n)
end do
do i=n,2,-1
    Here the "right" range of the sift-down is decremented from n-1 down to 1 during the
    "retirement-and-promotion" (heap selection) phase.
    call swap(arr(1),arr(i))          Clear a space at the end of the array, and
    call sift_down(1,i-1)             retire the top of the heap into it.
end do
CONTAINS
SUBROUTINE sift_down(l,r)
INTEGER(I4B), INTENT(IN) :: l,r

```

```

Carry out the sift-down on element arr(1) to maintain the heap structure.
INTEGER(I4B) :: j,jold
REAL(SP) :: a
a=arr(1)
jold=1
j=1+l
do                                "Do while j <= r."
    if (j > r) exit
    if (j < r) then
        if (arr(j) < arr(j+1)) j=j+1      Compare to the better underling.
    end if
    if (a >= arr(j)) exit

END SUBROUTINE sift_down
END SUBROUTINE sort_heap

```

★ ★ ★

Another opportunity provided by Fortran 90 for a fully parallelizable sort, at least pedagogically, is to use the language's allowed access to the actual floating-point representation and to code a radix sort [1] on its bits. This is *not* efficient, but it illustrates some Fortran 90 language features perhaps worthy of study for other applications.

```

SUBROUTINE sort_radix(arr)
USE nrtype; USE nrutil, ONLY : array_copy,nrerror
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
Sort an array arr by radix sort on its bits.
INTEGER(I4B), DIMENSION(size(arr)) :: narr,temp
LOGICAL, DIMENSION(size(arr)) :: msk
INTEGER(I4B) :: k,negm,ib,ia,n,nl,nerr
Because we are going to transfer reals to integers, we must check that the number of bits
is the same in each:
ib=bit_size(narr)
ia=ceiling(log(real(maxexponent(arr)-minexponent(arr),sp))/log(2.0_sp)) +
    digits(arr)
if (ib /= ia) call nrerror('sort_radix: bit sizes not compatible')
negm=not(ishftc(1,-1))                         Mask for all bits except sign bit.
n=size(arr)
narr=transfer(arr,narr,n)
where (btest(narr,ib-1)) narr=ieor(narr,negm)     Flip all bits on neg. numbers.
do k=0,ib-2
    Work from low- to high-order bits, and partition the array according to the value of the
    bit.
    msk=btest(narr,k)
    call array_copy(pack(narr,.not. msk),temp,nl,nerr)
    temp(nl+1:n)=pack(narr,msk)
    narr=temp
end do
msk=btest(narr,ib-1)                           The sign bit gets separate treat-
call array_copy(pack(narr,msk),temp,nl,nerr)      ment, since here 1 comes be-
temp(nl+1:n)=pack(narr,.not. msk)                 fore 0.
narr=temp
where (btest(narr,ib-1)) narr=ieor(narr,negm)     Unflip all bits on neg. numbers.
arr=transfer(narr,arr,n)
END SUBROUTINE sort_radix

```

```

* * *

 Just as in the case of sort, where an approximation of the underlying Quicksort partition-exchange algorithm can be captured with the Fortran 90 pack intrinsic, the same can be done with indexx. As before, although it is in principle parallelizable by the compiler, it is likely not competitive with library routines.

```

RECURSIVE SUBROUTINE index_bypack(arr,index,partial)
USE nrtype; USE nrutil, ONLY : array_copy,arth,assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: arr
INTEGER(I4B), DIMENSION(:), INTENT(INOUT) :: index
INTEGER, OPTIONAL, INTENT(IN) :: partial
    Indexes an array arr, i.e., outputs the array index of length N such that arr(index(j))
    is in ascending order for  $j = 1, 2, \dots, N$ . The method is to apply recursively the Fortran
    90 pack intrinsic. This is similar to Quicksort, but allows parallelization by the Fortran 90
    compiler. partial is an optional argument that is used only internally on the recursive calls.

* * *

The following routine, `select_inplace`, is renamed from Volume 1's `selip`.

```

FUNCTION select_inplace(k,arr)
USE nrtype
USE nr, ONLY : select
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: k
REAL(SP), DIMENSION(:), INTENT(IN) :: arr
REAL(SP) :: select_inplace
    Returns the kth smallest value in the array arr, without altering the input array. In Fortran
    90's assumed memory-rich environment, we just call select in scratch space.
REAL(SP), DIMENSION(size(arr)) :: tarr
tarr=arr
select_inplace=select(k,tarr)
END FUNCTION select_inplace

```

f90 Volume 1's `selip` routine uses an entirely different algorithm, for the purpose of avoiding any additional memory allocation beyond that of the input array. Fortran 90 presumes a richer memory environment, so `select_inplace` simply does the obvious (destructive) selection in scratch space. You can of course use the old `selip` if your in-core or in-cache memory is at a premium.

```

FUNCTION select_bypack(k,arr)
USE nrtype; USE nrutil, ONLY : array_copy,assert,swap
IMPLICIT NONE
INTEGER(I4B), INTENT(IN) :: k
REAL(SP), DIMENSION(:), INTENT(INOUT) :: arr
REAL(SP) :: select_bypack
    Returns the kth smallest value in the array arr. The input array will be rearranged to have
    this value in location arr(k), with all smaller elements moved to arr(1:k-1) (in arbitrary
    order) and all larger elements in arr(k+1:) (also in arbitrary order). This implementation
    allows parallelization in the Fortran 90 pack intrinsic.
LOGICAL, DIMENSION(size(arr)) :: mask

f90 CHARACTER(1), DIMENSION(ISCR,JSCR) :: scr In Fortran 90, the length of variables of type character should be declared as CHARACTER(1) or CHARACTER(len=1) (for a variable of length 1), rather than the older form CHARACTER*1. While the older form is still legal syntax, the newer one is more consistent with the syntax of other type declarations. (For variables of length 1, you can actually omit the length specifier entirely, and just say CHARACTER.)

```

Determine the spacing appropriate to the mesh.

Evaluate the function at the mesh points.

Record where the sign changes occur.

Number of sign changes.

Store the bounds of each bracket.

This routine shows how to return arrays xb1 and xb2 whose size is not known in advance. The coding is explained in the subsection on pointers in §21.5.

```

f90 $b(m+1:1:-1)=poly_term \dots f=poly(x,d(2:m))$ The `poly_term` function in `nrutil` tabulates the partial sums of a polynomial, while `poly` evaluates the polynomial at `x`. In this example, we use `poly_term` on the coefficient array in reverse order, so that the value of the polynomial ends up in `b(1)` and the value of its first derivative in `d(1)`.

`dx=exp(cmplx(log(1.0_sp+abx),iter,kind=spc))` The intrinsic function `cmplx` returns a quantity of type default complex unless the `kind` argument is present. To facilitate converting our routines from single to double precision, we always include the `kind` argument explicitly so that when you redefine `spc` in `nrttype` to be double-precision complex the conversions are carried out correctly.

REAL(SP), PARAMETER :: TOLF=1.0e-4_sp,TOLMIN=1.0e-6_sp,TOLX=epsilon(x),&

STPMX=100.0

Given an initial guess x for a root in N dimensions, find the root by a globally convergent Newton's method. The length N vector of functions to be zeroed, called `fvec` in the routine below, is returned by a user-supplied routine that *must* be called `funcv` and have the declaration FUNCTION `funcv(x)`. The output quantity `check` is false on a normal return and true if the routine has converged to a local minimum of the function `fmin` defined below. In this case try restarting from a different initial guess.

Parameters: `MAXITS` is the maximum number of iterations; `TOLF` sets the convergence criterion on function values; `TOLMIN` sets the criterion for deciding whether spurious convergence to a minimum of `fmin` has occurred; `TOLX` is the convergence criterion on δx ; `STPMX` is the scaled maximum step length allowed in line searches.

        RETURN
    end do
    call nrerror('MAXITS exceeded in newt')
END SUBROUTINE newt

```

f90 USE fminln Here we have an example of how to pass an array `fvec` to a function `fmin` without making it an argument of `fmin`. In the language of §21.5, we are using Method 2: We define a pointer `fmin_fvecp` in the module `fminln`:

```
REAL(SP), DIMENSION(:, ), POINTER :: fmin_fvecp
```

`fvec` itself is declared as an automatic array of the appropriate size in `newt`:

```
REAL(SP), DIMENSION(size(x)), TARGET :: fvec
```

On entry into `newt`, the pointer is associated:

```
fmin_fvecp=>fvec
```

The pointer is then used in `fmin` as a synonym for `fvec`. If you are sufficiently paranoid, you can test whether `fmin_fvecp` has in fact been associated on entry into `fmin`. Heeding our admonition always to deallocate memory when it no longer is needed, you may ask where the deallocation takes place in this example. Answer: On exit from `newt`, the automatic array `fvec` is automatically freed.

The Method 1 way of setting up this task is to declare an allocatable array in the module:

```
REAL(SP), DIMENSION(:, ), ALLOCATABLE :: fvec
```

On entry into `newt` we allocate it appropriately:

```
allocate(fvec,size(x))
```

and it can now be used in both `newt` and `fmin`. Of course, we must remember to deallocate explicitly `fvec` on exit from `newt`. If we forget, all kinds of bad things would happen on a second call to `newt`. The status of `fvec` on the first return from `newt` becomes undefined. The status cannot be tested with `if(allocated(...))`, and `fvec` may not be referenced in any way. If we tried to guard against this by adding the `SAVE` attribute to the declaration of `fvec`, then we would generate an error from trying to allocate an already-allocated array.

TOLX=EPS,STPMX=100.0
Given an initial guess x for a root in N dimensions, find the root by Broyden's method
embedded in a globally convergent strategy. The length N vector of functions to be zeroed,
called fvec in the routine below, is returned by a user-supplied routine that must be
called funcv and have the declaration FUNCTION funcv(x). The subroutine fdjac and
the function fmin from newt are used. The output quantity check is false on a normal
return and true if the routine has converged to a local minimum of the function fmin or if
Broyden's method can make no further progress. In this case try restarting from a different
initial guess.
Parameters: MAXITS is the maximum number of iterations; EPS is the machine precision;
TOLF sets the convergence criterion on function values; TOLMIN sets the criterion for de-
ciding whether spurious convergence to a minimum of fmin has occurred; TOLX is the
convergence criterion on  $\delta\mathbf{x}$ ; STPMX is the scaled maximum step length allowed in line
searches.

USE fminln See discussion for **newt** on p. 1197.

qt(k:n,:)=...outerprod...matmul Another example of the coding of equation (22.1.6).

where (lower_triangle(n,n))... The **lower_triangle** function in **nrutil** returns a lower triangular logical mask. As used here, the mask is true everywhere in the lower triangle of an $n \times n$ matrix, excluding the diagonal. An optional integer argument **extra** allows additional diagonals to be set to true. With **extra=1** the lower triangle including the diagonal would be true.

call put_diag(d(:,),r(:, :)) This subroutine in **nrutil** sets the diagonal values of the matrix **r** to the values of the vector **d**. It is overloaded so that **d** could be a scalar, in which case the scalar value would be broadcast onto the diagonal of **r**.

Chapter B10. Minimization or Maximization of Functions

```

SUBROUTINE mnbrak(ax,bx,cx,fa,fb,fc,func)
USE nrtype; USE nrutil, ONLY : swap
IMPLICIT NONE
REAL(SP), INTENT(INOUT) :: ax,bx

END INTERFACE
INTEGER(I4B), PARAMETER :: ITMAX=5000
REAL(SP), PARAMETER :: TINY=1.0e-10
Minimization of the function func in  $N$  dimensions by the downhill simplex method of Nelder and Mead. The  $(N+1) \times N$  matrix p is input. Its  $N+1$  rows are  $N$ -dimensional vectors that are the vertices of the starting simplex. Also input is the vector y of length  $N+1$ , whose components must be preinitialized to the values of func evaluated at the  $N+1$  vertices (rows) of p; and ftol the fractional convergence tolerance to be achieved in the function value (n.b.!). On output, p and y will have been reset to  $N+1$  new points all within ftol of a minimum function value, and iter gives the number of function evaluations taken.
Parameters: The maximum allowed number of function evaluations, and a small number.
INTEGER(I4B) :: ihi,ndim                                     Global variables.

f90 The only action taken by the subroutine `amoeba` is to call the internal subroutine `amoeba_private`. Why this structure? The reason has to do with meeting the twin goals of data hiding (especially for “safe” scope of variables) and program readability. The situation is this: Logically, `amoeba` does most of the calculating, but calls an internal subroutine `amotry` at several different points, with several values of the parameter `fac`. However, `fac` is not the only piece of data that must be shared with `amotry`; the latter also needs access to several shared variables (`ihi`, `ndim`, `psum`) and arguments of `amoeba` (`p`, `y`, `func`).

The obvious (but not best) way of coding this would be to put the computational guts in `amoeba`, with `amotry` as the sole internal subprogram. Assuming that `fac` is passed as an argument to `amotry` (it being the parameter that is being rapidly altered), one must decide whether to pass all the other quantities to `amotry` (i) as additional arguments (as is done in the Fortran 77 version), or (ii) “automatically,” i.e., doing nothing except using the fact that an internal subprogram has automatic access to all of its host’s entities. Each of these choices has strong disadvantages. Choice (i) is inefficient (all those arguments) and also obscures the fact that `fac` is the primary changing argument. Choice (ii) makes the program extremely difficult to read, because it wouldn’t be obvious without careful cross-comparison of the routines *which* variables in `amoeba` are actually global variables that are used by `amotry`.

Choice (ii) is also “unsafe scoping” because it gives a nontrivially complicated internal subprogram, `amotry`, access to all the variables in its host. A common and difficult-to-find bug is the accidental alteration of a variable that one “thought”

was local, but is actually shared. (Simple variables like *i*, *j*, and *n* are the most common culprits.)

We are therefore led to reject both choice (i) and choice (ii) in favor of a structure previously described in the subsection on Scope, Visibility, and Data Hiding in §21.5. The guts of amoeba are put in amoeba_private, a *sister routine* to amoeba. These two siblings have mutually private name spaces. However, any variables that they need to share (including the top-level arguments of amoeba) are declared as variables in the enclosing amoeba routine. The presence of these “global variables” serves as a warning flag to the reader that data are shared between routines.

An alternative attractive way of coding the above situation would be to use a module containing amoeba and amoetry. Everything would be declared private except the name amoeba. The global variables would be at the top level, and the arguments of amoeba that need to be passed to amoetry would be handled by pointers among the global variables. Unfortunately, Fortran 90 does not support pointers to functions. Sigh!

ilo=iminloc...ihi=maxloc... See discussion of these functions on p. 1017.

call swap(y(1))...call swap(p(1,:))... Here the swap routine in nrutil is called once with a scalar argument and once with a vector argument. Inside nrutil scalar and vector versions have been overloaded onto the single name swap, hiding all the implementation details from the calling routine.

f90 USE f1dim_mod At first sight this situation is like the one involving USE fminln in newt on p. 1197: We want to pass arrays p and xi from linmin to f1dim without having them be arguments of f1dim. If you recall the discussion in §21.5 and on p. 1197, there are two ways of effecting this: via pointers or via allocatable arrays. There is an important difference here, however. The arrays p and xi are themselves arguments of linmin, and so cannot be allocatable arrays in the module. If we did want to use allocatable arrays in the module, we would have to copy p and xi into them. The pointer implementation is much more elegant, since no unnecessary copying is required. The construction here is identical to the one in fminln and newt, except that p and xi are arguments instead of automatic arrays.

END INTERFACE
INTEGER(I4B), PARAMETER :: ITMAX=200
REAL(SP), PARAMETER :: STPMX=100.0_sp,EPS=epsilon(p),TOLX=4.0_sp*EPS
Given a starting point p that is a vector of length N, the Broyden-Fletcher-Goldfarb-Shanno
variant of Davidon-Fletcher-Powell minimization is performed on a function func, using its
gradient as calculated by a routine dfunc. The convergence requirement on zeroing the
gradient is input as gtol. Returned quantities are p (the location of the minimum), iter
(the number of iterations that were performed), and fret (the minimum value of the
function). The routine lnsrch is called to perform approximate line minimizations.
Parameters: ITMAX is the maximum allowed number of iterations; STPMX is the scaled
maximum step length allowed in line searches; EPS is the machine precision; TOLX is the
convergence criterion on x values.

```

Find the maximum coefficient of the auxiliary objective function.

Auxiliary objective function is still negative and can't be improved, hence no feasible solution exists.

Auxiliary objective function is zero and can't be improved. This signals that we have a feasible starting vector. Clean out the artificial variables corresponding to any remaining equality constraints and then eventually exit phase one.

Found an artificial variable for an equality constraint.

Exchange with column corresponding to maximum pivot element in row.

Change sign of row for any m2 constraints still present from the initial basis.

Go to phase two.

Locate a pivot element (phase one).

Maximum of auxiliary objective function is unbounded, so no feasible solution exists.

Exchange a left- and a right-hand variable.

Exchanged out an artificial variable for an equality constraint. Make sure it stays out by removing it from the l1 list.

Exchanged out an m2 type constraint.

If it's the first time, correct the pivot column for the minus sign and the implicit artificial variable.

Update lists of left- and right-hand variables.

If still in phase one, go back again.

```

f90 `main_procedure: do` The routine `simplx` makes extensive use of named do-loops to control the program flow. The various `exit` statements have the names of the do-loops attached to them so we can easily tell where control is being transferred to. We believe that it is almost never necessary to use `goto` statements: Code will always be clearer with well-constructed block structures.

`phase1a: do...end do phase1a` This is not a real do-loop: It is executed only once, as you can see from the unconditional `exit` before the `end do`. We use this construction to define a block of code that is traversed once but that has several possible exit points.

```
where (spread(l3(1:m12-m1),2,n+1) == 1) &
      a(m1+2:m12+1,1:n+1)=-a(m1+2:m12+1,1:n+1)
```

These lines are equivalent to

```
do i=m1+1,m12
   if (l3(i-m1) == 1) a(i+1,1:n+1)=-a(i+1,1:n+1)
end do

INTEGER(I4B), DIMENSION(:, ), INTENT(IN) :: n
This routine performs a path segment reversal.  $iorder$  is an input array giving the present itinerary. The vector  $n$  has as its first four elements the first and last cities  $n(1)$ ,  $n(2)$  of the path segment to be reversed, and the two cities  $n(3)$  and  $n(4)$  that immediately precede and follow this segment.  $n(3)$  and  $n(4)$  are found by subroutine revcst. On output,  $iorder$  contains the segment from  $n(1)$  to  $n(2)$  in reversed order.
INTEGER(I4B) :: j,k,l,nn,ncity
ncity=size(iorder)
nn=(1+mod(n(2)-n(1)+ncity,ncity))/2          This many cities must be swapped to effect
do j=1,nn                                       the reversal.
    k=1+mod((n(1)+j-2),ncity)                 Start at the ends of the segment and swap
    l=1+mod((n(2)-j+ncity),ncity)             pairs of cities, moving toward the center.
    call swap(iorder(k),iorder(l))
end do

INTEGER(I4B), DIMENSION(:), INTENT(INOUT) :: iorder
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: n
This routine does the actual path transport, once metrop has approved. iorder is an
input array giving the present itinerary. The array n has as its six elements the beginning
n(1) and end n(2) of the path to be transported, the adjacent cities n(3) and n(4)
between which the path is to be placed, and the cities n(5) and n(6) that precede and
follow the path. n(4), n(5), and n(6) are calculated by subroutine trncst. On output,
iorder is modified to reflect the movement of the path segment.
INTEGER(I4B) :: m1,m2,m3,nn,ncity
INTEGER(I4B), DIMENSION(size(iorder)) :: jorder
ncity=size(iorder)
m1=1+mod((n(2)-n(1)+ncity),ncity)           Find number of cities from n(1) to n(2) ...
m2=1+mod((n(5)-n(4)+ncity),ncity)           ...and the number from n(4) to n(5)
m3=1+mod((n(3)-n(6)+ncity),ncity)           ...and the number from n(6) to n(3).
jorder(1:m1)=iorder(1+mod((arth(1,1,m1)+n(1)-2),ncity))   Copy the chosen segment.
nn=m1
jorder(nn+1:mm2)=iorder(1+mod((arth(1,1,m2)+n(4)-2),ncity))
Then copy the segment from n(4) to n(5).
nn=nn+m2
jorder(nn+1:mm3)=iorder(1+mod((arth(1,1,m3)+n(6)-2),ncity))
Finally, the segment from n(6) to n(3).
iorder(1:ncity)=jorder(1:ncity)                 Copy jorder back into iorder.

INTEGER(I4B), PARAMETER :: NMAX=200
Minimization of the  $N$ -dimensional function func by simulated annealing combined with the
downhill simplex method of Nelder and Mead. The  $(N+1) \times N$  matrix p is input. Its  $N+1$ 
rows are  $N$ -dimensional vectors that are the vertices of the starting simplex. Also input is
the vector y of length  $N+1$ , whose components must be preinitialized to the values of func
evaluated at the  $N+1$  vertices (rows) of p; ftol, the fractional convergence tolerance to be
achieved in the function value for an early return; iter, and temptr. The routine makes
iter function evaluations at an annealing temperature temptr, then returns. You should
then decrease temptr according to your annealing schedule, reset iter, and call the routine
again (leaving other arguments unaltered between calls). If iter is returned with a positive
value, then early convergence and return occurred. If you initialize yb to a very large value
on the first call, then yb and pb (an array of length  $N$ ) will subsequently return the best
function value and point ever encountered (even if it is no longer a point in the simplex).

 As discussed in Volume 1, `jacobi` is generally not competitive with `tql1` in terms of efficiency. However, `jacobi` can be parallelized whereas `tql1` uses an intrinsically serial algorithm. The version of `jacobi` implemented here is likely to be adequate for a small-scale parallel (SSP) machine, but is probably still not competitive with `tql1`. For a massively multiprocessor (MMP) machine, the order of the rotations needs to be chosen in a more complicated pattern than here so that the rotations can be executed in parallel. In this case the Jacobi algorithm may well turn out to be the method of choice. Parallel replacements for `tql1` based on a divide and conquer algorithm have also been proposed. See the discussion after `tql1` on p. 1229.

f90 `call unit_matrix...b(:)=get_diag...` These routines in `nrutil` both require access to the diagonal of a matrix, an operation that is not conveniently provided for in Fortran 90. We have split them off into `nrutil` in case your compiler provides parallel library routines so you can replace our standard versions.

`sm=sum(abs(a),mask=upper_triangle(n,n))` The `upper_triangle` function in `nrutil` returns an upper triangular logical mask. As used here, the mask is true everywhere in the upper triangle of an $n \times n$ matrix, excluding the diagonal. An optional integer argument `extra` allows additional diagonals to be set to true. With `extra=1` the upper triangle including the diagonal would be true. By using the mask, we can conveniently sum over the desired matrix elements in parallel.

`SUBROUTINE jrotate(a1,a2)` This internal subroutine also uses the values of `s` and `tau` from the calling subroutine `jacobi`. Variables in the calling routine are visible to an internal subprogram, but you should be circumspect in making use of this fact. It is easy to overwrite a value in the calling program inadvertently, and it is

often difficult to figure out the logic of an internal routine if not all its variables are declared explicitly. However, `jrotate` is so simple that there is no danger here.

END SUBROUTINE tred2

```

Begin accumulation of transformation matrices.

Reset row and column of a to identity matrix for next iteration.

f90 This routine gives a nice example of the usefulness of optional arguments. The routine is written under the assumption that usually you will want to find both eigenvalues and eigenvectors. In this case you just supply the arguments *a*, *d*, and *e*. If, however, you want only eigenvalues, you supply the additional logical argument *novectors* with the value *.true.*. The routine then skips the unnecessary computations. Supplying *novectors* with the value *.false.* has the same effect as omitting it.

IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: d,e
REAL(SP), DIMENSION(:, :), OPTIONAL, INTENT(INOUT) :: z

```

QL algorithm with implicit shifts, to determine the eigenvalues and eigenvectors of a real, symmetric, tridiagonal matrix, or of a real, symmetric matrix previously reduced by *tred2*

§11.2. d is a vector of length N . On input, its elements are the diagonal elements of the tridiagonal matrix. On output, it returns the eigenvalues. The vector e inputs the subdiagonal elements of the tridiagonal matrix, with $e(1)$ arbitrary. On output e is destroyed. When finding only the eigenvalues, the optional argument z is omitted. If the eigenvectors of a tridiagonal matrix are desired, the $N \times N$ matrix z is input as the identity matrix. If the eigenvectors of a matrix that has been reduced by `tred2` are required, then z is input as the matrix output by `tred2`. In either case, the k th column of z returns the normalized eigenvector corresponding to $d(k)$.

END SUBROUTINE tqli

```

The routine `tqli` is intrinsically serial. A parallel replacement based on a divide and conquer algorithm has been proposed [1,2]. The idea is to split the tridiagonal matrix recursively into two tridiagonal matrices of

half the size plus a correction. Given the eigensystems of the two smaller tridiagonal matrices, it is possible to join them together and add in the effect of the correction. When some small size of tridiagonal matrix is reached during the recursive splitting, its eigensystem is found directly with a routine like `tql1`. Each of these small problems is independent and can be assigned to an independent processor. The procedures for sewing together can also be done independently. For very large matrices, this algorithm can be an order of magnitude faster than `tql1` even on a serial machine, and no worse than a factor of 2 or 3 slower, depending on the matrix. Unfortunately the parallelism is not well expressed in Fortran 90. Also, the sewing together requires quite involved coding. For an implementation see the LAPACK routine `SSTECD`. Another parallel strategy for eigensystems uses inverse iteration, where each eigenvalue and eigenvector can be found independently [3].

f90 This routine uses `z` as an optional argument that is required only if eigenvectors are being found as well as eigenvalues.

`iterate: do` See discussion of named do loops after `simplx` on p. 1219.

END SUBROUTINE elmhes

```

f₉₀ $y(m+1:n)=\dots$ If the four lines of code starting here were all coded for a serial machine in a single do-loop starting with `do i=m+1,n` (see Volume 1), it would pay to test whether y was zero because the next three lines could then be skipped for that value of i. There is no convenient way to do this here, even with a `where`, since the shape of the arrays on each of the three lines is different. For a parallel machine it is probably best just to do a few unnecessary multiplies and skip the test for zero values of y.

Go back for next iteration on current eigen-value.

`anorm=sum(abs(a),mask=upper_triangle(n,n,extra=2))` See the discussion of `upper_triangle` after `jacobi` on p. 1226. Setting `extra=2` here picks out the upper Hessenberg part of the matrix.

`iterate: do` We use a named loop to improve the readability and structuring of the routine. The if-blocks that test for one or two roots end with `exit iterate`, transferring control back to the outermost loop and thus starting a search for the next root.

`call diagadd...` The routines that operate on the diagonal of a matrix are collected in `nrutil` partly so you can write clear code and partly in the hope that compiler writers will provide parallel library routines. Fortran 90 does not provide convenient parallel access to the diagonal of a matrix.

Chapter B12. Fast Fourier Transform

The algorithms underlying the parallel routines in this chapter are described in §22.4. As described there, the basic building block is a routine for simultaneously taking the FFT of each row of a two-dimensional matrix:

```
SUBROUTINE fourrow_sp(data,isign)
USE nrtype; USE nrutil, ONLY : assert,swap
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:, :, ), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
    Replaces each row (constant first index) of data(1:M,1:N) by its discrete Fourier transform (transform on second index), if isign is input as 1; or replaces each row of data by N times its inverse discrete Fourier transform, if isign is input as -1. N must be an integer power of 2. Parallelism is M-fold on the first index of data.
INTEGER(I4B) :: n,i,istep,j,m,mmax,n2
REAL(DP) :: theta
COMPLEX(SPC), DIMENSION(size(data,1)) :: temp
COMPLEX(DPC) :: w,wp                               Double precision for the trigonometric recurrences.
COMPLEX(SPC) :: ws
n=size(data,2)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in fourrow_sp')
n2=n/2
j=n2
This is the bit-reversal section of the routine.
do i=1,n-2
    if (j > i) call swap(data(:,j+1),data(:,i+1))
    m=n2
    do
        if (m < 2 .or. j < m) exit
        j=j-m
        m=m/2
    end do
    j=j+m
end do
mmax=1
Here begins the Danielson-Lanczos section of the routine.
do                                     Outer loop executed  $\log_2 N$  times.
    if (n <= mmax) exit
    istep=2*mmax
    theta=PI_D/(isign*mmax)           Initialize for the trigonometric recurrence.
    wp=cmplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
    w=cmplx(1.0_dp,0.0_dp,kind=dpc)
    do m=1,mmax                         Here are the two nested inner loops.
        ws=w
        do i=m,n,istep
            j=i+mmax
            temp=ws*data(:,j)          This is the Danielson-Lanczos formula.
            data(:,j)=data(:,i)-temp
            data(:,i)=data(:,i)+temp
        end do
        w=w*wp+w
    end do
    mmax=istep
    Trigonometric recurrence.
```

```
end do
END SUBROUTINE fourrow_sp
```

f90 call assert(iand(n,n-1)==0 ... All the Fourier routines in this chapter require the dimension N of the data to be a power of 2. This is easily tested for by AND'ing N and $N - 1$: N should have the binary representation 10000..., in which case $N - 1 = 01111....$

Here now are implementations of the method of §22.4 for the FFT of one-dimensional single- and double-precision complex arrays:

```

SUBROUTINE four1_sp(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
USE nr, ONLY : fourrow
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
      Replaces a complex array data by its discrete Fourier transform, if isign is input as 1;
      or replaces data by its inverse discrete Fourier transform times the size of data, if isign
      is input as -1. The size of data must be an integer power of 2. Parallelism is achieved
      by internally reshaping the input array to two dimensions. (Use this version if fourrow is
      faster than fourcol on your machine.)
COMPLEX(SPC), DIMENSION(:,:), ALLOCATABLE :: dat,temp
COMPLEX(DPC), DIMENSION(:), ALLOCATABLE :: w,wp
REAL(DP), DIMENSION(:), ALLOCATABLE :: theta
INTEGER(I4B) :: n,m1,m2,j
n=size(data)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in four1_sp')
      Find dimensions as close to square as possible, allocate space, and reshape the input array.
m1=2**ceiling(0.5_sp*log(real(n,sp))/0.693147_sp)
m2=n/m1
allocate(dat(m1,m2),theta(m1),w(m1),wp(m1),temp(m2,m1))
dat=reshape(data,shape(dat))
call fourrow(dat,isign)                         Transform on second index.

```

```

theta=arth(0,isign,m1)*TWOPI_D/n      Set up recurrence.
wp=cmplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
w=cmplx(1.0_dp,0.0_dp,kind=dpc)
do j=2,m2                         Multiply by the extra phase factor.
    w=w*wp+w
    dat(:,j)=dat(:,j)*w
end do
temp=transpose(dat)                  Transpose, and transform on (original) first index.
call fourrow(temp,isign)
data=reshape(temp,shape(data))      Reshape the result back to one dimension.
deallocate(dat,w,wp,theta,temp)
END SUBROUTINE four1_sp

```

```

SUBROUTINE four1_dp(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
USE nr, ONLY : fourrow
IMPLICIT NONE
COMPLEX(DPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
COMPLEX(DPC), DIMENSION(:,:), ALLOCATABLE :: dat,temp
COMPLEX(DPC), DIMENSION(:), ALLOCATABLE :: w,wp
REAL(DP), DIMENSION(:), ALLOCATABLE :: theta
INTEGER(I4B) :: n,m1,m2,j
n=size(data)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in four1_dp')
m1=2**ceiling(0.5_sp*log(real(n,sp))/0.693147_sp)
m2=n/m1
allocate(dat(m1,m2),theta(m1),w(m1),wp(m1),temp(m2,m1))
dat=reshape(data,shape(dat))
call fourrow(dat,isign)
theta=arth(0,isign,m1)*TWOPI_D/n
wp=cmplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
w=cmplx(1.0_dp,0.0_dp,kind=dpc)
do j=2,m2
    w=w*wp+w
    dat(:,j)=dat(:,j)*w
end do
temp=transpose(dat)
call fourrow(temp,isign)
data=reshape(temp,shape(data))
deallocate(dat,w,wp,theta,temp)
END SUBROUTINE four1_dp

```

The above routines use `fourrow` exclusively, on the assumption that it is faster than its sibling `fourcol`. When that is the case (as we typically find), it is likely that `four1_sp` is also faster than Volume 1's scalar `four1`. The reason, on scalar machines, is that `fourrow`'s parallelism is taking better advantage of cache memory locality.

If `fourrow` is *not* faster than `fourcol` on your machine, then you should instead try the following alternative FFT version that uses `fourcol` only.

```

SUBROUTINE four1_alt(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
USE nr, ONLY : fourcol
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
Replaces a complex array data by its discrete Fourier transform, if isign is input as 1; or
replaces data by its inverse discrete Fourier transform times the size of data, if isign is

```

input as -1 . The size of data must be an integer power of 2. Parallelism is achieved by internally reshaping the input array to two dimensions. (Use this version *only* if fourcol is faster than fourrow on your machine.)

```

COMPLEX(SPC), DIMENSION(:, :, :), ALLOCATABLE :: dat,temp
COMPLEX(DPC), DIMENSION(:, :, :), ALLOCATABLE :: w,wp
REAL(DP), DIMENSION(:, :, :), ALLOCATABLE :: theta
INTEGER(I4B) :: n,m1,m2,j
n=size(data)
call assert(iand(n,n-1)==0, 'n must be a power of 2 in four1_alt')
   Find dimensions as close to square as possible, allocate space, and reshape the input array.
m1=2**ceiling(0.5_sp*log(real(n,sp))/0.693147_sp)
m2=n/m1
allocate(dat(m1,m2),theta(m1),w(m1),wp(m1),temp(m2,m1))
dat=reshape(data,shape(dat))
temp=transpose(dat)                                     Transpose and transform on (original) second index.
call fourcol(temp,isign)                               Set up recurrence.
theta=arth(0,isign,m1)*TWOPI_D/n
wp=cmplx(-2.0_dp*sin(0.5_dp*theta)**2,sin(theta),kind=dpc)
w=cmplx(1.0_dp,0.0_dp,kind=dpc)
do j=2,m2                                         Multiply by the extra phase factor.
   w=w*wp+w
   temp(j,:)=temp(j,:)*w
end do
dat=transpose(temp)                                     Transpose, and transform on (original) first index.
call fourcol(dat,isign)
temp=transpose(dat)                                     Transpose and then reshape the result back to one dimension.
data=reshape(temp,shape(data))
deallocate(dat,w,wp,theta,temp)
END SUBROUTINE four1_alt

```

* * *

With all the machinery of fourrow and fourcol, two-dimensional FFTs are extremely straightforward. Again there is an alternative version provided in case your hardware favors fourcol (which would be, we think, unusual).

```

SUBROUTINE four2(data,isign)
USE nrtype
USE nr, ONLY : fourrow
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:, :, :), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
   Replaces a 2-d complex array data by its discrete 2-d Fourier transform, if isign is input as 1; or replaces data by its inverse 2-d discrete Fourier transform times the product of its two sizes, if isign is input as  $-1$ . Both of data's sizes must be integer powers of 2 (this is checked for in fourrow). Parallelism is by use of fourrow.
COMPLEX(SPC), DIMENSION(size(data,2),size(data,1)) :: temp
call fourrow(data,isign)                                Transform in second dimension.
temp=transpose(data)                                    Tranpose.
call fourrow(temp,isign)                               Transform in (original) first dimension.
data=transpose(temp)                                    Tranpose into data.
END SUBROUTINE four2

```

```

SUBROUTINE realft_sp(data,isign,zdata)
USE nrtype; USE nrutil, ONLY : assert,assert_eq,zroots_unity
USE nr, ONLY : four1
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
COMPLEX(SPC), DIMENSION(:), OPTIONAL, TARGET :: zdata
When isign = 1, calculates the Fourier transform of a set of  $N$  real-valued data points,
input in the array data. If the optional argument zdata is not present, the data are replaced
by the positive frequency half of its complex Fourier transform. The real-valued first and
last components of the complex transform are returned as elements data(1) and data(2),
respectively. If the complex array zdata of length  $N/2$  is present, data is unchanged and
the transform is returned in zdata.  $N$  must be a power of 2. If isign = -1, this routine
calculates the inverse transform of a complex data array if it is the transform of real data.
(Result in this case must be multiplied by  $2/N$ .) The data can be supplied either in data,
with zdata absent, or in zdata.

SUBROUTINE four3(data,isign)
USE nrtype
USE nr, ONLY : fourrow_3d
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:,:,:,:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
    Replaces a 3-d complex array  $data$  by its discrete 3-d Fourier transform, if  $isign$  is input as 1; or replaces  $data$  by its inverse 3-d discrete Fourier transform times the product of its

```

three sizes, if `isign` is input as `-1`. All three of `data`'s sizes must be integer powers of `2` (this is checked for in `fourrow_3d`). Parallelism is by use of `fourrow_3d`.

```
COMPLEX(SPC), DIMENSION(:,:,:), ALLOCATABLE :: dat2,dat3
call fourrow_3d(data,isign)           Transform in third dimension.
allocate(dat2(size(data,2),size(data,3),size(data,1)))
dat2=reshape(data,shape=shape(dat2),order=(/3,1,2/))   Transpose.
call fourrow_3d(dat2,isign)          Transform in (original) first dimension.
allocate(dat3(size(data,3),size(data,1),size(data,2)))
dat3=reshape(dat2,shape=shape(dat3),order=(/3,1,2/))   Transpose.
deallocate(dat2)
call fourrow_3d(dat3,isign)          Transform in (original) second dimension.
data=reshape(dat3,shape=shape(data),order=(/3,1,2/))   Transpose back to output order.
deallocate(dat3)
END SUBROUTINE four3
```

The `reshape` intrinsic, used with an `order=` parameter, is the multidimensional generalization of the two-dimensional transpose operation. The line

```
dat2=reshape(data,shape=shape(dat2),order=(/3,1,2/))
```

is equivalent to the do-loop

```
do j=1,size(data,1)
    dat2(:,:,j)=data(j,:,:)
end do
```

Incidentally, we have found some Fortran 90 compilers that (for scalar machines) are significantly *slower* executing the `reshape` than executing the equivalent do-loop. This, of course, shouldn't happen, since the `reshape` basically *is* an implicit do-loop. If you find such inefficient behavior on your compiler, you should report it as a bug to your compiler vendor! (Only thus will Fortran 90 compilers be brought to mature states of efficiency.)

```
SUBROUTINE four3_alt(data,isign)
USE nrtype
USE nr, ONLY : fourcol_3d
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:,:,:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign
    Replaces a 3-d complex array data by its discrete 2-d Fourier transform, if isign is input as 1; or replaces data by its inverse 3-d discrete Fourier transform times the product of its three sizes, if isign is input as -1. All three of data's sizes must be integer powers of 2 (this is checked for in fourcol_3d). Parallelism is by use of fourcol_3d. (Use this version only if fourcol_3d is faster than fourrow_3d on your machine.)
COMPLEX(SPC), DIMENSION(:,:,:), ALLOCATABLE :: dat2,dat3
call fourcol_3d(data,isign)           Transform in first dimension.
allocate(dat2(size(data,2),size(data,3),size(data,1)))
dat2=reshape(data,shape=shape(dat2),order=(/3,1,2/))   Transpose.
call fourcol_3d(dat2,isign)          Transform in (original) second dimension.
allocate(dat3(size(data,3),size(data,1),size(data,2)))
dat3=reshape(dat2,shape=shape(dat3),order=(/3,1,2/))   Transpose.
deallocate(dat2)
call fourcol_3d(dat3,isign)          Transform in (original) third dimension.
data=reshape(dat3,shape=shape(data),order=(/3,1,2/))   Transpose back to output order.
deallocate(dat3)
END SUBROUTINE four3_alt
```

Note that `four3` uses `fourrow_3d`, the three-dimensional counterpart of `fourrow`, while `four3_alt` uses `fourcol_3d`, the three-dimensional counterpart of `fourcol`. You may want to time these programs to see which is faster on your machine.

* * *

In Volume 1, a single routine named `rlft3` was able to serve both as a three-dimensional real FFT, and as a two-dimensional real FFT. The trick is that the Fortran 77 version doesn't care whether the input array data is dimensioned as two- or three-dimensional. Fortran 90 is not so indifferent, and better programming practice is to have two separate versions of the algorithm:

```
SUBROUTINE rlft2(data,spec,speq,isign)
USE nrtype; USE nrutil, ONLY : assert,assert_eq
USE nr, ONLY : four2
REAL(SP), DIMENSION(:,:), INTENT(INOUT) :: data
COMPLEX(SPC), DIMENSION(:,:), INTENT(INOUT) :: spec
COMPLEX(SPC), DIMENSION(:, ), INTENT(INOUT) :: speq
INTEGER(I4B), INTENT(IN) :: isign
Given a two-dimensional real array data(1:M,1:N), this routine returns (for isign=1)
the complex fast Fourier transform as two complex arrays: On output, spec(1:M/2,1:N)
contains the zero and positive frequency values of the first frequency component, while
speq(1:N) contains the Nyquist critical frequency values of the first frequency component.
The second frequency components are stored for zero, positive, and negative frequencies,
in standard wrap-around order. For isign=-1, the inverse transform (times M × N/2 as
a constant multiplicative factor) is performed, with output data deriving from input spec
and speq. For inverse transforms on data not generated first by a forward transform, make
sure the complex input data array satisfies property (12.5.2). The size of all arrays must
always be integer powers of 2.

★ ★ ★

Referring back to the discussion of parallelism, §22.4, that led to `four1`'s implementation with \sqrt{N} parallelism, you might wonder whether Fortran 90 provides sufficiently powerful high-level constructs to enable an FFT routine with N -fold parallelism. The answer is, “*It does, but you wouldn't want to use them!*” Access to arbitrary interprocessor communication in Fortran 90 is through the mechanism of the “vector subscript” (one-dimensional array of indices in arbitrary order). When a vector subscript is on the right-hand side of an assignment statement, the operation performed is effectively a “gather”; when it is on the left-hand side, the operation is effectively a “scatter.”

It is quite possible to write the classic FFT algorithm in terms of gather and scatter operations. In fact, we do so now. The problem is efficiency: The computations involved in constructing the vector subscripts for the scatter/gather operations, and the actual scatter/gather operations themselves, tend to swamp the underlying very lean FFT algorithm. The result is very slow, though theoretically perfectly parallelizable, code. Since small-scale parallel (SSP) machines can saturate their processors with \sqrt{N} parallelism, while massively multiprocessor (MMP) machines inevitably come with architecture-optimized FFT library calls, there is really no niche for these routines, except as pedagogical demonstrations. We give here a one-dimensional routine, and also an arbitrary-dimensional routine modeled on Volume 1's `fourn`. Note the complete absence of do-loops of size N ; the loops that remain are over $\log N$ stages, or over the number of dimensions.

```

SUBROUTINE four1_gather(data,isign)
USE nrtype; USE nrutil, ONLY : arth,assert
IMPLICIT NONE
COMPLEX(SPC), DIMENSION(:), INTENT(INOUT) :: data
INTEGER(I4B), INTENT(IN) :: isign

```

Replaces a complex array `data` by its discrete Fourier transform, if `isign` is input as 1; or replaces `data` by `size(data)` times its inverse discrete Fourier transform, if `isign` is input as -1. The size of `data` must be an integer power of 2. This routine demonstrates coding the FFT algorithm in high-level Fortran 90 constructs. Generally the result is *very*

much slower than library routines coded for specific architectures, and also significantly slower than the parallelization-by-rows method used in the routine four1.

FUNCTION convlv(data,respns,isign)
USE nrtype; USE nrutil, ONLY : assert,nrerror
USE nr, ONLY : realft
IMPLICIT NONE
REAL(SP), DIMENSION(:, ), INTENT(INOUT) :: data
REAL(SP), DIMENSION(:, ), INTENT(IN) :: respns
INTEGER(I4B), INTENT(IN) :: isign
REAL(SP), DIMENSION(size(data)) :: convlv
    Convolves or deconvolves a real data set data (of length  $N$ , including any user-supplied zero padding) with a response function respns, stored in wrap-around order in a real array of length  $M \leq N$ . ( $M$  should be an odd integer,  $N$  a power of 2.) Wrap-around order means that the first half of the array respns contains the impulse response function at positive times, while the second half of the array contains the impulse response function at negative times, counting down from the highest element respns( $M$ ). On input isign is +1 for convolution, -1 for deconvolution. The answer is returned as the function convlv, an array of length  $N$ . data has INTENT(INOUT) for consistency with realft, but is actually unchanged.

END FUNCTION convlv
```

f90 `tmp1=cmplx(...kind=spc)` The intrinsic function `cmplx` returns a quantity of type default complex unless the `kind` argument is present. It is therefore a good idea always to include this argument. The intrinsic functions `real` and `aimag`, on the other hand, when called with a complex argument, return the same kind as their argument. So it is a good idea *not* to put in a `kind` argument for these. (In fact, `aimag` doesn't allow one.) Don't confuse these situations, regarding complex variables, with the completely unrelated use of `real` to convert a real or integer variable to a real value of specified kind. In this latter case, `kind` should be specified.

```

Starting frequency.
Initialize values for the trigonometric recurrences at each data point. The recurrences are done in double precision.

Main loop over the frequencies to be evaluated.
First, loop over the data to get τ and related quantities.
Then, loop over the data again to get the periodogram value.
Update the trigonometric recurrences.
The next frequency.
Evaluate statistical significance of the maximum.

f90 This routine shows another example of how to return arrays whose size is not known in advance (cf. `zbrac` in Chapter B9). The coding is explained in the subsection on pointers in §21.5. The size of the output arrays, `nout` in the code, is available as `size(px)`.

`jmax=imaxloc...` See discussion of `imaxloc` on p. 1017.

```

SUBROUTINE fasper(x,y,ofac,hifac,px,py,jmax,prob)

f90 This routine shows another example of how to return arrays whose size is not known in advance (cf. zbrac in Chapter B9). The coding is explained in the subsection on pointers in §21.5. The size of the output arrays, nout in the code, is available as `size(px)`.

`jmax=imaxloc...` See discussion of `imaxloc` on p. 1017.

`if (x == real(ix,sp)) then` Without the explicit kind type parameter `sp`, `real` returns a value of type default `real` for an integer argument. This prevents automatic conversion of the routine from single to double precision. Here all you have to do is redefine `sp` in `nrtype` to get double precision.

cr(n:1:-2) = -cr(n:1:-2)
END SUBROUTINE pwtset

```

f90 Here we need to have as global variables arrays whose dimensions are known only at run time. At first sight the situation is the same as with the module `fminln` in `newt` on p. 1197. If you review the discussion there and in §21.5, you will recall that there are two good ways to implement this: with allocatable arrays (“Method 1”) or with pointers (“Method 2”). There is a difference here that makes allocatable arrays simpler. We do not wish to deallocate the arrays on exiting `pwtset`. On the contrary, the values in `cc` and `cr` need to be preserved for use in `pwt`. Since allocatable arrays are born in the well-defined state of “not currently allocated,” we can declare the arrays here as

```
REAL(SP), DIMENSION(:), ALLOCATABLE, SAVE :: cc,cr
```

and test whether they were used on a previous call with

```

if (allocated(cc)) deallocate(cc)
if (allocated(cr)) deallocate(cr)

```

We are then ready to allocate the new storage:

```
allocate(cc(n),cr(n))
```

With pointers, we would need the additional machinery of nullifying the pointers on the initial call, since pointers are born in an undefined state (see §21.5).

There is an additional important point in this example. The module variables need to be used by a “sibling” routine, `pwt`. We need to be sure that they do not become undefined when we exit `pwtset`. We could ensure this by putting a `USE pwtcom` in the main program that calls both `pwtset` and `pwt`, but it’s easy to forget to do this. It is preferable to put explicit `SAVEs` on all the module variables.

```

USE nr, ONLY : probks,sort2
IMPLICIT NONE
REAL(SP), INTENT(OUT) :: d,prob
REAL(SP), DIMENSION(:), INTENT(IN) :: data1,data2
Given arrays data1 and data2, which can be of different length, this routine returns the
K-S statistic d, and the significance level prob for the null hypothesis that the data sets
are drawn from the same distribution. Small values of prob show that the cumulative
distribution function of data1 is significantly different from that of data2. The arrays
data1 and data2 are not modified.
INTEGER(I4B) :: n1,n2
REAL(SP) :: en1,en2,en
REAL(SP), DIMENSION(size(data1)+size(data2)) :: dat,org
n1=size(data1)
n2=size(data2)
en1=n1
en2=n2
dat(1:n1)=data1
dat(n1+1:)=data2
Copy the two data sets into a single ar-
ray.

```

```

org(1:n1)=0.0
org(n1+1:)=1.0
call sort2(dat,org)                                Define an array that contains 0 when the
                                                    corresponding element comes from
                                                    data1, 1 from data2.

Sort the array of 1's and 0's into the order of the merged data sets.
d=maxval(abs(cumsum(org)/en2-cumsum(1.0_sp-org)/en1))
Now use cumsum to get the c.d.f. corresponding to each set of data.
en=sqrt(en1*en2/(en1+en2))
prob=probks((en+0.12_sp+0.11_sp/en)*d)           Compute significance.
END SUBROUTINE kstwo

```

The problem here is how to compute the cumulative distribution function (c.d.f.) corresponding to each set of data, and then find the corresponding KS statistic, without a serial loop over the data. The trick is to define an array that contains 0 when the corresponding element comes from the first data set and 1 when it's from the second data set. Sort the array of 1's and 0's into the same order as the merged data sets. Now tabulate the partial sums of the array. Every time you encounter a 1, the partial sum increases by 1. So if you normalize the partial sums by dividing by the number of elements in the second data set, you have the c.d.f. of the second data set.

If you subtract the array of 1's and 0's from an array of all 1's, you get an array where 1 corresponds to an element in the first data set, 0 the second data set. So tabulating its partial sums and normalizing gives the c.d.f. of the first data set. As we've seen before, tabulating partial sums can be done with a parallel algorithm (`cumsum` in `nrutil`). The KS statistic is just the maximum absolute difference of the c.d.f.'s, computed in parallel with Fortran 90's `maxval` function.

end if
call array_copy(pack(idx(:),tie(:)<eoshift(tie(:),1)),tstart,nties,ndum)

```

```

Look for 0 → 1 transitions in tie, which mean that the 0 element is the start of a tie run.
Store index of each transition in tstart. nties is the number of ties found.
tend(1:nties)=pack(idx(:,),tie(:)>eoshift(tie(:,1)))
Look for 1 → 0 transitions in tie, which mean that the 1 element is the end of a tie run.
do i=1,nties
    w(tstart(i):tend(i))=(tstart(i)+tend(i))/2.0_sp
    Midrank assignments.
end do
tend(1:nties)=tend(1:nties)-tstart(1:nties)+1      Now calculate s.
s=sum(tend(1:nties)**3-tend(1:nties))
END SUBROUTINE crank
END SUBROUTINE spear

```

To understand how the parallel version of `crank` works, let's consider an example of 9 elements in the array `w`, which is input in sorted order to `crank`. The elements in our example are given in the second line of the following table:

index	1	2	3	4	5	6	7	8	9
data in w	0	0	1	1	1	2	3	4	4
shift right	0	0	0	1	1	1	2	3	4
compare	1	1	0	1	1	0	0	0	1
tie array	0	1	0	1	1	0	0	0	1
shift left	1	0	1	1	0	0	0	1	0
0 → 1		1		3				8	start index
1 → 0				2				5	stop index

We look for ties by comparing this array with itself, right shifted by one element (“shift right” in table). We record a 1 for each element that is the same, a 0 for each element that is different (“compare”). A 1 indicates the element is part of a tie with the *preceding* element, so we always set the first element to 0, even if it was a 1 as in our example. This gives the “tie array.” Now wherever the tie array makes a transition 0 → 1 indicates the start of a tie run, while a 1 → 0 transition indicates the end of a tie run. We find these transitions by comparing the tie array to itself left shifted by one (“shift left”). If the tie array element is smaller than the shifted array element, we have a 0 → 1 transition and we record the corresponding index as the start of a tie. Similarly if the tie array element is larger we record the index as the end of a tie. Note that the shifts must be end-off shifts with zeros inserted in the gaps for the boundary conditions to work.

f90

```
call array_copy(pack(idx(:,),tie(:)<eoshift(tie(:,1)),
```

```
        tstart,nties,ndum)
```

The start indices (1, 3, and 8 in our example above) are here packed into the first few elements of `tstart`. `array_copy` is a useful routine in `nrutil` for copying elements from one array to another, when the number of elements to be copied is not known in advance. This line of code is equivalent to

```
tstart(:)=0
tstart(:)=pack(idx(:,), tie(:) < eoshift(tie(:,1)),tstart(:))
nties=count(tstart(:) > 0)
```

The point is that we don't know how many elements `pack` is going to select. We have to make sure the dimensions of both sides of the `pack` statement are the same,

so we set the optional third argument of `pack` to `tstart`. We then make a separate pass through `tstart` to count how many elements we copied. Alternatively, we could have used an additional logical array `mask` and coded this as

```
mask(:)=tie(:) < eoshift(tie(:,1),1)
nties=count(mask)
tstart(1:nties)=pack(idx(:,1),mask)
```

But we still need two passes through the `mask` array. The beauty of the `array_copy` routine is that `nties` is determined from the *size* of the first argument, without the necessity for a second pass through the array.

prob=erfcc(abs(z)/SQRT2)
END SUBROUTINE kend12

```

Get cumulative sums leftward along rows.
Tally the extra-y pairs.
Get counts of points to lower-right of each cell in `cum`.
Total number of entries in table.
Tally the concordant pairs.
Now get counts of points to upper-right of each cell in `cum`, giving tally of discordant points.
Finally, get cumulative sums upward along columns, giving the count of extra-x pairs, and compute desired results.

The underlying algorithm in `kend12` might seem to require looping over all *pairs* of cells in the two-dimensional table `tab`. Actually, however, clever use of the `cumsum` utility function reduces this to a simple loop over all the cells; moreover this “loop” parallelizes into a simple parallel product and call to the `sum` intrinsic. The basic idea is shown in the following table:

		<i>d</i>	<i>d</i>
	<i>t</i>	<i>y</i>	<i>y</i>
	<i>x</i>	<i>c</i>	<i>c</i>
	<i>x</i>	<i>c</i>	<i>c</i>
	<i>x</i>	<i>c</i>	<i>c</i>

Relative to the cell marked *t* (which we use to denote the numerical value it contains), the cells marked *d* contribute to the “discordant” tally in Volume 1’s equation (14.6.8),

while the cells marked c contribute to the “concordant” tally. Likewise, the cells marked x and y contribute, respectively, to the “extra- x ” and “extra- y ” tallies. What about the cells left blank? Since we want to count pairs of cells only *once*, without duplication, these cells will be counted, relative to the location shown as t , when t itself moves into the blank-cell area.

Symbolically we have

$$\begin{aligned}\text{concordant} &= \sum_n t_n \left(\sum_{\text{lower right}} c_m \right) \\ \text{discordant} &= \sum_n t_n \left(\sum_{\text{upper right}} d_m \right) \\ \text{extra-}x &= \sum_n t_n \left(\sum_{\text{below}} x_m \right) \\ \text{extra-}y &= \sum_n t_n \left(\sum_{\text{to the right}} y_m \right)\end{aligned}\tag{B14.1}$$

Here n varies over all the positions in the table, while the limits of the inner sums are relative to the position of n . (The letters t_n , c_m , d_m , x_m , y_m all represent the value in a cell; we use different letters only to make the relation with the above table clear.) Now the final trick is to recognize that the inner sums, over cells to the lower- or upper-right, below, and to the right can be done in parallel by cumulative sums (`cumsum`) sweeping to the right and up. The routine does these in a nonintuitive order merely to be able to reuse maximally the scratch spaces `cum` and `cumt`.

end if
END SUBROUTINE fit

```

For unweighted data evaluate typical sig using chi2, and adjust the standard deviations.

f90 REAL(SP), DIMENSION(:), POINTER :: wt...wt=>t When standard deviations are supplied in sig, we need to compute the weights for the least squares fit in a temporary array wt. Later in the routine, we need another temporary array, which we call t to correspond to the variable in equation (15.2.15). It would be confusing to use the same name for both arrays. In Fortran 77 the arrays could share storage with an EQUIVALENCE declaration, but that is a deprecated feature in Fortran 90. We accomplish the same thing by making wt a pointer alias to t.

Given a set of N data points x, y with individual standard deviations sig , all arrays of length N , use χ^2 minimization to fit for some or all of the M coefficients a of a function that depends linearly on a , $y = \sum_{i=1}^M a_i \times \text{afunc}_i(x)$. The input logical array maska of length M indicates by true entries those components of a that should be fitted for, and by false entries those components that should be held fixed at their input values. The program returns values for a , $\chi^2 = \text{chisq}$, and the $M \times M$ covariance matrix covar . (Parameters held fixed will return zero covariances.) The user supplies a subroutine $\text{funcs}(x, \text{afunc})$ that returns the M basis functions evaluated at $x = x$ in the array afunc .

f₉₀

This is the first of several uses of `maska` in this routine to control which elements of an array are to be used. Here we include in the sum only elements for which `maska` is false, i.e., elements corresponding to parameters that are not being fitted for.

`covar(j,1:k)=covar(j,1:k)+wt*pack(afunc(1:l),maska(1:l))` Here `maska` controls which elements of `afunc` get packed into the covariance matrix.

`call diagmult(covar(1:mfit,1:mfit),0.5_sp)` See discussion of `diagadd` after `hqr` on p. 1234.

`a(1:ma)=unpack(beta(1:ma,1),maska,a(1:ma))` And here `maska` controls which elements of `beta` get unpacked into the appropriate slots in `a`. Where `maska` is false, corresponding elements are selected from the third argument of `unpack`, here `a` itself. The net effect is that those elements remain unchanged.

REAL(SP), PARAMETER :: TOL=1.0e-5_sp
Given a set of  $N$  data points  $x, y$  with individual standard deviations  $\text{sig}$ , all arrays of length
 $N$ , use  $\chi^2$  minimization to determine the  $M$  coefficients  $a$  of a function that depends linearly
on  $a$ ,  $y = \sum_{i=1}^M a_i \times \text{afunc}_i(x)$ . Here we solve the fitting equations using singular value
decomposition of the  $N \times M$  matrix, as in §2.6. On output, the  $M \times M$  array  $v$  and the
vector  $w$  of length  $M$  define part of the singular value decomposition, and can be used
to obtain the covariance matrix. The program returns values for the  $M$  fit parameters  $a$ ,
and  $\chi^2$ ,  $\text{chisq}$ . The user supplies a function  $\text{funcs}(x, \text{afunc})$  that returns the  $M$  basis
functions evaluated at  $x = X$  in the array  $\text{afunc}$ .
Parameter: Above value of  $\text{TOL}$  is for single precision and variables scaled to order unity.
INTEGER(I4B) :: i,ma,n
REAL(SP), DIMENSION(size(x)) :: b,sigi
REAL(SP), DIMENSION(size(x),size(a)) :: u,usav
n(assert_eq(size(x),size(y),size(sig),'svdfit: n'))
ma(assert_eq(size(a),size(v,1),size(v,2),size(w),'svdfit: ma'))
sigi=1.0_sp/sig
Accumulate coefficients of the fitting matrix in
b=y*sigi
u.
do i=1,n
  usav(i,:)=funcs(x(i),ma)
end do
u=usav*spread(sigi,dim=2,ncopies=ma)
usav=u
call svdcmp(u,w,v)
where (w < TOL*maxval(w)) w=0.0
Singular value decomposition.
call svbksb(u,w,v,b,a)
Edit the singular values, given  $\text{TOL}$  from the pa-
parameter statement.
chisq=vabs(matmul(usav,a)-b)**2
Evaluate chi-square.
END SUBROUTINE svdfit

```

f90 $u=usav*spread(sigi,dim=2,ncopies=ma)$ Remember how `spread` works:
the vector `sigi` is copied *along* the dimension 2, making a matrix whose
columns are each a copy of `sigi`. The multiplication here is element by
element, so each row of `usav` is multiplied by the corresponding element of `sigi`.

$\text{chisq}=vabs(\text{matmul}(\text{usav},\text{a})-\text{b})**2$ Fortran 90's `matmul` intrinsic allows us to
evaluate χ^2 from the mathematical definition in terms of matrices. `vabs` in `nrutil`
returns the length of a vector (L_2 norm).

```

SUBROUTINE svdvar(v,w,cvm)
USE nrtype; USE nrutil, ONLY : assert_eq
IMPLICIT NONE
REAL(SP), DIMENSION(:, :), INTENT(IN) :: v
REAL(SP), DIMENSION(:, :), INTENT(IN) :: w
REAL(SP), DIMENSION(:, :, :), INTENT(OUT) :: cvm

```

To evaluate the covariance matrix `cvm` of the fit for M parameters obtained by `svdfit`, call this routine with matrices `v,w` as returned from `svdfit`. The dimensions are M for `w` and $M \times M$ for `v` and `cvm`.

```
INTEGER(I4B) :: ma
REAL(SP), DIMENSION(size(w)) :: wti
ma=assert_eq((/size(v,1),size(v,2),size(w),size(cvm,1),size(cvm,2)/),&
'svdvar')
where (w /= 0.0)
    wti=1.0_sp/(w*w)
elsewhere
    wti=0.0
end where
cvm=v*spread(wti,dim=1,ncopies=ma)
cvm=matmul(cvm,transpose(v))           Covariance matrix is given by (15.4.20).
END SUBROUTINE svdvar
```

f90 where (`w /= 0.0`)...`elsewhere`...`end where` This is the standard Fortran 90 construction for doing different things to a matrix depending on some condition. Here we want to avoid inverting elements of `w` that are zero.

`cvm=v*spread(wti,dim=1,ncopies=ma)` Each column of `v` gets multiplied by the corresponding element of `wti`. Contrast the construction `spread(...dim=2...)` in `svdfit`.

    END SUBROUTINE funcs
END INTERFACE
Levenberg-Marquardt method, attempting to reduce the value  $\chi^2$  of a fit between a set of  $N$  data points  $x$ ,  $y$  with individual standard deviations  $sig$ , and a nonlinear function dependent on  $M$  coefficients  $a$ . The input logical array  $maska$  of length  $M$  indicates by true entries those components of  $a$  that should be fitted for, and by false entries those components that should be held fixed at their input values. The program returns current best-fit values for the parameters  $a$ , and  $\chi^2 = chisq$ . The  $M \times M$  arrays  $covar$  and  $alpha$  are used as working space during most iterations. Supply a subroutine  $funcs(x,a,yfit,dyda)$  that evaluates the fitting function  $yfit$ , and its derivatives  $dyda$  with respect to the fitting parameters  $a$  at  $x$ . On the first call provide an initial guess for the parameters  $a$ , and set  $alamda < 0$  for initialization (which then sets  $alamda = .001$ ). If a step succeeds  $chisq$  becomes smaller and  $alamda$  decreases by a factor of 10. If a step fails  $alamda$  grows by a factor of 10. You must call this routine repeatedly until convergence is achieved. Then, make one final call with  $alamda = 0$ , so that  $covar$  returns the covariance matrix, and  $alpha$  the curvature matrix. (Parameters held fixed will return zero covariances.)

f90 The organization of this routine is similar to that of amoeba discussed on p. 1209. We want to keep the argument list of rofunc to a minimum, but we want to make clear what global variables it accesses and protect medfit_private's name space. In the Fortran 77 version, we kept the only argument as b by passing the global variables in a common block. This required us to make copies of the arrays x and y. An alternative Fortran 90 implementation would be to use a module with pointers to the arguments of medfit like x and y that need to be passed to rofunc. We think the medfit_private construction is simpler.

```

f90 MODULE ode_path The situation here is similar to rkdump_path, except we don't know at run time how much storage to allocate. We may need to use `realloc` from `nrutil` to increase the storage. The solution is pointers to arrays, with a `nullify` to be sure the pointer status is well-defined at the beginning of the routine.

SUBROUTINE save_a_step An internal subprogram with no arguments is like a macro in C: you could imagine just copying its code wherever it is called in the parent routine.

f₉₀ $a(:)=\text{cumsum}(nseq,1)$ The function `cumsum` in `nrutil` with the optional argument `seed=1` gives a direct implementation of equation (16.4.6).

where `(upper_triangle(KMAXX,KMAXX))...` The `upper_triangle` function in `nrutil` returns an upper triangular logical mask. As used here, the mask is true everywhere in the upper triangle of a $KMAXX \times KMAXX$ matrix, excluding the diagonal. An optional integer argument `extra` allows additional diagonals to be set to true. With `extra=1` the upper triangle including the diagonal would be true.

`main_loop: do` Using a named do-loop provides clear structured code that required `goto`'s in the Fortran 77 version.

`kopt=1+iminloc(...)` See the discussion of `imaxloc` on p. 1017.

Stoermer's rule for integrating $y'' = f(x, y)$ for a system of n equations. On input y contains y in its first n elements and y' in its second n elements, all evaluated at xs . $d2y$ contains the right-hand-side function f (also evaluated at xs) in its first n elements. Its second n elements are not referenced. Also input is $htot$, the total step to be taken, and $nstep$, the number of substeps to be used. The output is returned as $yout$, with the same storage arrangement as y . $derivs$ is the user-supplied subroutine that calculates f .

Fourth order Rosenbrock step for integrating stiff ODEs, with monitoring of local truncation error to adjust stepsize. Input are the dependent variable vector y and its derivative dydx at the starting value of the independent variable x. Also input are the stepsize to be attempted htry, the required accuracy eps, and the vector yscal against which the error is scaled. On output, y and x are replaced by their new values, hdid is the stepsize that was actually accomplished, and hnext is the estimated next stepsize. derivs is a user-supplied subroutine that computes the derivatives of the right-hand side with respect to x, while jacobn (a fixed name) is a user-supplied subroutine that computes the Jacobi matrix of derivatives of the right-hand side with respect to the components of y. y, dydx, and yscal must have the same length.
Parameters: GROW and SHRNK are the largest and smallest factors by which stepsize can change in one step; ERRCON=(GROW/SAFETY)**(1/PGROW) and handles the case when errmax ≈ 0.

    REDMIN=0.7_sp,TINY=1.0e-30_sp,SCALMX=0.1_sp
Semi-implicit extrapolation step for integrating stiff ODEs, with monitoring of local truncation error to adjust stepsize. Input are the dependent variable vector y and its derivative dydx at the starting value of the independent variable x. Also input are the stepsize to be attempted htry, the required accuracy eps, and the vector yscal against which the error is scaled. On output, y and x are replaced by their new values, hdid is the stepsize that was actually accomplished, and hnext is the estimated next stepsize. derivs is a user-supplied subroutine that computes the derivatives of the right-hand side with respect to x, while jacobn (a fixed name) is a user-supplied subroutine that computes the Jacobi matrix of derivatives of the right-hand side with respect to the components of y. y, dydx, and yscal must all have the same length. Be sure to set htry on successive steps to the value of hnext returned from the previous step, as is the case if the routine is called by odeint.

Chapter B17. Two Point Boundary Value Problems

```
! FUNCTION shoot(v) is named "funcv" for use with "newt"
FUNCTION funcv(v)
USE nrtype
USE nr, ONLY : odeint,rkqs
USE sphoot_caller, ONLY : nvar,x1,x2; USE ode_path, ONLY : xp,yp
IMPLICIT NONE
REAL(SP), DIMENSION(:,), INTENT(IN) :: v
REAL(SP), DIMENSION(size(v)) :: funcv
REAL(SP), PARAMETER :: EPS=1.0e-6_sp
      Routine for use with newt to solve a two point boundary value problem for N coupled
      ODEs by shooting from x1 to x2. Initial values for the ODEs at x1 are generated from
      the n2 input coefficients v, using the user-supplied routine load. The routine integrates
      the ODEs to x2 using the Runge-Kutta method with tolerance EPS, initial stepsize h1,
      and minimum stepsize hmin. At x2 it calls the user-supplied subroutine score to evaluate
      the n2 functions funcv that ought to be zero to satisfy the boundary conditions at x2.
      The functions funcv are returned on output. newt uses a globally convergent Newton's
      method to adjust the values of v until the functions funcv are zero. The user-supplied
      subroutine derivs(x,y,dydx) supplies derivative information to the ODE integrator (see
      Chapter 16). The module sphoot_caller receives its values from the main program so
      that funcv can have the syntax required by newt. Set nvar = N in the main program.

!  FUNCTION shootf(v) is named "funcv" for use with "newt"
FUNCTION funcv(v)
USE nrtype
USE nr, ONLY : odeint,rkqs
USE sphfpt_caller, ONLY : x1,x2,xf,nn2; USE ode_path, ONLY : xp,yp
IMPLICIT NONE
REAL(SP), DIMENSION(:), INTENT(IN) :: v
REAL(SP), DIMENSION(size(v)) :: funcv
REAL(SP), PARAMETER :: EPS=1.0e-6_sp
Routine for use with newt to solve a two point boundary value problem for  $N$  coupled ODEs by shooting from  $x_1$  and  $x_2$  to a fitting point  $xf$ . Initial values for the ODEs at  $x_1$  ( $x_2$ ) are generated from the  $n_2$  ( $n_1$ ) coefficients  $V_1$  ( $V_2$ ), using the user-supplied routine load1 (load2). The coefficients  $V_1$  and  $V_2$  should be stored in a single array  $v$  of length  $N$  in the main program, and referenced by pointers as  $v1=>v(1:n_2)$ ,  $v2=>v(n_2+1:N)$ . Here  $N = n_1 + n_2$ . The routine integrates the ODEs to  $xf$  using the Runge-Kutta method with tolerance EPS, initial stepsize  $h_1$ , and minimum stepsize  $h_{\min}$ . At  $xf$  it calls the user-supplied subroutine score to evaluate the  $N$  functions  $f_1$  and  $f_2$  that ought to match at  $xf$ . The differences funcv are returned on output. newt uses a globally convergent Newton's method to adjust the values of  $v$  until the functions funcv are zero. The user-supplied subroutine derivs( $x,y,dydx$ ) supplies derivative information to the ODE integrator (see Chapter 16). The module sphfpt_caller receives its values from the main program so that funcv can have the syntax required by newt. Set nn2 =  $n_2$  in the main program.

REAL(SP), DIMENSION(:), INTENT(IN) :: scalv
INTEGER(I4B), DIMENSION(:), INTENT(IN) :: indexv
REAL(SP), DIMENSION(:, :, ), INTENT(INOUT) :: y
Driver routine for solution of two point boundary value problems with  $N$  equations by
relaxation.  $itmax$  is the maximum number of iterations.  $conv$  is the convergence criterion
(see text).  $slowc$  controls the fraction of corrections actually used after each iteration.
 $scalv$ , a vector of length  $N$ , contains typical sizes for each dependent variable, used to
weight errors.  $indexv$ , also of length  $N$ , lists the column ordering of variables used to
construct the matrix  $s$  of derivatives. (The  $nb$  boundary conditions at the first mesh point
must contain some dependence on the first  $nb$  variables listed in  $indexv$ .) There are a total of  $M$  mesh points.  $y$  is the  $N \times M$  array that contains the initial guess for all the dependent
variables at each mesh point. On each iteration, it is updated by the calculated correction.

    call unit_matrix(a)                           Left-hand side goes in ma-
    a=a-0.5_sp*h*ak(t(i),t(i))                  trix  $a$ .
    call ludcmp(a,indx,d)                         Solve linear equations.
    call lubksb(a,indx,b)
    f(:,i)=b(:,i)
end do
END SUBROUTINE voltra

```

FUNCTION $g(t)$...REAL(SP), DIMENSION(:), POINTER :: g The routine $voltra$ requires an argument that is a function returning a vector, but we don't know the dimension of the vector at compile time. The solution is to make the function return a *pointer* to the vector. This is not the same thing as a pointer to a function, which is not allowed in Fortran 90. When you use the pointer in the routine, Fortran 90 figures out from the context that you want the vector of values, so the code remains highly readable. Similarly, the argument ak is a function returning a pointer to a matrix.

The coding of the user-supplied functions g and ak deserves some comment: functions returning pointers to arrays are potential memory leaks if the arrays are allocated dynamically in the functions. Here the user knows in advance the dimension of the problem, and so there is no need to use dynamical allocation in the functions. For example, in a two-dimensional problem, you can code g as follows:

```

FUNCTION g(t)
USE nrtype
IMPLICIT NONE
REAL(SP), INTENT(IN) :: t
REAL(SP), DIMENSION(:), POINTER :: g
REAL(SP), DIMENSION(2), TARGET, SAVE :: gg
g=>gg
g(1)=...
g(2)=...
END FUNCTION g

```

and similarly for `ak`.

Suppose, however, we coded `g` with dynamical allocation:

```
FUNCTION g(t)
USE nrtype
IMPLICIT NONE
REAL(SP), INTENT(IN) :: t
REAL(SP), DIMENSION(:), POINTER :: g
allocate(g(2))
g(1)=...
g(2)=...
END FUNCTION g
```

Now `g` never gets deallocated; each time we call the function fresh memory gets consumed. If you have a problem that really does require dynamical allocation in a pointer function, you have to be sure to deallocate the pointer in the calling routine. In `voltra`, for example, we would declare pointers `gtemp` and `aktemp`. Then instead of writing simply

```
b=g(t(i))+...
```

we would write

```
gtemp=>g(t(i))
b=gtemp+...
deallocate(gtemp)
```

and similarly for each pointer function invocation.

`call array_copy(g(t(1)),f(:,1),ncop,nerr)` The routine would work if we replaced this statement with simply `f(:,1)=g(t(1))`. The purpose of using `array_copy` from `nrutil` is that we can check that `f` and `g` have consistent dimensions with a call to `assert_eq`.

END MODULE kermom_info

FUNCTION kermom(y,m)

USE nrtype

USE kermom_info

IMPLICIT NONE

REAL(DP), INTENT(IN) :: y

INTEGER(I4B), INTENT(IN) :: m

Returns in `kermom(1:m)` the first m indefinite-integral moments of one row of the singular part of the kernel. (For this example, m is hard-wired to be 4.) The input variable `y` labels the column, while `kermom_x` (in the module `kermom_info`) is the row.

REAL(DP) :: x,d,df,clog,x2,x3,x4

We can take x as the lower limit of integration. Thus, we return the moment integrals either purely to the left or to the right of the line.

```
d=y-x
df=2.0_dp*sqrt(d)*d
kermom(1:4) = (/ df
```

purely to the right of the diagonal

```

df*((x/3.0_dp + 0.4_dp*d)*x + d**2/7.0_dp),&
df*((((x/3.0_dp + 0.6_dp*d)*x + 3.0_dp*d**2/7.0_dp)*x&
      + d**3/9.0_dp) /)
else
  x2=x**2
  x3=x2*x
  x4=x2*x2
  d=x-y
  clog=log(d)
  kermom(1:4) = (/ d*(clog-1.0_dp),&
    -0.25_dp*(3.0_dp*x+y-2.0_dp*clog*(x+y))*d,&
    (-11.0_dp*x3+y*(6.0_dp*x2+y*(3.0_dp*x+2.0_dp*y))&
      +6.0_dp*clog*(x3-y**3))/18.0_dp,&
    (-25.0_dp*x4+y*(12.0_dp*x3+y*(6.0_dp*x2+y*&
      (4.0_dp*x+3.0_dp*y)))+12.0_dp*clog*(x4-y**4))/48.0_dp /)
end if

resid(2:jm1:2,3:jm2:2)=a(2:jm1:2,3:jm2:2)*u(3:jmax:2,3:jm2:2)+&
b(2:jm1:2,3:jm2:2)*u(1:jm2:2,3:jm2:2)+&
c(2:jm1:2,3:jm2:2)*u(2:jm1:2,4:jm1:2)+&
d(2:jm1:2,3:jm2:2)*u(2:jm1:2,2:jm3:2)+&
e(2:jm1:2,3:jm2:2)*u(2:jm1:2,3:jm2:2)-f(2:jm1:2,3:jm2:2)
u(2:jm1:2,3:jm2:2)=u(2:jm1:2,3:jm2:2)-omega*&
resid(2:jm1:2,3:jm2:2)/e(2:jm1:2,3:jm2:2)
omega=1.0_dp/(1.0_dp-0.25_dp*rjac**2*omega)
anorm=sum(abs(resid(2:jm1,2:jm1)))
if (anorm < EPS*anormf) exit
end do
if (n > MAXITS) call nrerror('MAXITS exceeded in sor')
END SUBROUTINE sor

```

Red-black iterative schemes like the one used in `sor` are easily parallelizable. Updating the red grid points requires information only from the black grid points, so they can all be updated independently. Similarly the black grid points can all be updated independently. Since nearest neighbors are involved in the updating, communication costs can be kept to a minimum.

There are several possibilities for coding the red-black iteration in a data parallel way using only Fortran 90 and no parallel language extensions.

One way is to define an $N \times N$ logical mask `red` that is true on the red grid points and false on the black. Then each iteration consists of an update governed by a `where(red)...end where` block and a `where(.not. red)...end where` block. We have chosen a more direct coding that avoids the need for storage of the array `red`. The red update corresponds to the even-even and odd-odd grid points, the black to the even-odd and odd-even points. We can code each of these four cases directly with array sections, as in the routine above.

The array section notation used in `sor` is rather dense and hard to read. We could use pointer aliases to try to simplify things, but since each array section is different, we end up merely giving names to each term that was there all along. Pointer aliases do help if we code `sor` using a logical mask. Since there may be machines on which this version is faster, and since it is of some pedagogic interest, we give the alternative code:

f₉₀ The Fortran 90 version of `mglin` (and of `mgfas` below) is quite different from the Fortran 77 version, although the algorithm is identical. First, we use a recursive implementation. This makes the code much more transparent. It also makes the memory management much better: we simply define the new arrays `res` and `v` as automatic arrays of the appropriate dimension on each recursive call to a coarser level. And a third benefit is that it is trivial to change the code to increase the number of multigrid iterations done at level $j - 1$ by each iteration at level j , i.e., to set the quantity γ in §19.6 to a value greater than one. (Recall that $\gamma = 1$ as chosen in `mglin` gives V-cycles, $\gamma = 2$ gives W-cycles.) Simply enclose the recursive call in a do-loop:

```

do i=1,merge(gamma,1,j /= 2)
    call mg(j-1,v,res)
end do

```

The merge expression ensures that there is no more than one call to the coarsest level, where the problem is solved exactly.

A second improvement in the Fortran 90 version is to make the procedures `resid`, `interp`, and `rstrct` functions instead of subroutines. This allows us to code the algorithm exactly as written mathematically.

`TYPE ptr2d...` The right-hand-side quantity ρ is supplied initially on the finest grid in the argument `u`. It has to be defined on the coarser grids by restriction, and then supplied as the right-hand side to `mg` in the nested iteration loop. This loop starts at the coarsest level and progresses up to the finest level. We thus need a data structure to store ρ on all the grid levels. A convenient way to implement this in Fortran 90 is to define a type `ptr2d`, a pointer to a two-dimensional array `a` that represents a grid. (In three dimensions, `a` would of course be three-dimensional.) We then declare the variable `rho` as an allocatable array of type `ptr2d`:

```
TYPE(ptr2d), ALLOCATABLE :: rho(:)
```

Next we allocate storage for ρ on each level. The number of levels or grids, `ng`, is known only at run time:

```
allocate(rho(ng))
```

Then we allocate storage as needed on particular sized grids. For example,

```
allocate(rho(ngrid)%a(nn,nn))
```

allocates an $nn \times nn$ grid for `rho` on grid number `ngrid`.

The various subsidiary routines of `mglin` such as `rstrct` and `interp` are written to accept two-dimensional arrays as arguments. With the data structure we've employed, using these routines is simple. For example,

```
rho(ngrid)%a=rstrct(rho(ngrid+1)%a)
```

will restrict `rho` from the grid `ngrid+1` to the grid `ngrid`. The statement is even more readable if we mentally ignore the `%a` that is tagged onto each variable. (If

we actually did omit %a in the code, the compiler would think we meant the array of type `ptr2d` instead of the grid array.)

Note that while Fortran 90 does not allow you to declare an array of pointers directly, you can achieve the same effect by declaring your own type, as we have done with `ptr2d` in this example.

```

See the discussion after `mglin` on p. 1336 for the changes made in the Fortran 90 versions of the multigrid routines from the Fortran 77 versions.

`TYPE ptr2d...` See discussion after `mglin` on p. 1336.

`RECURSIVE SUBROUTINE mg(j,u,rhs,trerr)` Recall that `mgfas` solves the problem $\mathcal{L}u = 0$, but that nonzero right-hand sides appear during the solution. We implement this by having `rhs` be an optional argument to `mg`. On the first call at a given level j , the right-hand side is zero and so you just omit it from the calling sequence. On the other hand, the truncation error `trerr` is computed only on the first call at a given level, so it is also an optional argument that does get supplied on the first call:

```
call mg(j,uj,trerr=trerr)
```

The second and subsequent calls at a given level supply `rhs=tau` but omit `trerr`:

```
call mg(j-1,v,tau)
```

Note that we can omit the keyword `rhs` from this call because the variable `tau` appears in the correct order of arguments. However, in the other call above, the keyword `trerr` must be supplied because `rhs` has been omitted.

The example equation that is solved in `mgfas`, equation (19.6.44), is almost linear, and the code is set up so that ρ is supplied as part of the right-hand side instead of pulling it over to the left-hand side. The variable `rho` is visible to `mg` by host association. Note also that the function `lop` does not include `rho`, but that the statement

```
tau=lop(ut)-rstrct(lop(u))
```

is nevertheless correct, since `rho` would cancel out if it were included in `lop`. This feature is also true in the Fortran 77 code.

Chapter B20. Less-Numerical Algorithms

f90 Volume 1's Fortran 77 routine `machar` performed various clever contortions (due to Cody, Malcolm, and others) to discover the underlying properties of a machine's floating-point representation. Fortran 90, by contrast, provides a built-in set of "numeric inquiry functions" that accomplish the same goal. The routine `machar` included here makes use of these and is included largely for compatibility with the previous version.

```
SUBROUTINE machar(ibeta,it,irnd,ngrd,machep,negep,iexp,minexp,&
    maxexp,eps,epsneg,xmin,xmax)
USE nrtype
IMPLICIT NONE
INTEGER(I4B), INTENT(OUT) :: ibeta,iexp,irnd,it,machep,maxexp,minexp,negep,ngrd
REAL(SP), INTENT(OUT) :: eps,epsneg,xmax,xmin
REAL(SP), PARAMETER :: RX=1.0
    Determines and returns machine-specific parameters affecting floating-point arithmetic. Re-
turned values include ibeta, the floating-point radix; it, the number of base-ibeta digits in
the floating-point mantissa; eps, the smallest positive number that, added to 1.0, is
not equal to 1.0; epsneg, the smallest positive number that, subtracted from 1.0, is not
equal to 1.0; xmin, the smallest representable positive number; and xmax, the largest rep-
resentable positive number. See text for description of other returned parameters. Change
all REAL(SP) declarations to REAL(DP) to find double-precision parameters.
REAL(SP) :: a,beta,betah,one,temp,tempa,two,zero
ibeta=radix(RX)                                Most of the parameters are easily determined
it=digits(RX)                                    from intrinsic functions.
machep=exponent(nearest(RX,RX)-RX)-1
negep=exponent(nearest(RX,-RX)-RX)-1
minexp=minexponent(RX)-1
maxexp=maxexponent(RX)
iexp=nint(log(real(maxexp-minexp+2,sp))/log(2.0_sp))
eps=real(ibeta,sp)**machep
epsneg=real(ibeta,sp)**negep
xmax=huge(RX)
xmin=tiny(RX)
one=RX                                         Determine irnd.
two=one+one
zero=one-one
beta=real(ibeta,sp)
a=beta**(-negep)
irnd=0
betah=beta/two
temp=a+betah
if (temp-a /= zero) irnd=1
tempa=a+beta
temp=tempa+betah
if ((irnd == 0) .and. (temp-tempa /= zero)) irnd=2
ngrd=0                                         Determine ngrd.
```

```

temp=one+eps
if ((irnd == 0) .and. (temp*one-one /= zero)) ngrd=1
temp=xmin/two
if (temp /= zero) irnd=irnd+3           Adjust irnd to reflect partial underflow.
END SUBROUTINE machar

```

ch=char(i+48)                      Convert to ASCII.
END FUNCTION decchk

```

f90 Note the use of the utility function `ifirstloc` to find the first (in this case, the only) correct check digit.

* * *

f90 The Huffman and arithmetic coding routines exemplify the use of modules to encapsulate user-defined data types. In these algorithms, “the code” is a fairly complicated construct containing scalar and array data. We define types `huffcode` and `arithcode`, then can pass “the code” from the routine that constructs it to the routine that uses it as a single variable.

C1. Listing of Utility Modules (nrtype and nrutil)

C1.1 Numerical Recipes Types (nrtype)

The file supplied as `nrtype.f90` contains a single module named `nrtype`, which in turn contains definitions for a number of named constants (that is, `PARAMETER`s), and a couple of elementary derived data types used by the sparse matrix routines in this book. Of the named constants, by far the most important are those that define the `KIND` types of virtually all the variables used in this book: `I4B`, `I2B`, and `I1B` for integer variables, `SP` and `DP` for real variables (and `SPC` and `DPC` for the corresponding complex cases), and `LGT` for the default logical type.

```
MODULE nrtype
  Symbolic names for kind types of 4-, 2-, and 1-byte integers:
  INTEGER, PARAMETER :: I4B = SELECTED_INT_KIND(9)
  INTEGER, PARAMETER :: I2B = SELECTED_INT_KIND(4)
  INTEGER, PARAMETER :: I1B = SELECTED_INT_KIND(2)
  Symbolic names for kind types of single- and double-precision reals:
  INTEGER, PARAMETER :: SP = KIND(1.0)
  INTEGER, PARAMETER :: DP = KIND(1.0D0)
  Symbolic names for kind types of single- and double-precision complex:
  INTEGER, PARAMETER :: SPC = KIND((1.0,1.0))
  INTEGER, PARAMETER :: DPC = KIND((1.0D0,1.0D0))
  Symbolic name for kind type of default logical:
  INTEGER, PARAMETER :: LGT = KIND(.true.)
  Frequently used mathematical constants (with precision to spare):
  REAL(SP), PARAMETER :: PI=3.141592653589793238462643383279502884197_sp
  REAL(SP), PARAMETER :: PI02=1.57079632679489661923132169163975144209858_sp
  REAL(SP), PARAMETER :: TWOPI=6.283185307179586476925286766559005768394_sp
  REAL(SP), PARAMETER :: SQRT2=1.41421356237309504880168872420969807856967_sp
  REAL(SP), PARAMETER :: EULER=0.5772156649015328606065120900824024310422_sp
  REAL(DP), PARAMETER :: PI_D=3.141592653589793238462643383279502884197_dp
  REAL(DP), PARAMETER :: PI02_D=1.57079632679489661923132169163975144209858_dp
  REAL(DP), PARAMETER :: TWOPI_D=6.283185307179586476925286766559005768394_dp
  Derived data types for sparse matrices, single and double precision (see use in Chapter B2):
  TYPE sprs2_sp
    INTEGER(I4B) :: n,len
    REAL(SP), DIMENSION(:, ), POINTER :: val
    INTEGER(I4B), DIMENSION(:, ), POINTER :: irow
    INTEGER(I4B), DIMENSION(:, ), POINTER :: jcol
  END TYPE sprs2_sp
  TYPE sprs2_dp
    INTEGER(I4B) :: n,len
    REAL(DP), DIMENSION(:, ), POINTER :: val
```

```

INTEGER(I4B), DIMENSION(:), POINTER :: irow
INTEGER(I4B), DIMENSION(:), POINTER :: jcol
END TYPE sprs2_dp
END MODULE nrtype

```

About Converting to Higher Precision

You might hope that changing all the Numerical Recipes routines from single precision to double precision would be as simple as redefining the values of SP and DP in *nrtype*. Well . . . not quite.

Converting algorithms to a higher precision is not a purely mechanical task because of the distinction between “roundoff error” and “truncation error.” (Please see Volume 1, §1.2, if you are not familiar with these concepts.) While increasing the precision implied by the kind values SP and DP will indeed reduce a routine’s roundoff error, it will not reduce any truncation error that may be intrinsic to the algorithm. Sometimes, a routine contains “accuracy parameters” that can be adjusted to reduce the truncation error to the new, desired level. In other cases, however, the truncation error cannot be so easily reduced; then, a whole new algorithm is needed. Clearly such new algorithms are beyond the scope of a simple mechanical “conversion.”

If, despite these cautionary words, you want to proceed with converting some routines to a higher precision, here are some hints:

If your machine has a kind type that is distinct from, and has equal or greater precision than, the kind type that we use for DP, then, in *nrtype*, you can simply redefine DP to this new highest precision and redefine SP to what was previously DP. For example, DEC machines usually have a “quadruple precision” real type available, which can be used in this way. You should not need to make any further edits of *nrtype* or *nrutil*.

If, on the other hand, the kind type that we already use for DP is the highest precision available, then you must leave DP defined as it is, and redefine SP in *nrtype* to be this same kind type. Now, however, you will also have to edit *nrutil*, because some overloaded routines that were previously distinguishable (by the different kind types) will now be seen by the compiler as indistinguishable — and it will object strenuously. Simply delete all the “_dp” function names from the list of overloaded procedures (i.e., from the MODULE PROCEDURE statements). Note that it is not necessary to delete the routines from the MODULE itself. Similarly, in the interface file *nr.f90* you must delete the “_dp” interfaces, *except* for the *sprs...sp* routines. (Since they have TYPE(*sprs2_dp*) or TYPE(*sprs2_sp*), they are treated as distinct even though they have functionally equivalent kind types.)

Finally, the following table gives some suggestions for changing the accuracy parameters, or constants, in some of the routines. Please note that this table is not necessarily complete, and that higher-precision performance is not guaranteed for all the routines, *even if* you make all the changes indicated. The above edits, and these suggestions, do, however, work in the majority of cases.

C1.2 Numerical Recipes Utilities (*nrutil*)

The file supplied as *nrutil.f90* contains a single module named *nrutil*, which contains specific implementations for all the Numerical Recipes utility functions described in detail in Chapter 23.

The specific implementations given are something of a compromise between demonstrating parallel techniques (when they can be achieved in Fortran 90) and running efficiently on conventional, serial machines. The parameters at the beginning of the module (names beginning with *NPAR_*) are typically related to array lengths *below which* the implementations revert to serial operations. On a purely serial machine, these can be set to large values to suppress many parallel constructions.

The length and repetitiveness of the *nrutil.f90* file stems in large part from its extensive use of overloading. Indeed, the file would be even longer if we overloaded versions for all the applicable data types that each utility could, in principle, instantiate. The descriptions in Chapter 23 detail both the full set of intended data types and shapes for each routine, and also the types and shapes actually here implemented (which can also be gleaned by examining the file). The intended result of all this overloading is, in essence, to give the utility routines the desirable properties of many of the Fortran 90 intrinsic functions, namely, to be both *generic* (apply to many data types) and *elemental* (apply element-by-element to arbitrary shapes). Fortran 95's provision of user-defined elemental functions will reduce the multiplicity of overloading in some of our routines; unfortunately the necessity to overload for multiple data types will still be present.

Finally, it is worth reemphasizing the following point, already made in Chapter 23: The purpose of the *nrutil* utilities is to remove from the Numerical Recipes programs just those programming tasks and "idioms" whose efficient implementation is *most* hardware and compiler dependent, so as to allow for specific, efficient implementations on different machines. One should therefore not expect the utmost in efficiency from the general purpose, one-size-fits-all, implementation listed here.

Correspondingly, we would encourage the incorporation of efficient *nrutil* implementations, and/or comparable capabilities under different names, with as broad as possible a set of overloaded data types, in libraries associated with specific compilers or machines. In support of this goal, we have specifically put this Appendix C1, and the files *nrtype.f90* and *nrutil.f90*, into the public domain.

MODULE nrutil

TABLE OF CONTENTS OF THE NRUTIL MODULE:

- routines that move data:
 - array_copy*, *swap*, *reallocate*
 - routines returning a location as an integer value
 - ifirstloc*, *imaxloc*, *iminloc*
- routines for argument checking and error handling:
 - assert*, *assert_eq*, *nrerror*
- routines relating to polynomials and recurrences
 - arth*, *geop*, *cumsum*, *cumprod*, *poly*, *polyterm*,
zroots, *unity*
- routines for "outer" operations on vectors
 - outerand*, *outersum*, *outerdiff*, *outerprod*, *outerdiv*
- routines for scatter-with-combine
 - scatter_add*, *scatter_max*
- routines for skew operations on matrices
 - diagadd*, *diagmult*, *get_diag*, *put_diag*,

```

        unit_matrix, lower_triangle, upper_triangle
miscellaneous routines
vabs

USE nrtype
Parameters for crossover from serial to parallel algorithms (these are used only within this
nrutil module):
IMPLICIT NONE
INTEGER(I4B), PARAMETER :: NPAR_ARTH=16,NPAR2_ARTH=8      Each NPAR2 must be  $\leq$  the
INTEGER(I4B), PARAMETER :: NPAR_GEOP=4,NPAR2_GEOP=2          corresponding NPAR.
INTEGER(I4B), PARAMETER :: NPAR_CUMSUM=16
INTEGER(I4B), PARAMETER :: NPAR_CUMPROD=8
INTEGER(I4B), PARAMETER :: NPAR_POLY=8
INTEGER(I4B), PARAMETER :: NPAR_POLYTERM=8

Next, generic interfaces for routines with overloaded versions. Naming conventions for ap-
pended codes in the names of overloaded routines are as follows: r=real, d=double pre-
cision, i=integer, c=complex, z=double-precision complex, h=character, l=logical. Any of
r,d,i,c,z,h,l may be followed by v=vector or m=matrix (v,m suffixes are used only when
needed to resolve ambiguities).

Routines that move data:
INTERFACE array_copy
  MODULE PROCEDURE array_copy_r, array_copy_d, array_copy_i
END INTERFACE
INTERFACE swap
  MODULE PROCEDURE swap_i,swap_r,swap_rv,swap_c, &
    swap_cv,swap_cm,swap_z,swap_zv,swap_zm, &
    masked_swap_rs,masked_swap_rv,masked_swap_rm
END INTERFACE
INTERFACE reallocate
  MODULE PROCEDURE deallocate_rv,deallocate_rm,&
    deallocate_iv,deallocate_im,deallocate_hv
END INTERFACE
Routines returning a location as an integer value (ifirstloc, iminloc are not currently over-
loaded and so do not have a generic interface here):
INTERFACE imaxloc
  MODULE PROCEDURE imaxloc_r,imaxloc_i
END INTERFACE
Routines for argument checking and error handling (nrerror is not currently overloaded):
INTERFACE assert
  MODULE PROCEDURE assert1,assert2,assert3,assert4,assert_v
END INTERFACE
INTERFACE assert_eq
  MODULE PROCEDURE assert_eq2,assert_eq3,assert_eq4,assert_eqn
END INTERFACE
Routines relating to polynomials and recurrences (cumprod, zroots_unity are not currently
overloaded):
INTERFACE arth
  MODULE PROCEDURE arth_r, arth_d, arth_i
END INTERFACE
INTERFACE geop
  MODULE PROCEDURE geop_r, geop_d, geop_i, geop_c, geop_cv
END INTERFACE
INTERFACE cumsum
  MODULE PROCEDURE cumsum_r,cumsum_i
END INTERFACE
INTERFACE poly
  MODULE PROCEDURE poly_rr,poly_rrv,poly_dd,poly_ddv,&
    poly_rc,poly_cc,poly_msk_rrv,poly_msk_ddv
END INTERFACE
INTERFACE poly_term
  MODULE PROCEDURE poly_term_rr,poly_term_cc
END INTERFACE
Routines for "outer" operations on vectors (outerand, outersum, outerdiv are not currently
overloaded):
INTERFACE outerprod

```

```

MODULE PROCEDURE outerprod_r,outerprod_d
END INTERFACE
INTERFACE outerdiff
  MODULE PROCEDURE outerdiff_r,outerdiff_d,outerdiff_i
END INTERFACE
  Routines for scatter-with-combine, scatter_add, scatter_max:
INTERFACE scatter_add
  MODULE PROCEDURE scatter_add_r,scatter_add_d
END INTERFACE
INTERFACE scatter_max
  MODULE PROCEDURE scatter_max_r,scatter_max_d
END INTERFACE
  Routines for skew operations on matrices (unit_matrix, lower_triangle, upper_triangle not
  currently overloaded):
INTERFACE diagadd
  MODULE PROCEDURE diagadd_rv,diagadd_r
END INTERFACE
INTERFACE diagmult
  MODULE PROCEDURE diagmult_rv,diagmult_r
END INTERFACE
INTERFACE get_diag
  MODULE PROCEDURE get_diag_rv, get_diag_dv
END INTERFACE
INTERFACE put_diag
  MODULE PROCEDURE put_diag_rv, put_diag_r
END INTERFACE
  Other routines (vabs is not currently overloaded):
CONTAINS
  Routines that move data:
SUBROUTINE array_copy_r(src,dest,n_copied,n_not_copied)

Other routines:

```

```
FUNCTION vabs(v)
    Return the length (ordinary L2 norm) of a vector.
REAL(SP), DIMENSION(:), INTENT(IN) :: v
REAL(SP) :: vabs
vabs=sqrt(dot_product(v,v))
END FUNCTION vabs
END MODULE nrutil
```

C2. Alphabetical Listing of Explicit Interfaces

The file supplied as `nr.f90` contains explicit interfaces for all the Numerical Recipes routines (except those already in the module `nrutil`). The interfaces are in alphabetical order, by the generic interface name, if one exists, or by the specific routine name if there is no generic name.

The file `nr.f90` is normally invoked via a `USE` statement within a main program or subroutine that references a Numerical Recipes routine. See §21.1 for an example.

```

C3. Index of Programs and Dependencies

The following table lists, in alphabetical order, all the routines in Volume 2 of *Numerical Recipes*. When a routine requires subsidiary routines, either from this book or else user-supplied, the full dependency tree is shown: A routine calls directly all routines to which it is connected by a solid line in the column immediately to its right; it calls indirectly the connected routines in all columns to its right. Typographical conventions: Routines from this book are in typewriter font (e.g., `eulsum`, `gammLn`). The smaller, slanted font is used for the second and subsequent occurrences of a routine in a single dependency tree. (When you are getting routines from the *Numerical Recipes* machine-readable media or hypertext archives, you need specify names only in the larger, upright font.) User-supplied routines are indicated by the use of text font and square brackets, e.g., `[funcv]`. Consult the text for individual specifications of these routines. The right-hand side of the table lists chapter and page numbers for each program.

General Index to Volumes 1 and 2

In this index, page numbers 1 through 934 refer to Volume 1, *Numerical Recipes in Fortran 77*, while page numbers 935 through 1446 refer to Volume 2, *Numerical Recipes in Fortran 90*. Front matter in Volume 1 is indicated by page numbers in the range 1/i through 1/xxxii, while front matter in Volume 2 is indicated 2/i through 2/xx.
